The components of the innate system are always on guard, ready to unleash a limited, rather crude, repertoire of defence mechanisms at any and every invader. Of the immune effector cells, the neutrophils and macrophages—both phagocytic specialists—are especially important in innate defence. Several groups of plasma proteins also play key roles. The various non-specific immune responses are set in motion in response to generic molecular patterns associated with threatening agents, such as cell surface carbohydrates found on bacteria but not on human cells. The responding phagocytic cells are studded with a recently discovered type of plasma membrane protein known as **toll-like receptors (TLRs)**. TLRs have been dubbed the “eyes of the innate immune system” because these immune sensors recognize and bind with the telltale bacterial markers, allowing the effector cells of the innate system to recognize pathogens as distinct from self-cells. A TLR’s recognition of a pathogen triggers the phagocyte to engulf and destroy the infectious microorganism. Moreover, activation of the TLR induces the phagocytic cell to secrete chemicals, some of which contribute to inflammation—an important innate response to microbial invasion.

TLRs link the innate and adaptive branches of the immune system, because still other chemicals secreted by the phagocytes are important in activating cells of the adaptive immune system. Furthermore, foreign particles are deliberately marked for phagocytic ingestion by being coated with antibodies produced by the B cells of the adaptive immune system—another link between the innate and adaptive branches. These are but a few examples of how various components of the immune system are highly interactive and interdependent. The most significant cooperative relationships among the immune effectors are pointed out throughout this chapter.

The innate mechanisms give us all a rapid but limited and nonselective response to unfriendly challenges of all kinds, whereas innate immunity largely contains and limits the spread of infection. These nonspecific responses are important for keeping the invading pathogen under control until the adaptive immune system can be prepared to take over and mount strategies to eliminate the pathogen.

ADAPTIVE IMMUNE SYSTEM

The responses of the adaptive or acquired immune system are mediated by the B and T lymphocytes. Each B and T cell can recognize and defend against only one particular type of foreign material, such as one kind of bacterium. Among the millions of B and T cells in the body, only the ones specifically equipped to recognize the unique molecular features of a particular infectious agent are called into action to defend against this particular agent. This specialization is similar to modern military personnel who are specially trained to accomplish a very specific task. The chosen lymphocytes multiply, expanding the pool of

specialists that can launch a highly targeted attack against the invading pathogen.

The adaptive immune system is the ultimate weapon against most pathogens. The repertoire of activated and expanded B and T cells is constantly changing in response to the pathogens encountered. In this way, each person’s adaptive immune system adapts to the specific pathogens in their environment. The targets of the adaptive immune system vary among people, depending on the types of immune assaults each individual meets. Furthermore, the adaptive immune system can remember each pathogen, so that when rechallenged by that pathogen, its response is much quicker. This is accomplished by forming a pool of memory cells.

We will first examine in more detail the innate immune responses and then look more closely at adaptive immunity.

Check Your Understanding 11.3

1. Define *immunity*.
2. Explain why innate immune responses are considered nonspecific and adaptive immune responses are said to be specific.

11.4 | Innate Immunity

Innate defences include the following features:

1. *Inflammation*, a nonspecific response to tissue injury in which the phagocytic specialists—neutrophils and macrophages—play a major role, along with supportive input from other immune cell types
2. *Interferon*, a family of proteins that nonspecifically defend against viral infection
3. *Natural killer cells*, a special class of lymphocyte—like cells that spontaneously and nonspecifically lyse (rupture) and thereby destroy virus-infected host cells and cancer cells
4. The *complement system*, a group of inactive plasma proteins that, when sequentially activated, bring about destruction of foreign cells by attacking their plasma membranes

In this section, we discuss each of these in turn, beginning with inflammation.

Inflammation

The term **inflammation** refers to an innate, nonspecific series of highly interrelated events set into motion in response to foreign invasion, tissue damage, or both. The ultimate goal of inflammation is to bring to the invaded or injured area phagocytes and plasma proteins that can (1) isolate, destroy, or inactivate the invaders; (2) remove debris; and (3) prepare for subsequent healing and repair. The overall inflammatory response is

remarkably similar no matter what the triggering event (bacterial invasion, chemical injury, or mechanical trauma), although some subtle differences may be evident, depending on the injurious agent or the site of damage. The following sequence of events typically occurs during the inflammatory response. We use the example of bacterial entry into a break in the skin, and > Figure 11-3 corresponds to our discussion.

DEFENCE BY RESIDENT TISSUE MACROPHAGES

When bacteria invade through a break in the external barrier of skin, macrophages already in the area immediately begin phagocytizing the foreign microbes. Although usually not enough

resident macrophages are present to meet the challenge alone, they defend against infection during the first hour or so, before other mechanisms can be mobilized. Macrophages are usually rather stationary—gobbling debris and contaminants that come their way—but when necessary, they become mobile and migrate to sites of battle against invaders (> Figure 11-3, step **1**).

LOCALIZED VASODILATION

Almost immediately on microbial invasion, arterioles within the area dilate. The vasodilation, increased permeability, and slowing of blood velocity are induced by the actions of various inflammatory mediators, such as histamine released from the mast cells

1 A break in the skin introduces bacteria, which reproduce at the wound site. Activated resident macrophages engulf the pathogens and secrete cytokines and chemotaxins.

2 Activated mast cells release histamine.

3 Histamine dilates local blood vessels and widens the capillary pores. The cytokines cause neutrophils and monocytes to stick to the blood vessel wall.

4 Chemotaxins attract neutrophils and monocytes, which squeeze out between cells of the blood vessel wall, a process called diapedesis, and migrate to the infection site.

5 Monocytes enlarge into macrophages. Newly arriving macrophages and neutrophils engulf the pathogens and destroy them.

> **FIGURE 11-3 Steps producing inflammation.** Chemotaxins released at the site of damage attract phagocytes to the scene. Note the leukocytes emigrating from the blood into the tissues by assuming an amoeba-like behaviour and squeezing through the capillary pores. Mast cells secrete vessel-dilating, pore-widening histamine. Macrophages secrete cytokines that exert multiple local and systemic effects.

(the connective tissue—bound “cousins” of circulating basophils) (steps 2 and 3). In the damaged tissue area, vasodilation occurs first in the arterioles, then progresses to the capillaries, and brings about an increase in the amount of blood present, causing redness and heat. Increased local delivery of blood also brings to the site more phagocytic leukocytes and plasma proteins, both crucial to the defence response.

INCREASED CAPILLARY PERMEABILITY

Released histamine also increases the capillaries’ permeability by enlarging the capillary pores (the spaces between the endothelial cells), so the plasma proteins normally prevented from leaving the blood can escape into the inflamed tissue.

LOCALIZED OEDEMA

Accumulation of leaked plasma proteins in the interstitial fluid raises the local interstitial fluid—colloid osmotic pressure. Furthermore, the increased local blood flow elevates capillary blood pressure. Because both these pressures tend to move fluid out of the capillaries, these changes favour enhanced ultrafiltration and reduced reabsorption of fluid across the involved capillaries. The end result of this shift in fluid balance is localized oedema (p. 413). Thus, the familiar swelling that accompanies inflammation is due to histamine-induced vascular changes. Likewise, the other well-known gross manifestations of inflammation, such as redness and heat, are largely caused by the enhanced flow of warm arterial blood to the damaged tissue. Pain is caused by local distension within the swollen tissue and also by the direct effect of locally produced substances on the receptor endings of afferent neurons that supply the area. These observable characteristics of the inflammatory process (swelling, redness, heat, and pain) are coincidental to the primary purpose of the vascular changes in the injured area—that is, to increase the number of leukocytic phagocytes and crucial plasma proteins in the area (► Figure 11-4).

► FIGURE 11-4 Gross manifestations and outcomes of inflammation

WALLING OFF THE INFLAMED AREA

The leaked plasma proteins most critical to the immune response are those in the complement system and also the clotting and anticlotting factors. On exposure to tissue thromboplastin in the injured tissue and to specific chemicals secreted by phagocytes on the scene, fibrinogen—the final factor in the clotting system—is converted into fibrin (p. 449). Fibrin forms interstitial fluid clots in the spaces around the bacterial invaders and damaged cells. This walling off of the injured region from the surrounding tissues prevents, or at least delays, the spread of bacterial invaders and their toxic products. Later, the more slowly activated anticlotting factors gradually dissolve the clots after they are no longer needed (p. 452).

EMIGRATION OF LEUKOCYTES

Within an hour after injury, the area is teeming with leukocytes that have left the vessels. Neutrophils arrive first, followed during the next 8 to 12 hours by the slower-moving monocytes. The latter swell and mature into macrophages during the next 8 to 12 hours. Once neutrophils or monocytes leave the bloodstream, they never recycle back to the blood.

Leukocytes can emigrate from the blood into the tissues by means of the following steps:

- Blood-borne leukocytes, especially neutrophils and monocytes, stick to the inner endothelial lining of capillaries in the affected tissue, a process called **margination** (► Figure 11-3, step 3). *Selectins*, a type of cell adhesion molecule (CAM; p. 32) that protrudes from the inner endothelial lining, cause leukocytes flowing by in the blood to slow down and roll along the interior of the vessel, much as the nap of a carpet slows down a child's rolling toy car. This slowing down allows the leukocytes enough time to check for local activating factors—"SOS signals" from nearby injured or infected tissues. When present, these activating factors cause the leukocytes to adhere firmly to the endothelial lining by means of interaction with another type of CAM, the *integrins*.
- Soon, the adhered leukocytes start leaving by a mechanism known as **diapedesis**. Assuming *amoeba-like behaviour*, an adhered leukocyte pushes a long, narrow projection through a capillary pore; then the remainder of the cell flows forward into the projection. In this way, the leukocyte is able to wriggle its way through the capillary pore, even though it is much larger than the pore (► Figure 11-3, step 4). Outside the vessel, the leukocyte crawls toward the injured area. Neutrophils arrive on the inflammatory scene earliest because they are more mobile than monocytes.
- **Chemotaxis** guides phagocytic cells in the direction of migration; that is, the cells are attracted to certain chemical mediators, known as *chemotaxins* or *chemokines*, released at the site of damage. Binding of chemotaxins with protein receptors on the plasma membrane of a phagocytic cell increases calcium entry into the cell. Calcium, in turn, switches on the cellular contractile apparatus that leads to the amoeba-like crawling. Because the concentration of chemotaxins progressively increases toward the site of injury, phagocytic cells move unerringly toward this site along a chemotaxin concentration gradient.

LEUKOCYTE PROLIFERATION

Resident tissue macrophages as well as leukocytes that exited from the blood and migrated to the inflammatory site are soon joined by new phagocytic recruits from the bone marrow. Within a few hours after the onset of the inflammatory response, the number of neutrophils in the blood may increase up to four to five times that of normal. This increase is due partly to the transfer into the blood of large numbers of preformed neutrophils stored in the bone marrow and partly to increased production of new neutrophils by the bone marrow. A slower-commencing but longer-lasting increase in monocyte production by the bone marrow also occurs, making available larger

numbers of these macrophage precursor cells (► Figure 11-3, step 5). In addition, the multiplication of resident macrophages adds to the pool of these important immune cells. Proliferation of new neutrophils, monocytes, and macrophages and mobilization of stored neutrophils are stimulated by various chemical mediators released from the inflamed region.

MARKING OF BACTERIA FOR DESTRUCTION BY OPSONINS

Phagocytes must be able to distinguish between normal cells and foreign or abnormal cells before accomplishing their destructive mission. Otherwise, they could not selectively engulf and destroy only the unwanted materials. First, as you have learned, phagocytes, by means of their TLRs, recognize and subsequently engulf infiltrators that have standard bacterial cell wall components not found in human cells. Second, foreign particles are deliberately marked for phagocytic ingestion by being coated with chemical mediators generated by the immune system. Such body-produced chemicals that make bacteria more susceptible to phagocytosis are known as **opsonins**. Opsonins are antibodies, and they are one of the activated proteins of the complement system.

An opsonin enhances phagocytosis by linking the foreign cell to a phagocytic cell (► Figure 11-5). One portion of an opsonin molecule binds nonspecifically to the surface of an invading bacterium, whereas another portion of the opsonin molecule binds to receptor sites specific for it on the phagocytic cell's plasma membrane. This link ensures that the bacterial victim does not have a chance to get away before the phagocyte can perform its lethal attack.

LEUKOCYTIC DESTRUCTION OF BACTERIA

Neutrophils and macrophages clear the inflamed area of infectious and toxic agents as well as tissue debris by both phagocytic and nonphagocytic means; this clearing action is the main function of the inflammatory response.

Phagocytosis involves the engulfment and intracellular degradation (breakdown) of foreign particles and tissue debris. Macrophages can engulf a bacterium in less than 0.01 second. Recall that phagocytic cells contain an abundance of lysosomes,

► **FIGURE 11-5 Mechanism of opsonin action.** One of the activated complement molecules, C3b, links a foreign cell, such as a bacterium, and a phagocytic cell by nonspecifically binding with the foreign cell and specifically binding with a receptor on the phagocyte. This link ensures that the foreign material does not escape before it can be engulfed by the phagocyte.

which are organelles filled with hydrolytic enzymes. After a phagocyte has internalized targeted material, a lysosome fuses with the membrane that encloses the engulfed matter and releases its hydrolytic enzymes within the confines of the vesicle, where the enzymes begin breaking down the entrapped material (p. 48). Phagocytes eventually die from the accumulation of toxic by-products from foreign particle degradation or from inadvertent release of destructive lysosomal chemicals into the cytosol. Neutrophils usually succumb after phagocytizing from 5 to 25 bacteria, whereas macrophages survive much longer and can engulf up to 100 or more bacteria. Indeed, the longer-lived macrophages even clear the area of dead neutrophils and other tissue debris. The **pus** that forms in an infected wound is a collection of these phagocytic cells, both living and dead; necrotic (dead) tissue liquefied by lysosomal enzymes released from the phagocytes; and bacteria.

MEDIATION OF THE INFLAMMATORY RESPONSE BY PHAGOCYTE-SECRETED CHEMICALS

Microbe-stimulated phagocytes release many chemicals that function as mediators of inflammation. All chemicals other than antibodies that leukocytes secrete are collectively called **cytokines**. Macrophages, monocytes, neutrophils, a type of T cell called a helper T cell, and some nonimmune cells, such as endothelial cells (cells lining blood vessels) and fibroblasts (fibroformers in the connective tissue), all secrete cytokines. More than 100 cytokines have been identified, and the list continues to grow as researchers unravel the complicated chemical means by which immune effector cells communicate with one another to coordinate their activities. Unlike antibodies, cytokines do not interact directly with the antigen (foreign material) that induces their production. Instead, cytokines largely spur other immune cells into action to help ward off the invader. Cytokines typically act locally as paracrine on cells in the vicinity, but some circulate in the blood to exert endocrine effects at distant sites. The cytokines released by phagocytes induce a range of interrelated immune activities, varying from local responses to the systemic manifestations that accompany microbe invasion. Some cytokines have names related to their first identified or most important function—examples include specific *colony-stimulating factors*. Other cytokines are designated as specific numbered *interleukins*, such as interleukin 1 (IL-1), interleukin 2 (IL-2), and so on (*interleukin* means “between leukocytes”); 35 interleukins have been identified to date, numbered in the order of their discovery. Interleukins orchestrate a wide variety of independent and overlapping immune activities. The following are among the most important functions of phagocytic secretions:

1. Some of the chemicals, which are very destructive, directly kill microbes by nonphagocytic means. For example, macrophages secrete *nitric oxide (NO)*, a multipurpose chemical that is toxic to nearby microbes. As a more subtle means of destruction, neutrophils secrete **lactoferrin**, a protein that tightly binds with iron, making it unavailable for use by invading bacteria. Bacterial multiplication depends on high concentrations of available iron.

2. Several chemicals released by macrophages, namely **interleukin 1 (IL-1)**, **interleukin 6 (IL-6)**, and **tumour necrosis factor (TNF)**, collectively act to bring about a diverse array of effects locally and throughout the body, all of which are geared toward defending the body against infection or tissue injury. They promote inflammation and are largely responsible for the systemic manifestation accompanying an infection. (Tumour necrosis factor is named for its role in killing cancer cells, but it also exerts other effects.)
3. IL-1, IL-6, and TNF also function together as **endogenous pyrogen (EP)**, which induces the development of fever (*endogenous* means “from within the body”; *pyro* means “fire” or “heat”; and *gen* means “production”). This response occurs especially when the invading organisms have spread into the blood. Endogenous pyrogen causes release within the hypothalamus of *prostaglandins*; these are locally acting chemical messengers that turn up the hypothalamic “thermostat” that regulates body temperature. The function of the resulting elevation in body temperature in fighting infection remains unclear. The fact that fever is such a common systemic manifestation of inflammation suggests the raised temperature plays an important, beneficial role in the overall inflammatory response, as supported by recent evidence. For example, higher temperatures augment phagocytosis and increase the rate of the many enzyme-dependent inflammatory activities. Furthermore, an elevated body temperature may interfere with bacterial multiplication by increasing bacterial requirements for iron. Resolving the controversial issue of whether a fever can be beneficial is extremely important, given the widespread use of drugs that suppress fever.

Although a mild fever may possibly be beneficial, there is no doubt that an extremely high fever can be detrimental, particularly by harming the central nervous system. Young children, whose temperature-regulating mechanisms are not as stable as those of more mature individuals, occasionally have convulsions in association with high fevers.

4. An additional role for IL-1, IL-6, and TNF is to decrease the plasma concentration of iron by altering iron metabolism within the liver, spleen, and other tissues. This action reduces the amount of iron available to support bacterial multiplication.
5. Furthermore, IL-1, IL-6, and TNF stimulate the release of **acute phase proteins** from the liver. This collection of proteins, which have not yet been sorted out by scientists, exerts a multitude of wide-ranging effects associated with the inflammatory process, tissue repair, and immune cell activities. One of the better-known acute phase proteins is *C-reactive protein*, considered clinically as a blood-borne marker of inflammation (p. 376).
6. TNF stimulates the release of histamine from mast cells in the vicinity. Histamine, in turn, promotes the local vasodilation and increased capillary permeability of inflammation.

7. A chemical secreted by neutrophils, **kallikrein**, converts specific plasma protein precursors produced by the liver into activated **kinins**. Activated kinins augment a variety of inflammatory events. For example, the end product of the kinin cascade, **bradykinin**, activates nearby pain receptors and thus partially produces the soreness associated with inflammation. Bradykinin also contributes to blood vessel dilation, reinforcing the effects of histamine. In a positive-feedback fashion, kinins also act as powerful chemotaxins to entice more neutrophils to join the battle.
8. Some phagocytic chemical mediators trigger both the *clotting* and *anticoagulating* systems to first enhance the walling-off process and then facilitate gradual dissolution of the fibrous clot after it is no longer needed.

This list of events augmented by phagocyte-secreted chemicals is not complete, but it illustrates the diversity and complexity of responses these mediators elicit. Furthermore, there are other important macrophage—lymphocyte interactions that do not depend on the release of chemicals from phagocytic cells. Thus, the effect that phagocytes, especially macrophages, ultimately have on microbial invaders far exceeds their engulf-and-destroy tactics.

TISSUE REPAIR

The ultimate purpose of the inflammatory process is to isolate and destroy injurious agents and to clear the area for tissue repair. In some tissues (e.g., skin, bone, and liver), the healthy organ-specific cells surrounding the injured area undergo cell division to replace the lost cells, often repairing the wound perfectly. In typically non-regenerative tissues, such as nerve and muscle, however, lost cells are replaced by **scar tissue**. Fibroblasts, a type of connective tissue cell, start to divide rapidly in the vicinity and secrete large quantities of the protein collagen, which fills in the region vacated by the lost cells and results in the formation of scar tissue. Even in a tissue as readily replaceable as skin, scars sometimes form when complex underlying structures, such as hair follicles and sweat glands, are permanently destroyed by deep wounds.

INNATE IMMUNITY AND EXERCISE

Acute (short-term) exercise in untrained persons has been shown to stimulate phagocytic activity by increasing the activity of the monocytes, neutrophils, and macrophages. Well-trained athletes tend to demonstrate clinically normal monocyte and neutrophil counts, whereas complement levels may be suppressed. Also, there is evidence of suppressed neutrophil function at rest and following intense exercise in well-trained athletes (research has focused on endurance athletes). It has been proposed that the mild innate immune suppression (e.g., down-regulation of neutrophils) observed in some well-trained athletes may be due to a down-regulation of the inflammatory response as a result of the chronic tissue damage associated with high training volumes.

NSAIDs and glucocorticoids

Many drugs can suppress the inflammatory process. The most effective are the *nonsteroidal anti-inflammatory drugs*, or **NSAIDs** (aspirin, ibuprofen, and related

compounds) and **glucocorticoids** (drugs similar to the steroid hormone cortisol, which is secreted by the adrenal cortex; p. 256). For example, aspirin interferes with the inflammatory response by decreasing histamine release, thus reducing pain, swelling, and redness. Furthermore, aspirin reduces fever by inhibiting production of prostaglandins, the local mediators of endogenous pyrogen-induced fever.

Glucocorticoids, which are potent anti-inflammatory drugs, suppress almost every aspect of the inflammatory response. In addition, they destroy lymphocytes within lymphoid tissue and reduce antibody production. These therapeutic agents are useful for treating undesirable immune responses, such as allergic reactions (e.g., poison ivy rash and asthma) and the inflammation associated with arthritis. However, by suppressing inflammatory and other immune responses that localize and eliminate bacteria, such therapy also reduces the body's ability to resist infection. For this reason, glucocorticoids should be used discriminately.

Is naturally secreted cortisol likewise counterproductive to the immune defence system? Traditionally, cortisol has not been considered to display anti-inflammatory activity at normal blood concentrations. Instead, anti-inflammatory action has been attributed only to blood concentrations that are higher than the normal physiological range brought about by the administration of exogenous (from outside the body) cortisol-like drugs. Recent evidence, however, suggests that cortisol, whose secretion is increased in response to any stressful situation, does exert anti-inflammatory activity even at normal physiological levels. According to this proposal, the anti-inflammatory effect of cortisol modulates stress-activated immune responses, preventing them from overshooting, and thus protecting us against damage by potentially overreactive defence mechanisms.

Now let's shift attention from inflammation to interferon, another component of innate immunity.

Interferon and viruses

Besides the inflammatory response, another innate defence mechanism is the release of **interferon** from virus-infected cells. Interferon briefly provides nonspecific resistance to viral infections by transiently interfering with replication of the same or unrelated viruses in other host cells. In fact, interferon was named for its ability to *interfere* with viral replication.

ANTIVIRAL EFFECT OF INTERFERON

When a virus invades a cell, in response to being exposed to viral nucleic acid, the cell synthesizes and secretes interferon. Once released into the ECF from a virus-infected cell, interferon binds with receptors on the plasma membranes of healthy neighbouring cells or even distant cells that it reaches through the blood, signalling these cells to prepare for possible viral attack. Interferon thus acts as a “whistle-blower,” forewarning healthy cells of potential viral attack and helping them prepare to resist. Interferon does not have a direct antiviral effect; instead, it triggers the production of virus-blocking enzymes by potential host cells. When interferon binds with these other cells, they synthesize enzymes that can break down viral messenger RNA (p. A-22) and inhibit protein synthesis. Both these processes are essential

for viral replication. Although viruses are still able to invade these forewarned cells, these pathogens cannot govern cellular protein synthesis for their own replication (► Figure 11-6).

The newly synthesized inhibitory enzymes remain inactive within the tipped-off potential host cell unless it is actually invaded by a virus, at which time the enzymes are activated by the presence of viral nucleic acid. This activation requirement protects the cell's own messenger RNA and protein-synthesizing machinery from unnecessary inhibition by these enzymes should viral invasion not occur. Because activation can take place only during a limited time span, this is a short-term defence mechanism.

Interferon is released nonspecifically from any cell infected by any virus and, in turn, can induce temporary self-protective activity against many different viruses in any other cells that it reaches. In this way, it provides a general, rapidly responding defence strategy against viral invasion until more specific, but slower-responding, immune mechanisms come into play.

In addition to facilitating inhibition of viral replication, interferon reinforces other immune activities. For example, it enhances macrophage phagocytic activity, stimulates production of antibodies, and boosts the power of killer cells.

ANTICANCER EFFECTS OF INTERFERON

Interferon exerts anticancer as well as antiviral effects. It markedly enhances the actions of cell-killing cells—the natural killer cells and a special type of T lymphocyte, *cytotoxic T cells*—which attack and destroy both virus-infected cells and cancer cells. Furthermore, interferon itself slows cell division and suppresses tumour growth.

Natural killer cells

As well as the functions of inflammation and interferon, **natural killer (NK) cells** are naturally occurring, lymphocyte-like cells that nonspecifically destroy virus-infected cells and cancer cells by directly lysing the membranes of such cells on first exposure to them. Their mode of action and major targets are similar to those of cytotoxic T cells, but the latter can fatally attack only the specific types of virus-infected cells and cancer cells to which they have been previously exposed. Furthermore, after exposure, cytotoxic T cells require a maturation period before they can launch their lethal assault. NK cells provide an immediate, nonspecific defence against virus-invaded cells and cancer cells before the more specific and more abundant cytotoxic T cells become functional.

► **FIGURE 11-6 Mechanism of action of interferon in preventing viral replication.** Interferon, which is released from virus-infected cells, binds with other uninvaded host cells and induces these cells to produce inactive enzymes capable of blocking viral replication. These inactive enzymes are activated only if a virus subsequently invades one of these prepared cells.

© 2016 Cengage

The complement system

The **complement system**, the last of the four innate immunity defences, is brought into play nonspecifically in response to invading organisms. This system can be activated in two ways:

1. By exposure to particular carbohydrate chains present on the surfaces of microorganisms, but not found on human cells, generating a nonspecific innate immune response
2. By exposure to antibodies produced against a specific foreign invader, generating an adaptive immune response

In fact, the system derives its name from the fact that it *complements* the action of antibodies; it is the primary mechanism activated by antibodies to kill foreign cells. It does so by forming membrane attack complexes that punch holes in the victim cells. In addition to bringing about direct lysis of the invader, the powerful complement cascade reinforces other general inflammatory tactics.

FORMATION OF THE MEMBRANE ATTACK COMPLEX

In the same mode as the clotting and anticlotting systems, the complement system consists of plasma proteins that are produced by the liver and circulate in the blood in inactive form. Once the first component, C1, is activated, it activates the next component, C2, and so on, in a cascade sequence of activation reactions. The five final components, C5 through C9, assemble into a large, doughnut-shaped protein complex, the **membrane attack complex (MAC)**, which embeds itself in the surface membrane of nearby microorganisms, creating a large channel through the membrane (▶ Figure 11-7). In other words, the parts make a hole. This hole-punching technique makes the membrane extremely leaky; the resulting osmotic flux of water into the victim cell causes it to swell and burst. This complement-induced lysis is the major means of directly killing microbes without phagocytizing them.

▶ **FIGURE 11-7** Membrane attack complex (MAC) of the complement system. Activated complement proteins C5, C6, C7, C8, and a number of C9s aggregate to form a porelike channel in the plasma membrane of the target cell. The resulting leakage leads to destruction of the cell.

AUGMENTING INFLAMMATION

Unlike the other cascade systems, in which the sole function of the various components leading up to the end step is activation of the next precursor in the sequence, several activated proteins in the complement cascade also act on their own to augment the inflammatory process—by the following methods:

- *Serving as chemotaxins*, which attract and guide professional phagocytes to the site of complement activation (i.e., the site of microbial invasion)
- *Acting as opsonins*, by binding with microbes and thereby enhancing their phagocytosis
- *Promoting vasodilation and increased vascular permeability*, thus increasing blood flow to the invaded areas
- *Stimulating release of histamine* from mast cells in the vicinity, which in turn enhances the local vascular changes characteristic of inflammation
- *Activating kinins*, which further reinforce inflammatory reactions

Several activated components in the cascade are very unstable. Because these unstable components can carry out the sequence only in the immediate area in which they are activated before they decompose, the complement attack is confined to the surface membrane of the microbe whose presence initiated activation of the system. Nearby host cells are thus spared from lytic attack.

We have now completed our discussion of innate immunity and are going to turn our attention to adaptive immunity.

Check Your Understanding 11.4

1. List and briefly describe the four types of innate defence.
2. What are the gross manifestations of inflammation, and what are their underlying physiological mechanisms?
3. Define *cytokines*.

11.5 | Adaptive Immunity: General Concepts

A specific adaptive immune response is a selective attack aimed at limiting or neutralizing a particular offending target for which the body has been specially prepared after previous exposure to it.

Antibody-mediated immunity and cell-mediated immunity

There are two classes of adaptive immune responses: **antibody-mediated (humoural) immunity**, involving production of antibodies by B lymphocyte derivatives known as *plasma cells*; and **cell-mediated immunity**, involving production of *activated T lymphocytes*, which directly attack unwanted cells.

Lymphocytes can specifically recognize and selectively respond to an almost limitless variety of foreign agents as well as cancer cells. The recognition and response processes are different in B and in T cells. In general, B cells recognize free-existing foreign invaders, such as bacteria and their toxins, and a few viruses, which they combat by secreting antibodies specific for the invaders. T cells specialize in recognizing and destroying body cells gone awry, including virus-infected cells and cancer cells. We are now going to explore the different life histories of B and T cells.

ORIGINS OF B AND T CELLS

Both types of lymphocytes, like all blood cells, are derived from common stem cells in the bone marrow. Whether a lymphocyte and all its progeny are destined to be B or T cells depends on the site of final differentiation and maturation of the original cell in the lineage (► Figure 11-8). B cells differentiate and mature

in the bone marrow. As for T cells, during fetal life and early childhood, some of the immature lymphocytes from the bone marrow migrate through the blood to the thymus, where they undergo further processing to become T lymphocytes (named for their site of maturation). The *thymus* is a lymphoid tissue located midline within the chest cavity above the heart in the space between the lungs (see ► Figure 11-2).

On being released into the blood from either the bone marrow or the thymus, mature B and T cells take up residence and establish lymphocyte colonies in the peripheral lymphoid tissues. Here, on appropriate stimulation, they undergo cell division to produce new generations of either B or T cells, depending on their ancestry. After early childhood, most new lymphocytes are derived from these peripheral lymphocyte colonies rather than from the bone marrow.

Each of us has an estimated 2 trillion lymphocytes, which, if aggregated in a mass, would be about the size of the brain. At any one time, most of these lymphocytes are concentrated in the various strategically located lymphoid tissues, but both B and T cells continually circulate among the lymph, blood, and body tissues, where they remain on constant surveillance.

ROLE OF THYMOSIN

Because most of the migration and differentiation of T cells occurs early in development, the thymus gradually atrophies and becomes less important as the person matures. It does, however, continue to produce **thymosin**, a hormone important in maintaining the T-cell lineage. Thymosin enhances proliferation of new T cells within the peripheral lymphoid tissues and augments the immune capabilities of existing T cells. Secretion of thymosin decreases after about 30 to 40 years of age. This decline has been suggested as a contributing factor in aging. Scientists further speculate that diminishing T-cell capacity with advancing age may be linked to increased susceptibility to viral infections and cancer, because T cells play an especially important role in defence against viruses and cancer.

Let's now see how lymphocytes detect their selected target.

Antigens

Both B and T cells must be able to specifically recognize the unwanted cells and other material to be destroyed or neutralized as being distinct from the body's own normal cells. The presence of antigens enables lymphocytes to make this distinction. An **antigen** is a large, foreign, unique molecule that triggers a specific immune response against itself when it gains entry into the body. In general, the more complex a molecule is, the greater its antigenicity. Foreign proteins are the most common antigens because of their size and structural complexity, although other macromolecules, such as large polysaccharides and lipids, can also act as antigens. Antigens may exist as isolated molecules, such as bacterial toxins, or they may be an integral part of a multimolecular structure, as when they are on the surface of an invading foreign microbe.

In the next section we examine how B cells respond to their targeted antigen. In Section 11.7, we look at the response of T cells to their antigen.

► **FIGURE 11-8** Origins of B and T cells. B cells are derived from lymphocytes that matured and differentiated in the bone marrow, whereas T cells are derived from lymphocytes that originated in the bone marrow but matured and differentiated in the thymus. After early childhood, new B and T cells are produced primarily by colonies of B and T cells established in peripheral lymphoid tissues during fetal life and early childhood.

1. State the two classes of adaptive immunity, and indicate which type of lymphocyte accomplishes each.
2. Define *antigen*.

11.6 | B Lymphocytes: Antibody-Mediated Immunity

Each B and T cell has receptors—**B-cell receptors (BCRs)** and **T-cell receptors (TCRs)**—on its surface for binding with one particular type of the multitude of possible antigens (▶ Figure 11-9). These receptors are the “eyes of the adaptive immune system,” although a given lymphocyte can see only one unique antigen. This is in contrast to the TLRs of the innate effector cells, which recognize generic trademarks found on the surface of all microbial invaders. Two important things to know about B cells are as follows:

- *The antigens to which B cells respond can be T-independent or T-dependent.* B cells can bind with and be directly activated by polysaccharide antigens without any assistance from T cells. These antigens, known as **T-independent antigens**, stimulate production of antibodies without any T-cell involvement. By contrast, **T-dependent antigens**, which are

typically protein antigens, do not directly stimulate the production of antibodies without the help of a special type of T cell, known as a *helper T cell*. The majority of antigens to which B cells respond are T-dependent antigens.

- *Antigens stimulate B cells to convert into plasma cells that produce antibodies.* When BCRs (▶ Figure 11-9a) bind with an antigen, most B cells differentiate into active *plasma cells*, whereas others become dormant *memory cells*.

We first examine the role of plasma cells and their antibodies and then turn our attention to memory cells.

Plasma cells

A **plasma cell** produces **antibodies** that can combine with the specific type of antigen that stimulated activation of the plasma cell. During differentiation into a plasma cell, a B cell swells as the rough endoplasmic reticulum (the site for synthesis of proteins to be exported) greatly expands (▶ Figure 11-10). Because antibodies are proteins, plasma cells essentially become prolific protein factories, producing up to 2000 antibody molecules per second. So great is the commitment of a plasma cell's protein-synthesizing machinery to antibody production that it cannot maintain protein synthesis for its own viability and growth. Consequently, it dies after a brief (five- to seven-day), highly productive lifespan.

Antibodies are directly secreted into the blood or lymph, depending on the location of the activated plasma cells, but all antibodies eventually gain access to the blood, where they are known as gamma globulins (immunoglobulins) (p. 435).

Antibody subclasses

Antibodies are grouped into five subclasses based on differences in their biological activity:

1. **IgM** immunoglobulin serves as the B-cell surface receptor for antigen attachment and is secreted in the early stages of plasma cell response.
2. **IgG**, the most abundant immunoglobulin in the blood, is produced copiously when the body is subsequently exposed to the same antigen. Together, IgM and IgG antibodies produce most specific immune responses against bacterial invaders and a few types of viruses.
3. **IgE** helps protect against parasitic worms and is the antibody mediator for common allergic responses, such as hay fever, asthma, and hives.

11

FIGURE 11-10 Comparison of an unactivated B cell and a plasma cell. Electron micrograph of (a) an unactivated B cell, or small lymphocyte, and (b) a plasma cell. A plasma cell is an activated B cell. It is filled with an abundance of rough endoplasmic reticulum distended with antibody molecules.

4. **IgA** immunoglobulins are found in secretions of the digestive, respiratory, and genitourinary systems, as well as in milk and tears.
5. **IgD** is present on the surface of many B cells, but its function is uncertain.

Note that this classification is based on different ways in which antibodies function. It does not imply there are only five different antibodies. Within each functional subclass are millions of different antibodies, each able to bind with a specific antigen only.

The basic functions of antibodies are as follows:

- binding antigens
- activating the complement system (cascade)
- binding and neutralizing bacterial toxins
- inhibiting bacterial access to host cells
- inhibiting viral entry into host cells
- assisting phagocytosis against parasites
- aiding cytotoxicity of T and NK cells

Antibody structure

Antibodies of all five subclasses are composed of four interlinked polypeptide chains—two long, heavy chains and two short, light chains—arranged in the shape of a Y (Figure 11-11). Characteristics of the arm regions of the Y determine the *specificity* of the antibody (i.e., with what antigen the antibody can bind). Properties of the tail portion of the antibody determine the *functional properties* of the antibody (what the antibody does once it binds with antigen).

An antibody has two identical antigen-binding sites, one at the tip of each arm. These **antigen-binding fragments (Fab)** are

unique for each different antibody, so that each antibody can interact only with an antigen that specifically matches it, much like a lock and key. The tremendous variation in the antigen-binding fragments of different antibodies leads to the extremely large number of unique antibodies that can bind specifically with millions of different antigens.

In contrast to these variable Fab regions at the arm tips, the tail portion of every antibody within each immunoglobulin subclass is identical. The tail, the antibody's so-called **constant (Fc) region**, contains binding sites for particular mediators of antibody-induced activities, which vary among the different subclasses. In fact, differences in the constant region are the basis for distinguishing between the different immunoglobulin subclasses. For example, the constant tail region of IgG antibodies, when activated by antigen binding in the Fab region, binds with phagocytic cells and serves as an opsonin to enhance phagocytosis. In comparison, the constant tail region of IgE antibodies attaches to mast cells and basophils, even in the absence of antigen. When the appropriate antigen gains entry to the body and binds with

FIGURE 11-11 Antibody structure. An antibody is Y-shaped. It is able to bind only with the specific antigen that “fits” its antigen-binding sites (Fab) on the arm tips. The tail region (Fc) binds with particular mediators of antibody-induced activities.

the attached antibodies, this triggers the release of histamine from the affected mast cells and basophils. Histamine, in turn, induces the allergic manifestations that follow.

Antibodies and immune responses

Immunoglobulins cannot directly destroy foreign organisms or other unwanted materials on binding with antigens on their surfaces. Instead, antibodies exert their protective influence by

physically hindering antigens or, more commonly, by amplifying innate immune responses (► Figure 11-12).

Neutralization and agglutination

Antibodies can physically hinder some antigens from exerting their detrimental effects. For example, by combining with bacterial toxins, antibodies can prevent these harmful chemicals from interacting with susceptible cells. This process is known

► **FIGURE 11-12** How antibodies help eliminate invading microbes. Antibodies physically hinder antigens through neutralization or (a) agglutination and precipitation. Antibodies amplify innate immune responses by (b) activating the complement system, (c) enhancing phagocytosis by acting as opsonins, and (d) stimulating killer cells.

as **neutralization**. Similarly, antibodies can bind with surface antigens on some types of viruses, preventing these viruses from entering cells, where they could exert their damaging effects. Sometimes multiple antibody molecules can cross-link numerous antigen molecules into chains or lattices of antigen—antibody complexes. The process in which foreign cells, such as bacteria or mismatched transfused red blood cells, bind together in such a clump is known as **agglutination**. When linked antigen—antibody complexes involve soluble antigens, such as tetanus toxin, the lattice can become so large that it precipitates out of solution. (**Precipitation** is the process in which a substance separates from a solution.) Within the body, these physical hindrance mechanisms play only a minor protective role against invading agents.

However, the tendency for certain antigens to agglutinate or precipitate on forming large complexes with antibodies specific for them is useful clinically and experimentally for detecting the presence of particular antigens or antibodies. Pregnancy diagnosis tests, for example, use this principle to detect, in urine, the presence of a hormone secreted soon after conception.

AMPLIFICATION OF INNATE IMMUNE RESPONSES

Antibodies' most important function by far is to profoundly augment the innate immune responses already initiated by the invaders. Antibodies mark foreign material as targets for destruction by the complement system, phagocytes, or natural killer (NK) cells. At the same time they enhance the activity of these defence systems by the following methods:

1. *Activating the complement system.* When an appropriate antigen binds with an antibody, receptors on the tail portion of the antibody bind with and activate C1, the first component of the complement system. This sets off the cascade of events leading to formation of the membrane attack complex, which is specifically directed at the membrane of the invading cell that bears the antigen that initiated the activation process. In fact, antibodies are the most powerful activators of the complement system. The biochemical attack subsequently unleashed against the invader's membrane is the most important mechanism by which antibodies exert their protective influence. Furthermore, various activated complement components enhance virtually every aspect of the inflammatory process. The same complement system is activated by an antigen—antibody complex regardless of the type of antigen. Although the binding of antigen to antibody is highly specific, the outcome, which is determined by the antibody's constant tail region, is identical for all activated antibodies within a given subclass; for example, all IgG antibodies activate the same complement system.
2. *Enhancing phagocytosis.* Antibodies, especially IgG, act as opsonins. The tail portion of an antigen-bound IgG antibody binds with a receptor on the surface of a phagocyte and subsequently promotes phagocytosis of the antigen-containing victim attached to the antibody.

3. *Stimulating NK cells.* Binding of antibody to antigen induces the attack of an antigen-bearing cell by NK cells. NK cells attack and destroy both antibody-coated cells and also MHC class I target cells.

In these ways, antibodies, although unable to directly destroy invading bacteria or other undesirable material, bring about destruction of the antigens to which they are specifically attached: specifically, by amplifying other nonspecific lethal defence mechanisms.

IMMUNE COMPLEX DISEASE

Occasionally an overzealous antigen—antibody response inadvertently causes damage to normal cells as well as to invading foreign cells. Typically, antigen—antibody complexes, formed in response to foreign invaders, are removed by phagocytic cells after having revved up nonspecific defence strategies. If large numbers of these complexes are continuously produced, however, the phagocytes cannot clear away all the immune complexes formed. Antigen—antibody complexes that are not removed continue to activate the complement system, among other things. Excessive amounts of activated complement and other inflammatory agents may “spill over,” damaging surrounding normal cells as well as the unwanted cells. Furthermore, destruction is not necessarily restricted to the initial site of inflammation. antigen—antibody complexes may circulate freely and become trapped in the kidneys, joints, brain, small vessels of the skin, and elsewhere, causing widespread inflammation and tissue damage. Such damage produced by immune complexes is referred to as an **immune complex disease**, which can be a complicating outcome of bacterial, viral, or parasitic infection.

More insidiously, immune complex disease can also stem from overzealous inflammatory activity prompted by immune complexes formed by *self-antigens* (proteins synthesized by the person's own body) and antibodies erroneously produced against them. *Rheumatoid arthritis* develops in this way.

Clonal selection

Consider the diversity of foreign molecules a person can potentially encounter during a lifetime. Yet each B cell is preprogrammed to respond to only one of these millions of different antigens. Other antigens cannot combine with the same B cell and induce it to secrete different antibodies. The astonishing implication is that each of us is equipped with millions of different preformed B lymphocytes, at least one for every possible antigen that we might ever encounter—including those specific for synthetic substances that do not exist in nature. The clonal selection theory proposes how a matching B cell responds to its antigen.

Early researchers in immunological theory believed antibodies were “made to order” whenever a foreign antigen gained entry to the body. In contrast, the currently accepted **clonal selection theory** proposes that diverse B lymphocytes are produced during fetal development, each capable of synthesizing an antibody against a particular antigen before ever being exposed

to it. All offspring of a particular ancestral B lymphocyte form a family of identical cells, or a **clone**, that is committed to producing the same specific antibody. B cells remain dormant, not actually secreting their particular antibody product nor undergoing rapid division until (or unless) they come into contact with the appropriate antigen. Lymphocytes that have not yet been exposed to their specific antigen are known as **naïve lymphocytes**. When an antigen gains entry to the body, the particular clone of B cells that bear receptors on their surface uniquely specific for that antigen is activated, or selected, by the antigen binding with the receptors, hence the term *clonal selection theory* (► Figure 11-13).

The first antibodies produced by a newly formed B cell are IgM immunoglobulins, which are inserted into the cell's plasma membrane rather than secreted. Here, they serve as receptor sites for binding with a specific kind of antigen, almost like advertisements for the kind of antibody the cell can produce. The binding of the appropriate antigen to a B cell amounts to placing an order for the manufacture and secretion of large quantities of that particular antibody.

Selected clones

Antigen binding causes the activated B-cell clone to multiply and differentiate into two cell types: plasma cells and memory cells. Most progeny are transformed into active plasma cells, which are prolific producers of customized antibodies that contain the same antigen-binding sites as the surface receptors. However, plasma cells switch to producing IgG antibodies, which are secreted rather than remaining membrane bound. In the blood, the secreted antibodies combine with the invading free antigen (not bound to lymphocytes), marking it for destruction by the complement system, phagocytic ingestion, or other means.

MEMORY CELLS

Not all the new B lymphocytes produced by the specifically activated clone differentiate into antibody-secreting plasma cells. A small proportion of them become **memory cells**, which do not participate in the current immune attack against the antigen, but instead remain dormant and expand the specific clone. If the person is ever re-exposed to the same antigen, these memory cells are primed and ready for even more immediate action than were the original lymphocytes in the clone.

Even though each of us has essentially the same original pool of different B-cell clones, the pool gradually becomes appropriately biased to respond most efficiently to each person's particular antigenic environment. Those clones specific for antigens to which a person is never exposed remain dormant for life, whereas those specific for antigens in the individual's environment typically become expanded and enhanced by forming highly responsive memory cells. The different naïve clones provide protection against unknown new pathogens, and the evolving populations of memory cells protect against the recurrence of infections encountered in the past.

11

© 2016 Cengage

► **FIGURE 11-13 Clonal selection theory.** The B-cell clone specific to the antigen proliferates and differentiates into plasma cells and memory cells. Plasma cells secrete antibodies that bind with free antigen not attached to B cells. Memory cells expand the specific clone and are primed and ready for subsequent exposure to the same antigen.

PRIMARY AND SECONDARY RESPONSES

During initial contact with a microbial antigen, the antibody response is delayed for several days until plasma cells are formed and does not reach its peak for a couple of weeks (► Figure 11-14). This response is known as the **primary response**. Meanwhile, symptoms characteristic of the particular microbial invasion persist until either the invader succumbs to the mounting specific immune attack against it or the infected person dies. After reaching the peak, the antibody levels gradually decline over a period of time, although some circulating antibody from

Vaccination: A Victory over Many Dreaded Diseases

MODERN SOCIETY HAS COME TO HOPE and even expect that vaccines can be developed to protect us from almost any dreaded infectious disease. This expectation has been brought into sharp focus by our current frustration over the inability to date to develop a successful vaccine against HIV, the virus that causes AIDS.

Nearly 2500 years ago, our ancestors were aware of the existence of immune protection. Writing about a plague that struck Athens in 430 BCE, Thucydides observed that the same person was never attacked twice by this disease. However, the ancients did not understand the basis of this protection, so they could not manipulate it to their advantage.

Early attempts to deliberately acquire lifelong protection against smallpox, a dreaded disease that was highly infectious and frequently fatal (up to 40% of the sick died), consisted of intentionally exposing oneself by coming into direct contact with a person suffering from a milder form of the disease. The hope was to protect against a future fatal bout of smallpox by deliberately inducing a mild case of the disease. By the beginning of the 17th century, this technique had evolved into using a needle to extract small amounts of pus from active smallpox pustules (the fluid-filled bumps on the skin, which leave a characteristic depressed scar or pock mark after healing) and introducing this infectious material into healthy individuals. This inoculation process was done by applying the pus directly to slight cuts in the skin or by inhaling dried pus.

Edward Jenner, an English physician, was the first to demonstrate that immunity against cowpox, a disease similar to but less serious than smallpox, could also protect humans against smallpox. Having observed that milkmaids who got cowpox seemed to be protected from smallpox, Jenner in 1796 inoculated a healthy boy with pus he had extracted from cowpox boils. After the boy recovered, Jenner (not being restricted by modern ethical standards of research on human subjects) deliberately inoculated him with what was considered a normally fatal dose of smallpox infectious material. The boy survived.

Jenner's results were not taken seriously, however, until a century later when, in the 1880s, Louis Pasteur, the first great experimental

immunologist, extended Jenner's technique. Pasteur demonstrated that the disease-inducing capability of organisms could be greatly reduced (attenuated) so they could no longer produce disease but would still induce antibody formation when introduced into the body—the basic principle of modern vaccines. His first vaccine was against anthrax, a deadly disease of sheep and cows. Pasteur isolated and heated anthrax bacteria, then injected these attenuated organisms into a group of healthy sheep. A few weeks later at a gathering of fellow scientists, Pasteur injected these vaccinated sheep as well as a group of unvaccinated sheep with fully potent anthrax bacteria. The result was dramatic—all the vaccinated sheep survived, but all the unvaccinated sheep died. Pasteur's notorious public demonstrations, such as this, coupled with his charismatic personality, caught the attention of physicians and scientists of the time, sparking the development of modern immunology.

Today, vaccinations work using the same principles as those used by Jenner and Pasteur, but we have developed other methods of delivering the foreign antigen. Three common methods of introducing the antigen follow:

1. Inserting an inactivated vaccine consisting of virus particles that have been grown in culture and then killed (e.g., by heat)
2. Using an attenuated vaccine consisting of live virus particles with low virulence
3. Establishing a subunit vaccine that presents an antigen to the immune system without introducing viral particles

this primary response may persist for a prolonged period. Long-term protection against the same antigen, however, is primarily attributable to the memory cells. If the same antigen ever reappears, the long-lived memory cells launch a more rapid, more potent, and longer-lasting **secondary response** than occurred during the primary response. This swifter, more powerful immune attack is frequently adequate to prevent or minimize overt infection on subsequent exposures to the same microbe, forming the basis of long-term immunity against a specific disease.

The original antigenic exposure that induces the formation of memory cells can occur through the person either actually having the disease or being vaccinated. Vaccination deliberately exposes the person to a pathogen that has been stripped of its disease-inducing capability but that can still induce antibody formation against itself. (For the early history of vaccination development, see Concepts, Challenges, and Controversies.)

Memory cells are not formed for some diseases, so lasting immunity is not conferred by an initial exposure, as in the case

FIGURE 11-14 Primary and secondary immune responses. (a) Primary response on first exposure to a microbial antigen. (b) Secondary response on subsequent exposure to the same microbial antigen. The primary response does not peak for a couple of weeks, whereas the secondary response peaks in a week. The magnitude of the secondary response is 100 times greater than the primary response. (The relative antibody response is in the logarithmic scale.)

of strep throat. The course and severity of the disease are the same each time a person is reinfected with a microbe that the immune system does not “remember,” regardless of the number of prior exposures.

B cells and gene fragments

Considering the millions of different antigens against which each of us has the potential to actively produce antibodies, how is it possible for an individual to have such a tremendous diversity of B lymphocytes, each capable of producing a different antibody? Antibodies are proteins synthesized in accordance with a nuclear DNA blueprint. However, because all cells of the body, including the antibody-producing cells, contain the same nuclear DNA, it is hard to imagine how enough DNA could be packaged within the nuclei of every cell to code for the millions of different antibodies (a different portion of the genetic code being used by each B-cell clone), along with all the other genetic instructions used by other cells. Actually, only a relatively small number of gene fragments code for antibody synthesis, but during B-cell development these fragments are cut, reshuffled, and spliced in a vast number of different combinations. Each different combination gives rise to a unique B-cell clone. Antibody genes are later even further diversified by somatic mutation (Appendix C, p. A-30). The antibody genes of already-formed B cells are highly prone to mutations in the region that codes for the variable antigen-binding sites on the antibodies. Each different mutant cell in turn gives rise to a new clone. Thus, the great diversity of antibodies is made possible by the reshuffling of a small set of gene fragments during B-cell development, as well as by further somatic mutation

in already-formed B cells. In this way, a huge antibody repertoire is possible using only a modest share of the genetic blueprint.

Active and passive immunity

The production of antibodies as a result of exposure to an antigen is referred to as **active immunity** against that antigen. A second way in which an individual can acquire antibodies is by the direct transfer of antibodies actively formed by another person (or animal). The immediate “borrowed” immunity conferred upon receipt of pre-formed antibodies is known as **passive immunity**. Such transfer of antibodies of the IgG class normally occurs from the mother to the fetus across the placenta during intrauterine development. In addition, a mother’s colostrum (first milk) contains IgA antibodies that provide further protection for breastfed babies. Passively transferred antibodies are usually broken down in less than a month, but meanwhile newborns are provided important immune protection (essentially the

same as their mother’s) until they can begin actively mounting their own immune responses. Antibody-synthesizing ability does not develop for about a month after birth.

Clinical Note Passive immunity is sometimes employed clinically to provide immediate protection or to bolster resistance against an extremely virulent infectious agent or potentially lethal toxin to which a person has been exposed: for example, rabies virus, tetanus toxin in nonimmunized individuals, and poisonous snake venom. Typically, the administered preformed antibodies have been harvested from another source (often nonhuman) that has been exposed to an attenuated form of the antigen. Frequently, horses or sheep are used in the deliberate production of antibodies to be collected for passive immunizations. Although injection of serum containing these antibodies—**antiserum (antitoxin)**—is beneficial in providing immediate protection against the specific disease or toxin, the recipient may develop an immune response against the injected antibodies themselves, because they are foreign proteins. The result may be a severe allergic reaction to the treatment, a condition known as **serum sickness**.

Check Your Understanding 11.6

1. Describe the structure and function of the Fab and Fc regions of an antibody.
2. List the means by which antibodies help to eliminate invading microbes.
3. According to the clonal selection theory, draw a flow diagram showing the formation of plasma cells and memory cells in response to the binding of an antigen to its specific B-cell receptor.

11.7 | T Lymphocytes: Cell-Mediated Immunity

As important as B lymphocytes and their antibody products are in specific defence against invading bacteria and other foreign material, they represent only half of the body's specific immune defences. T cells account for approximately 50 to 70 percent of the total lymphocyte number in circulation. The T lymphocytes are equally as important in defence against most viral infections as B lymphocytes are and also play an important regulatory role in immune mechanisms.

T cells and targets

Whereas B cells and antibodies defend against conspicuous invaders in the ECF, T cells defend against covert invaders that hide inside cells where antibodies and the complement system cannot reach them. Unlike B cells, which secrete antibodies that can attack antigen at long distances, T cells do not secrete antibodies. Instead, they must directly contact their targets, a process known as *cell-mediated immunity*. T cells of the killer type release chemicals that destroy targeted cells that they contact, such as virus-infected cells and cancer cells.

Like B cells, T cells are clonal and exquisitely antigen specific. On its plasma membrane, each T cell bears unique receptor proteins called T-cell receptors, similar although not identical to the surface receptors on B cells. Immature lymphocytes acquire their T-cell receptors in the thymus during their differentiation into T cells. Unlike B cells, T cells are activated by a foreign antigen only when it is on the surface of a cell that also carries a marker of the individual's own identity; that is, both foreign antigens and **self-antigens** known as **major histocompatibility complex (MHC) molecules** must be on a cell's surface before a T cell can bind with it. T cells learn to recognize foreign antigens only in combination with the person's own tissue antigens. This "thymic education," lets T cells pass on what they've learned to all T cells' future progeny. The importance of this dual antigen requirement and the nature of the MHC self-antigens are described in the section Class I and Class II MHC Glycoproteins.

A delay of a few days generally follows exposure to the appropriate antigen before **sensitized (activated) T cells** are prepared to launch a cell-mediated immune attack. When exposed to a specific antigen combination, cells of the complementary T-cell clone proliferate and differentiate for several days, a process that yields large numbers of activated effector T cells that carry out various cell-mediated responses.

Cytotoxic T cells, helper T cells, and regulatory T cells

There are three main subpopulations of T cells, depending on their roles when activated by antigens:

1. **CD8 cells (cytotoxic, or killer, T cells)** destroy host cells harbouring anything foreign and thus bearing foreign antigen, such as body cells invaded by viruses, cancer cells

that have mutated proteins resulting from malignant transformations, and transplanted cells.

2. **CD4 cells** enhance the development of antigen-stimulated B cells into antibody-secreting plasma cells, enhance activity of the appropriate cytotoxic cells, and activate macrophages. CD4 cells do not directly participate in immune destruction of invading pathogens. Instead, they modulate activities of other immune cells.

Helper T cells are by far the most numerous T cells, making up 60–80 percent of circulating T cells. Because of the important role these cells play in turning on the full power of all the other activated lymphocytes and macrophages, helper T cells constitute the immune system's master switch.

3. **Regulatory T cells (T_{reg})**, originally called **suppressor T cells**, are a recently identified small subset of CD4 cells. In addition, they also have CD25, a component of a receptor for IL-2, which promotes T_{reg} activities. Thus, these cells are also referred to as **CD4+CD25+T cells**.

Acquired immunodeficiency syndrome (AIDS), caused by the **human immunodeficiency virus (HIV)**, is extremely devastating to the immune defence system. The AIDS virus selectively invades helper T cells, destroying or incapacitating the cells that normally orchestrate much of the immune response (▶ Figure 11-15). The virus also invades macrophages, further crippling the immune system, and sometimes enters brain cells as well, leading to the dementia (severe impairment of intellectual capacity) noted in some AIDS victims.

MEMORY T CELLS

Like B cells, T cells form a memory pool and display both primary and secondary responses. Primary responses tend to be initiated in the lymphoid tissues, where naive lymphocytes and antigen-presenting cells interact. For a few weeks after the infection is cleared, more than 90 percent of the huge number of effector T cells generated during the primary response die by means of *apoptosis* (cell suicide). To stay alive, activated

© Lennart Nilsson/Scampix

▶ **FIGURE 11-15 AIDS virus.** Human immunodeficiency virus (HIV) (in grey), the AIDS-causing virus, on a helper T lymphocyte, HIV's primary target

T lymphocytes require the continued presence of their specific antigen and appropriate stimulatory signals. Once the foe succumbs, the vast majority of the now superfluous T lymphocytes commit suicide, because their supportive antigen and stimulatory signals are withdrawn. Elimination of most of the effector T cells following a primary response is essential to prevent congestion in the lymphoid tissues. (Such paring down is not needed for B cells because those that become plasma cells rather than memory B cells upon antigen stimulation rapidly work themselves to death while producing antibodies.) The remaining surviving effector T cells become long-lived memory T cells that migrate to all areas of the body, where they are poised for a swift secondary response to the same pathogen in the future.

Let's examine the T cells in further detail.

Cytotoxic T cells

Cytotoxic T cells are microscopic “hit men.” The targets of these destructive cells most frequently are host cells infected with viruses. When a virus invades a body cell, as it must to survive, the infected cell breaks down the envelope of proteins surrounding the virus and then loads a fragment of the viral antigen piggyback-style onto a newly synthesized self-antigen. This self-antigen and viral antigen complex is inserted into the host cell's surface membrane, where it serves as a red flag that indicates the cell is harbouring the invader (► Figure 11-16, steps **1** and **2**). To attack the intracellular virus, cytotoxic T cells must destroy the infected host cell in the process. Cytotoxic T cells of the clone that's specific for this particular virus recognize and bind to the viral antigen and self-antigen on the surface of an infected cell (Figure 11-16, step **3**). Thus sensitized by viral antigen, a cytotoxic T cell can kill the infected cell by either direct or indirect means, depending on the type of lethal chemicals the activated T cell releases. Let's elaborate.

- An activated cytotoxic T cell may directly kill the victim cell by releasing chemicals that lyse the attacked cell before viral replication can begin (Figure 11-16, step **4**). Specifically, cytotoxic T cells as well as NK cells destroy a targeted cell by releasing **perforin** molecules, which penetrate the target cell's surface membrane and join to form porelike channels (► Figure 11-17). This technique of killing a cell by punching holes in its membrane is similar to the method employed by the membrane attack complex of the complement cascade. This contact-dependent mechanism of killing has been nicknamed the “kiss of death.”
- A cytotoxic T cell can also indirectly bring about death of an infected host cell by releasing **granzymes**, which are enzymes similar to digestive enzymes. Granzymes enter the target cell through the perforin channels. Once inside, these chemicals trigger the virus-infected cell to self-destruct through apoptosis (cell suicide).

The virus released on destruction of the host cell by either of these methods is directly destroyed in the ECF by phagocytic cells, neutralizing antibodies, and the complement system. Meanwhile, the cytotoxic T cell, which has not been harmed in the process, can move on to kill other infected host cells.

► FIGURE 11-16 A cytotoxic T cell lysing a virus-invaded cell

- 1 The killer cell binds to its target cell.
- 2 As a result of this binding, the killer cell's perforin-containing granules fuse with the plasma membrane.
- 3 The granules discharge their perforin by exocytosis into a small pocket of intercellular space between the killer cell and its target.
- 4 On exposure to Ca^{2+} in this ECF space, the individual perforin molecules change from a spherical to a cylindrical shape.
- 5 The remodelled perforin molecules bind to the target cell membrane and insert into it.
- 6 Individual perforin molecules group together like staves of a barrel to form pores.
- 7 The pores admit salt and H_2O , causing the target cell to swell and burst.

11

The surrounding healthy cells replace the lost cells by means of cell division. Usually, to halt a viral infection, only some of the host cells must be destroyed. If the virus has had a chance to multiply, however, with the replicated virus leaving the original cell and spreading to other host cells, the cytotoxic T-cell defence mechanism may sacrifice so many of the host cells that serious malfunction may ensue.

Recall that other nonspecific defence mechanisms also come into play to combat viral infections, most notably NK cells, interferon, macrophages, and the complement system. As usual, an intricate web of interplay exists among the immune defences that are launched against viral invaders (■ Table 11-2).

ANTIVIRAL DEFENCE IN THE NERVOUS SYSTEM

The usual method of destroying virus-infected host cells is not appropriate for the nervous system. If cytotoxic T cells destroyed virus-infected neurons, the lost cells could not be replaced,

because neurons cannot reproduce. Fortunately, virus-infected neurons are spared from extermination by the immune system. But how are neurons protected from viruses? Immunologists long thought that the only antiviral defences for neurons were those aimed at free viruses in the extracellular fluid. Surprising new research has revealed, however, that antibodies not only target viruses for destruction in the extracellular fluid but can also eliminate viruses inside neurons. It is unclear whether antibodies actually enter the neurons and interfere directly with viral replication (neurons have been shown to take up antibodies near their synaptic endings) or bind with the surface of nerve cells and trigger intracellular changes that stop viral replication.

The fact that some viruses, such as the herpes virus, persist for years in nerve cells, occasionally flaring up to produce symptoms, demonstrates that the antibodies' intraneuronal mechanism does not provide a foolproof antiviral defence for neurons.

TABLE 11-2 Defences against Viral Invasion

When the virus is free in the ECF

Macrophages

Destroy the free virus by phagocytosis

Process and present the viral antigen to both B and T cells

Secrete interleukin 1, which activates B- and T-cell clones specific to the viral antigen

Plasma Cells Derived from B Cells Specific to the Viral Antigen Secrete Antibodies That

Neutralize the virus to prevent its entry into a host cell

Activate the complement cascade that directly destroys the free virus and enhances phagocytosis of the virus by acting as an opsonin

When the virus has entered a host cell (which it must do to survive and multiply, with the replicated viruses leaving the original host cell to enter the ECF in search of other host cells)

Interferon

Is secreted by virus-infected cells

Binds with and prevents viral replication in other host cells

Enhances the killing power of macrophages, natural killer cells, and cytotoxic T cells

Natural Killer Cells

Nonspecifically lyse virus-infected host cells

Cytotoxic T Cells

Are specifically sensitized by the viral antigen and lyse the infected host cells before the virus has a chance to replicate

Helper T Cells

Secrete cytokines, which enhance cytotoxic T-cell activity and B-cell antibody production

When a virus-infected cell is destroyed, the free virus is released into the ECF, where it is attacked directly by macrophages, antibodies, and the activated complement components.

Helper T cells

In contrast to cytotoxic T cells, helper T cells are not killer cells. Instead, helper T cells secrete chemicals classified as *cytokines* that help, or augment, nearly all aspects of the immune response. Cytokines are growth factors produced by leukocytes and other cells and have many functions, some of which are discussed next.

CYTOKINES

Exposure to antigens frequently activates both the B- and T-cell mechanisms simultaneously. Just as helper T cells can modulate the secretion of antibodies by B cells, antibodies may influence cytotoxic T cells' ability to destroy a victim cell. Most effects that

lymphocytes exert on other immune cells are mediated by secretion of chemical messengers. All chemicals other than the antibodies that leukocytes secrete are collectively called *cytokines*, most of which are produced by helper T cells. Unlike antibodies, cytokines do not interact directly with the antigen that induces their production. Instead, cytokines spur other immune cells into action to help ward off the invader. The following are among the best known of helper T-cell cytokines:

1. Helper T cells secrete several interleukins (*IL-4*, *IL-5*, and *IL-6*) that serve collectively as a **B-cell growth factor**, which contributes to B-cell function in concert with the *IL-1* secreted by macrophages. Antibody secretion is greatly reduced or absent without the assistance of helper T cells, especially in defence against T-dependent antigen.
2. Helper T cells similarly secrete **T-cell growth factor** (*IL-2*), which augments the activity of cytotoxic T cells and even of other helper T cells responsive to the invading antigen. In typical interplay fashion, *IL-1* secreted by macrophages not only enhances the activity of both the appropriate B- and T-cell clones but also stimulates secretion of *IL-2* by activated helper T cells.
3. Some chemicals secreted by T cells act as *chemotaxins* to lure more neutrophils and macrophages-to-be to the invaded area.
4. Once macrophages are attracted to the area, **macrophage-migration inhibition factor**, another important cytokine released from helper T cells, keeps these large phagocytic cells in the region by inhibiting their outward migration. As a result, a great number of chemotactically attracted macrophages accumulate in the infected area. This factor also confers greater phagocytic power to the gathered macrophages. These so-called **angry macrophages** have more powerful destructive ability. They are especially important in defending against the bacteria that cause tuberculosis, because such microbes can survive simple phagocytosis by nonactivated macrophages.
5. One cytokine secreted by helper T cells (*IL-5*) activates eosinophils, and another (*IL-4*) promotes the development of IgE antibodies for defence against parasitic worms.

T HELPER 1 AND T HELPER 2 CELLS

Not all helper cells secrete the same cytokines. Two subsets of helper T cells—**T helper 1** (T_H1) cells and **T helper 2** (T_H2) cells—augment different patterns of immune responses by secreting different types of cytokines. T_H1 cells rally a cell-mediated (cytotoxic T-cell) response, which is appropriate for infections with intracellular microbes, such as viruses, whereas T_H2 cells promote antibody-mediated immunity by B cells and rev up eosinophil activity for defence against parasitic worms.

Helper T cells produced in the thymus are in a naive state until they encounter the antigen they are primed to recognize. Whether a naive helper T cell becomes a T_H1 or T_H2 cell depends on which cytokines are secreted by macrophages and dendritic cells (macrophage-like cells) of the innate immune system that present the antigen to the uncommitted T cell. **Interleukin 12** (*IL-12*)

drives a naive T cell specific for the antigen to become a T_H1 cell, whereas **interleukin 4 (IL-4)** favours the development of a naive cell into a T_H2 cell. Thus, the **antigen-presenting cells** of the nonspecific immune system can influence the whole tenor of the specific immune response by determining whether the T_H1 or T_H2 cellular subset dominates. In the usual case, the secreted cytokines promote the appropriate specific immune response against the particular threat at hand.

Scientists have also recently discovered much smaller subsets of helper T cells: T_H17 cells and T follicular helper (T_{FH}) cells. **Helper T 17 (T_H17) cells** produce *IL-17* (accounting for the name of this subset). They promote inflammation and are effector molecules in the development of inflammatory autoimmune diseases such as multiple sclerosis. The newest discovered **T follicular helper (T_{FH}) cells** specifically interact with B cells in lymph node follicles (hence the name of this subset) to help them secrete antibodies in response to T-dependent antigens.

Clinical Connections

In the case of allergic asthma, the allergen causes macrophages to secrete cytokines that are presented to the naive helper T cell ($Th0$). These $Th0$ cells are transformed into $Th2$ cells, and these cells can then activate the humoral immune system to produce antibodies against the inhaled allergen. When the allergen is again inhaled, an adaptive immune response occurs, which results in the recruitment and infiltration of eosinophils.

The immune system and self-antigens

The term tolerance in this context refers to the phenomenon of preventing the immune system from attacking the person's own tissues. During the genetic “cut, shuffle, and paste process” that goes on during lymphocyte development, some B and T cells are by chance formed that could react against the body's own tissue antigens. If these lymphocyte clones were allowed to function, they would destroy the individual's body. Fortunately, the immune system normally does not produce antibodies or activated T cells against the body's own self-antigens, but instead directs its destructive tactics at foreign antigens only.

At least six different mechanisms are involved in tolerance:

1. **Clonal deletion.** In response to continuous exposure to body antigens early in development, lymphocyte clones specifically capable of attacking these self-antigens in most cases are permanently destroyed. This **clonal deletion** is accomplished by triggering apoptosis of immature cells that would react with the body's own proteins. This physical elimination is the major mechanism by which tolerance is developed.
2. **Clonal anergy.** The premise of **clonal anergy** is that a lymphocyte must receive two specific simultaneous signals to be activated (turned on), one from its compatible antigen and another from a stimulatory cosignal molecule known as **B7**, which is found only on the surface of an antigen-presenting cell. Both signals are present for foreign antigens, which are introduced to lymphocytes by antigen-presenting cells. Once a B or T cell is turned on by finding

its matching antigen in accompaniment with the cosignal, the cell no longer needs the cosignal to interact with other cells. For example, an activated cytotoxic T cell can destroy any virus-invaded cell that bears the viral antigen, even though the infected cell does not have the cosignal. In contrast, these dual signals—antigen plus cosignal—are never present for self-antigens because these antigens are not handled by cosignal-bearing, antigen-presenting cells. The first exposure to a single signal from a self-antigen turns off the compatible T cell, rendering the cell unresponsive to further exposure to the antigen instead of spurring the cell to proliferate. This reaction is referred to as **clonal anergy** (*anergy* means “lack of energy”) because T cells are being inactivated (“become lazy”) rather than activated by their antigens. Clonal anergy is a backup to clonal deletion. Anergized lymphocyte clones survive, but can't function.

3. **Receptor editing.** A newly identified means of ridding the body of self-reactive B cells is **receptor editing**. With this mechanism, once a B cell that bears a receptor for one of the body's own antigens encounters the self-antigen, the B cell escapes death or a lifetime of anergy by swiftly changing its antigen receptor to a nonself version. In this way, an originally self-reactive B cell survives but is “rehabilitated” so that it will never target the body's own tissues again.
4. **Inhibition by regulatory T cells.** These suppressor cells may play a role in tolerance by inhibiting throughout life some lymphocyte clones specific for the body's own tissues.
5. **Immunological ignorance**, alternatively known as *antigen sequestering*. Some self-molecules are normally hidden from the immune system, because they never come into direct contact with the ECF in which the immune cells and their products circulate. An example of such a segregated antigen is thyroglobulin, a complex protein sequestered within the hormone-secreting structures of the thyroid gland (p. 248).
6. **Immune privilege.** A few tissues, most notably the testes and the eyes, have **immune privilege**, because they escape immune attack even when they are transplanted in an unrelated individual. Scientists recently discovered that the cellular plasma membranes in these immune-privileged tissues have a specific molecule that triggers apoptosis of approaching activated lymphocytes that could attack the tissues.

Autoimmune diseases

Occasionally, the immune system fails to distinguish self-antigens from foreign antigens, which results in an attack on its own healthy cells. The nonrecognition of self-antigens is termed an **autoimmune disease**. An example of such a disease is lupus. There are different kinds of lupus, of which the most common is systemic lupus erythematosus, which affects many parts of the body, such as the heart, joints, skin, lungs, blood vessels, liver, kidneys, and nervous system. Systemic lupus erythematosus is unpredictable, with periods of illness (known as flares) alternating with periods of relief

(remission). Systemic lupus erythematosus can occur at any age and is more common in women. Other forms of lupus are discoid lupus, which causes a persistent rash; subacute cutaneous lupus, which is associated with sores after exposure to the sun; and neonatal lupus, which affects newborns. Currently, there is no cure for lupus, but lifestyle adjustments can help fight the disease and give an improved sense of well-being. Autoimmunity underlies more than 80 diseases, many of which are well known. Examples include multiple sclerosis, rheumatoid arthritis, and type 1 diabetes mellitus.

Autoimmune diseases may arise from a number of different causes:

1. Exposure of normally inaccessible self-antigens sometimes induces an immune attack against these antigens. Because the immune system is usually never exposed to hidden self-antigens, it does not learn to tolerate them. Inadvertent exposure of these normally inaccessible antigens to the immune system because of tissue disruption caused by injury or disease can lead to a rapid immune attack against the affected tissue, just as if these self-proteins were foreign invaders. *Hashimoto's disease*, which involves the production of antibodies against thyroglobulin and the destruction of the thyroid gland's hormone-secreting capacity, is one such example.
2. Normal self-antigens may be modified by factors, such as drugs, environmental chemicals, viruses, or genetic mutations, so that they are no longer tolerated by the immune system.
3. Exposure of the immune system to a foreign antigen structurally almost identical to a self-antigen may induce the production of antibodies or activated T lymphocytes that not only interact with the foreign antigen but also cross-react with the closely similar body antigen. An example of this molecular mimicry is the streptococcal bacteria responsible for strep throat. The bacteria possess antigens structurally very similar to self-antigens in the tissue covering the heart valves of some individuals, in which case the antibodies produced against the streptococcal organisms may also bind with this heart tissue. The resultant inflammatory response is responsible for the heart-valve lesions associated with *rheumatic fever*.
4. New studies hint at another possible trigger of autoimmune diseases, one that could explain why a whole host of these disorders are more common in women than in men. Traditionally, scientists have speculated that the sex bias of autoimmune diseases was somehow related to hormonal differences. Recent findings suggest, however, that the higher incidence of these self-destructive conditions in females may be a legacy of pregnancy. Researchers have learned that fetal cells, which often gain access to the mother's bloodstream during the trauma of labour and delivery, sometimes linger in the mother for decades after the pregnancy. The immune system typically clears these cells from the mother's body following childbirth, but studies involving one particular autoimmune disease demonstrated that those women with the condition were more

likely than healthy women to have persistent fetal cells in their blood. The persistence of similar but not identical fetal antigens that were not wiped out early on as being foreigners may somehow trigger a gradual, more subtle immune attack that eventually turns against the mother's own closely related antigens.

What is the nature of the self-antigens that the immune system learns to recognize as markers of a person's own cells? That is the topic of the next section.

The major histocompatibility complex

Self-antigens are plasma membrane-bound glycoproteins (proteins with sugar attached), known as *MHC molecules* because their synthesis is directed by a group of genes called the *major histocompatibility complex (MHC)*. These are the same MHC molecules that escort engulfed foreign antigen to the cell surface for presentation by antigen-presenting cells. The MHC genes are the most variable ones in humans. More than 100 different MHC molecules have been identified in human tissue, but each individual has a code for only three to six of these possible antigens. Because of the tremendous number of different combinations possible, the exact pattern of MHC molecules varies from one individual to another, much like a biochemical fingerprint or molecular identification card—except in identical twins, who have the same MHC self-antigens.

The major histocompatibility (*histo* means “tissue”; *compatibility* means “ability to get along”) complex was so named because these genes and the self-antigens they encode were first discerned in relation to tissue typing (similar to blood typing), which is done to obtain the most compatible matches for tissue grafting and transplantation. However, the transfer of tissue from one individual to another does not normally occur in nature. The natural function of MHC antigens lies in their ability to direct the responses of T cells, not in their artificial role in rejecting transplanted tissue.

MHC molecules on a cell's surface, which are always combined with a foreign antigen, signal to the immune cells. T cells typically bind with MHC self-antigens only when associated with a foreign antigen, such as a viral protein, also displayed on the cell surface in a groove on the top of the MHC molecule. Thus, T-cell receptors bind only with body cells, making the statement—by bearing both self- and nonself antigens on their surface—“I, one of your own kind, have been invaded. Here's a description of the enemy I am housing within.” Only T cells that specifically match up with both the self- and foreign antigen can bind with the infected cell.

LOADING OF FOREIGN PEPTIDE ON MHC MOLECULE

Unlike B cells, T cells cannot bind with foreign antigen that is not in association with self-antigen. It would be futile for T cells to bind with free, extracellular antigens; they cannot defend against foreign material unless it is intracellular. A foreign protein first must be enzymatically broken down within a body cell into small fragments known as peptides. These antigenic peptides are inserted into the binding groove of a newly synthesized MHC

molecule before the MHC-foreign antigen complex travels to the surface membrane. Once displayed at the cell surface, the combined presence of these self- and nonself antigens alerts the immune system to the presence of an undesirable agent within the cell. Highly specific T-cell receptors fit a particular MHC-foreign antigen complex in complementary fashion. This binding arrangement can be likened to a hot dog in a bun, with the MHC molecule being the bottom of the bun, the T-cell receptor the bun's top, and the foreign antigen the hot dog. In the case of cytotoxic T cells, the outcome of this binding is the destruction of the infected body cell. Because cytotoxic T cells do not bind to MHC self-antigens in the absence of foreign antigen, normal body cells are protected from a lethal immune attack.

CLASS I AND CLASS II MHC GLYCOPROTEINS

T cells become active only when they match a given MHC peptide combination. In addition to having to fit a specific foreign

peptide, the T-cell receptor must also match the appropriate MHC protein. Each individual has two main classes of MHC-encoded molecules that are differentially recognized by cytotoxic T and helper T cells: class I and class II MHC glycoproteins, respectively (Figure 11-18). The class I and II markers serve as signposts to guide cytotoxic and helper T cells to the precise cellular locations where their immune capabilities can be most effective.

Cytotoxic T cells can respond to foreign antigen only in association with **class I MHC glycoproteins**, which are found on the surface of virtually all nucleated body cells. To carry out their role of dealing with pathogens that have invaded host cells, it is appropriate that cytotoxic T cells bind only with cells of the organism's own body that viruses have infected—that is, with foreign antigen in association with self-antigen. Furthermore, these deadly T cells can also link up with any cancerous body cell, because class I MHC molecules also display mutated cellular proteins characteristic of these abnormal cells. Because any

- 1 Class I MHC molecules are found on the surface of all cells.
- 2 They are recognized only by cytotoxic (CD8+) T cells.
- 3 CD8 coreceptor links the two cells together.
- 4 Linked in this way, cytotoxic T cells can destroy body cells if invaded by foreign (viral) antigen.

(a) Class I MHC self-antigens

- 1 Class II MHC molecules are found on the surface of immune cells with which helper T cells interact: dendritic cells, macrophages, and B cells.
- 2 They are recognized only by helper (CD4+) T cells.
- 3 CD4 coreceptor links the two cells together.
- 4 To be activated, helper T cells must bind with a class II MHC-bearing APC (dendritic cell or macrophage). To activate B cells, helper T cell must bind with a class II MHC-bearing B cell with displayed foreign antigen.

(b) Class II MHC self-antigens

➤ **FIGURE 11-18 Distinctions between class I and class II major histocompatibility complex (MHC) glycoproteins.** Specific binding requirements for the two types of T cells ensure that these cells bind only with the targets that they can influence. Cytotoxic (CD8+) T cells can recognize and bind with foreign antigen only when the antigen is in association with class I MHC glycoproteins, which are found on the surface of all body cells. This requirement is met when a virus invades a body cell, whereupon the cell is destroyed by the cytotoxic T cells. Helper (CD4+) T cells, which are activated by or enhance the activities of dendritic cells, macrophages, and B cells, can recognize and bind with foreign antigen only when it is in association with class II MHC glycoproteins, which are found only on the surface of these other immune cells. The CD8+ or CD4+ T-cell's coreceptor CD8 or CD4 links these cells to the target cell's class I or class II MHC molecules, respectively.

nucleated body cell can be invaded by viruses or become cancerous, essentially all cells display class I MHC glycoproteins, thereby enabling cytotoxic T cells to attack any virus-invaded host cell or any cancer cell.

In contrast, **class II MHC glycoproteins**, which are recognized by helper T cells, are restricted to the surface of a few special types of immune cells. That is, a helper T cell can bind with foreign antigen only when it is found on the surfaces of immune cells with which the helper T cell interacts. These include the macrophages, which present antigen to helper T cells, as well as B cells and cytotoxic T cells, whose activities are enhanced by cytokines secreted by helper T cells. The capabilities of helper T cells would be squandered if these cells were able to bind with body cells other than these special immune cells. In this way, the specific binding requirements for the two types of T cells help ensure the appropriate T-cell responses.

TRANSPLANT REJECTION

T cells do bind with MHC antigens present on the surface of *transplanted cells* in the absence of foreign viral antigen. The ensuing destruction of the transplanted cells triggers the rejection of transplanted or grafted tissues. Presumably, some of the recipient's T cells mistake the MHC antigens of the donor cells for a closely resembling combination of a conventional viral foreign antigen complexed with the recipient's MHC self-antigens.

To minimize the rejection phenomenon, technicians match the tissues of donor and recipient according to MHC antigens as closely as possible. Therapeutic procedures to suppress the immune system then follow. In the past, the primary immunosuppressive tools included radiation therapy and drugs aimed at destroying the actively multiplying lymphocyte populations, plus anti-inflammatory drugs that suppressed growth of all lymphoid tissue. However, these measures not only suppressed the T cells that were primarily responsible for rejecting transplanted tissue but also depleted the antibody-secreting B cells. Unfortunately, the treated individual was left with little specific immune protection against bacterial and viral infections. In recent years, new therapeutic agents have become extremely useful in selectively depressing T-cell-mediated immune activity while leaving B-cell humoral immunity essentially intact. For example, *cyclosporin* blocks interleukin 2, the cytokine secreted by helper T cells that is required for expansion of the selected cytotoxic T-cell clone. Furthermore, a new technique under investigation may completely prevent rejection of transplanted tissues even from an unmatched donor. This technique involves the use of tailor-made antibodies that block specific facets of the rejection process. If proven safe and effective, the technique will have a tremendous impact on tissue transplantation.

Let's now look in more detail at the role of T cells in defending against cancer.

Immune surveillance

Besides destroying virus-infected host cells, another important function of the T-cell system is recognizing and destroying newly arisen, potentially cancerous tumour cells before they have a

chance to multiply and spread, a process known as **immune surveillance**. At least once a day, on average, your immune system destroys a mutated cell that could potentially become cancerous. Any normal cell may be transformed into a cancer cell if mutations occur within its genes that govern cell division and growth. Such mutations may occur by chance alone or, more frequently, by exposure to **carcinogenic** (cancer-causing) factors such as ionizing radiation, certain environmental chemicals, or physical irritants. Alternatively, a few cancers are caused by tumour viruses, which turn the cells they invade into cancer cells. Presumably the immune system recognizes cancer cells because they bear new and different surface antigens—due to either genetic mutation or invasion by a tumour virus—alongside the cell's normal self-antigens.

BENIGN AND MALIGNANT TUMOURS

Cell multiplication and growth are normally under strict control, but the regulatory mechanisms are largely unknown. Cell multiplication in an adult is generally restricted to replacing lost cells. Furthermore, cells normally respect their own place and space in the body's society of cells. If a cell that has transformed into a tumour cell manages to escape immune destruction, however, it defies the normal controls on its proliferation and position. Unrestricted multiplication of a single cancer cell results in a **tumour** that consists of a clone of cells identical to the original mutated cell.

If the mass is slow growing, stays put in its original location, and does not infiltrate the surrounding tissue, it is considered a **benign tumour**. In contrast, the transformed cell may multiply rapidly and form an invasive mass that lacks the “altruistic” behaviour characteristic of normal cells. Such invasive tumours are **malignant tumours**, or **cancer**. Malignant tumour cells usually do not adhere well to the neighbouring normal cells, so often some of the cancer cells break away from the parent tumour. These “emigrant” cancer cells are transported through the blood to new territories, where they continue to proliferate, forming multiple malignant tumours. The term **metastasis** is applied to this spreading of cancer to other parts of the body.

If a malignant tumour is detected early, before it has metastasized, it can be removed surgically. Once cancer cells have dispersed and seeded multiple cancerous sites, surgical elimination of the malignancy is impossible. In this case, agents that interfere with rapidly dividing and growing cells, such as certain chemotherapeutic drugs, are used in an attempt to destroy the malignant cells. Unfortunately, these agents also harm normal body cells, especially rapidly proliferating cells, such as blood cells and the cells lining the digestive tract.

Untreated cancer is eventually fatal in most cases, for several interrelated reasons. The uncontrollably growing malignant mass crowds out normal cells by vigorously competing with them for space and nutrients, yet the cancer cells cannot take over the functions of the cells they are destroying. Cancer cells typically remain immature and do not become specialized; they often resemble embryonic cells instead (► Figure 11-19). Such poorly differentiated malignant cells lack the ability to perform the specialized functions of the normal cell type from which

► **FIGURE 11-19 Comparison of normal and cancerous cells in the large respiratory airways.** The normal cells display specialized cilia, which constantly contract in whiplike motion to sweep debris and microorganisms from the respiratory airways so they do not gain entrance to the deeper portions of the lungs. The cancerous cells are not ciliated, so they are unable to perform this specialized defence task.

they mutated. Affected organs gradually become disrupted to the point that they can no longer perform their life-sustaining functions, and the person dies.

GENETIC MUTATIONS THAT DO NOT LEAD TO CANCER

Even though many body cells undergo mutations throughout a person's lifetime, most of these mutations do not result in malignancy, for three reasons:

1. Only a fraction of the mutations involve loss of control over the cell's growth and multiplication. More frequently, other facets of cellular function are altered.
2. A cell usually becomes cancerous only after an accumulation of multiple independent mutations. This requirement contributes at least in part to the much higher incidence of cancer in older individuals, in whom mutations have had more time to accumulate in a single-cell lineage.
3. Potentially cancerous cells that do arise are usually destroyed by the immune system early in their development.

EFFECTORS OF IMMUNE SURVEILLANCE

Immune surveillance against cancer depends on an interplay among three types of immune cells—*cytotoxic T cells*, *NK cells*, and *macrophages*—as well as *interferon*. Not only can all three of these immune cell types attack and destroy cancer cells

directly, but all three also secrete interferon. Interferon, in turn, inhibits multiplication of cancer cells and increases the killing ability of the immune cells (► Figure 11-20).

Because NK cells do not require prior exposure and sensitization to a cancer cell before being able to launch a lethal attack, they are the first line of defence against cancer. In addition, cytotoxic T cells take aim at cancer cells after being sensitized by mutated surface proteins alongside normal class I MHC molecules. On contacting a cancer cell, both these killer cells release perforin and other toxic chemicals that destroy the targeted mutant cell. Macrophages, in addition to clearing away the remains of the dead victim cell, can engulf and destroy cancer cells intracellularly.

The fact that cancer does sometimes occur means that cancer cells occasionally escape these immune mechanisms. Some cancer cells are believed to survive by evading immune detection, for example, by failing to display identifying antigens on their surface or by being surrounded by counterproductive **blocking antibodies** that interfere with T-cell function. Although B cells and antibodies are not believed to play a direct role in cancer defence, B cells may produce antibodies against a mutant cancer cell when they recognize it is not a normal self-cell. These antibodies, for unknown reasons, do not activate the complement system, which could destroy the cancer cells. Instead, the antibodies bind with the antigenic sites on the cancer cell, thereby hiding these sites from recognition by cytotoxic T cells. The coating of a tumour cell by blocking antibodies thus protects the harmful cell from attack by deadly T cells. A new finding reveals that still other successful cancer cells thwart immune attack by turning on their pursuers. They induce the T cells that bind with them to commit suicide.

► **FIGURE 11-20 Immune surveillance against cancer.** Anticancer interactions of cytotoxic T cells, natural killer cells, macrophages, and interferon

Regulatory loops

From the preceding discussion, it is obvious that complex controlling factors operate within the immune system itself. Until recently, the immune system was believed to function independently of other control systems in the body. Investigations now indicate, however, that the immune system both influences and is influenced by the two major regulatory systems—the nervous and endocrine systems. For example, interleukin 1 can turn on the stress response by activating a sequence of nervous and endocrine events that result in the secretion of cortisol, one of the major hormones released during stress. This linkage between a mediator of the immune response and a mediator of the stress response is appropriate. Cortisol mobilizes the body's nutrient stores so that metabolic fuel is readily available to keep pace with the body's energy demands at a time when the person is sick and may not be eating enough (or, in the case of an animal, may not be able to search for food). Furthermore, cortisol mobilizes amino acids, which serve as building blocks to repair any tissue damage sustained during the encounter that triggered the immune response.

In the reverse direction, lymphocytes and macrophages are responsive to blood-borne signals from the nervous system and from certain endocrine glands. These important immune cells possess receptors for a wide variety of neurotransmitters, hormones, and other chemical mediators. For example, cortisol and other chemical mediators of the stress response have a profound immunosuppressive effect, inhibiting many functions of lymphocytes and macrophages and decreasing the production of cytokines. Thus, a negative-feedback loop appears to exist between the immune system and the nervous and endocrine systems. Cytokines released by immune cells enhance the neurally and hormonally controlled stress response, whereas cortisol and related chemical mediators released during the stress response suppress the immune system. In large part because stress suppresses the immune system, stressful physical, psychological, and social life events are linked with increased susceptibility to infections and cancer. Thus, the body's resistance to disease *can* be influenced by the person's mental state—a case of “mind over matter.”

There are other important links between the immune and nervous systems in addition to the cortisol connection. For example, many immune system organs, such as the thymus, spleen, and lymph nodes, are innervated by the sympathetic nervous system, the branch of the nervous system called into play during stress-related fight-or-flight situations (p. 142). In the reverse direction, immune system secretions act on the brain to produce fever and other general symptoms that accompany infections.

Check Your Understanding 11.7

1. List the three major types of T cells, and state their functions.
2. Describe the role of antigen-presenting cells.
3. Define *immune surveillance*, and discuss how it is accomplished.

11.8 | Immune Diseases

Abnormal functioning of the immune system can lead to immune diseases in two general ways: immunodeficiency diseases (too little immune response) and inappropriate immune attacks (too much or mistargeted immune response).

Immunodeficiency

Immunodeficiency diseases occur when the immune system fails to respond adequately to foreign invasion. The condition may be congenital (present at birth) or acquired (nonhereditary), and it may specifically involve impairment of antibody-mediated immunity, or cell-mediated immunity, or both.

In a rare hereditary condition known as **severe combined immunodeficiency**, both B and T cells are lacking. Such people have extremely limited defences against pathogenic organisms and die in infancy unless maintained in a germ-free environment (i.e., live in a bubble). However, that verdict has changed with recent successes using gene therapy to cure the disease in some patients.

Acquired (nonhereditary) immunodeficiency states can arise from inadvertent destruction of lymphoid tissue during prolonged therapy with anti-inflammatory agents, such as cortisol derivatives, or from cancer therapy aimed at destroying rapidly dividing cells (which unfortunately include lymphocytes as well as cancer cells). The most recent, and tragically the most common, acquired immunodeficiency disease is AIDS, which, as described earlier, is caused by HIV, a virus that invades and incapacitates the critical helper T cells.

Let's now look at inappropriate immune attacks.

Allergies

Inappropriate adaptive immune attacks cause reactions harmful to the body. These include (1) *autoimmune responses*, in which the immune system turns against one of the body's own tissues; (2) *immune complex diseases*, which involve overexuberant antibody responses that “spill over” and damage normal tissue; and (3) *allergies*. The first two conditions have been described earlier in this chapter, so here we concentrate on allergies.

An **allergy** is the acquisition of an inappropriate specific immune reactivity, or **hypersensitivity**, to a normally harmless environmental substance, such as dust or pollen. The offending agent is known as an **allergen**. Subsequent re-exposure of a sensitized individual to the same allergen elicits an immune attack, which may vary from a mild, annoying reaction to a severe, body-damaging reaction that may even be fatal.

Allergic responses are classified into two categories: immediate hypersensitivity and delayed hypersensitivity. In **immediate hypersensitivity**, the allergic response appears within about 20 minutes after a sensitized person is exposed to an allergen. In **delayed hypersensitivity**, the reaction does not generally show up until a day or so following exposure. The difference in timing is due to the different mediators involved. A particular

allergen may activate either a B-cell or a T-cell response. Immediate allergic reactions involve B cells and are elicited by antibody interactions with an allergen; delayed reactions involve T cells and the more slowly responding process of cell-mediated immunity against the allergen. Let us examine the causes and consequences of each of these reactions in more detail.

TRIGGERS FOR IMMEDIATE HYPERSENSITIVITY

In immediate hypersensitivity, the antibodies involved and the events that ensue on exposure to an allergen differ from the typical antibody-mediated response to bacteria. The most common allergens that provoke immediate hypersensitivities are pollen grains, bee stings, penicillin, certain foods, moulds, dust, feathers, and animal fur. (Actually, people allergic to cats are not allergic to the fur itself. The true allergen is in the cat's saliva, which is deposited on the fur during licking. Likewise, people are not allergic to dust or feathers *per se*, but to tiny mites that inhabit the dust or feathers and eat the scales constantly being shed from the skin.) For unclear reasons, these allergens bind to and elicit the synthesis of IgE antibodies rather than the IgG antibodies associated with bacterial antigens. IgE antibodies are the least plentiful immunoglobulin, but their presence spells trouble. Without IgE antibodies, there would be no immediate hypersensitivity. When a person with an allergic tendency is first exposed to a particular allergen, compatible helper T cells secrete *interleukin 4*, a cytokine that prods compatible B cells to synthesize IgE antibodies specific for the allergen. During this initial **sensitization period**, no symptoms are evoked, but memory cells form that are primed for a more powerful response on subsequent re-exposure to the same allergen.

In contrast to the antibody-mediated response elicited by bacterial antigens, IgE antibodies do not freely circulate. Instead, their tail portions attach to mast cells and basophils, both of which produce and store an arsenal of potent inflammatory chemicals, such as histamine, in preformed granules. Mast cells are most plentiful in regions that come into contact with the external environment, such as the skin, the outer surface of the eyes, and the linings of the respiratory system and digestive tract. The binding of an appropriate allergen with the outreached arm regions of IgE antibodies lodged tail first in a mast cell or basophil triggers the rupture of the cell's granules. As a result, histamine and other chemical mediators spew forth into the surrounding tissue.

A single mast cell (or basophil) may be coated with a number of different IgE antibodies, each able to bind with a different allergen. Thus, the mast cell can be triggered to release its chemical products by any one of a number of different allergens (► Figure 11-21).

CHEMICAL MEDIATORS OF IMMEDIATE HYPERSENSITIVITY

The chemicals released by the mast cells cause the reactions that characterize immediate hypersensitivity. The most important chemicals released during immediate allergic reactions, and their functions, are as follows:

1. **Histamine** brings about vasodilation and increased capillary permeability as well as increased mucus production.

2. **Slow-reactive substance of anaphylaxis (SRS-A)** induces prolonged and profound contraction of smooth muscle, especially of the small respiratory airways. SRS-A is a leukotriene, a locally acting mediator similar to prostaglandins (p. 741).
3. **Eosinophil chemotactic factor** specifically attracts eosinophils to the area. Interestingly, eosinophils release enzymes that inactivate SRS-A and may also inhibit histamine, perhaps serving as an off-switch to limit the allergic response.

SYMPTOMS OF IMMEDIATE HYPERSENSITIVITY

Symptoms of immediate hypersensitivity vary depending on the site, allergen, and mediators involved. Most frequently, the reaction is localized to the body site in which the IgE-bearing cells first come into contact with the allergen. If the reaction is limited to the upper respiratory passages after a person inhales an allergen, such as ragweed pollen, the released chemicals bring about the symptoms characteristic of **hay fever**—for example, nasal congestion caused by histamine-induced localized oedema and sneezing and runny nose caused by increased mucus secretion. If the reaction is concentrated primarily within the bronchioles (the small respiratory airways that lead to the tiny air sacs within the lungs), **asthma** results. Contraction of the smooth muscle in the walls of the bronchioles in response to SRS-A narrows or constricts these passageways, making breathing difficult. Localized swelling in the skin because of allergy-induced histamine release causes **hives**. An allergic reaction in the digestive tract in response to an ingested allergen can lead to diarrhoea.

TREATMENT OF IMMEDIATE HYPERSENSITIVITY

Treatment of localized immediate allergic reactions with antihistamines often offers only partial relief of the symptoms, because some of the manifestations are invoked by other chemical mediators not blocked by these drugs. For example, antihistamines are not particularly effective in treating asthma, the most serious symptoms of which are invoked by SRS-A. Adrenergic drugs (which mimic the sympathetic nervous system) are helpful through their vasoconstrictor-bronchodilator actions in counteracting the effects of both histamine and SRS-A. Anti-inflammatory drugs, such as cortisol derivatives, are often used as the primary treatment for ongoing allergen-induced inflammation, such as that associated with asthma. Newer drugs that inhibit leukotrienes, including SRS-A, have been added to the arsenal for combating immediate allergies.

ANAPHYLACTIC SHOCK

A life-threatening systemic reaction can occur if the allergen becomes blood borne or if very large amounts of chemicals are released from the localized site into the circulation. When large amounts of these chemical mediators gain access to the blood, the extremely serious systemic (involving the entire body) reaction known as **anaphylactic shock** occurs. Severe hypotension that can lead to circulatory shock (p. 426) results from widespread vasodilation and a massive shift of plasma fluid into the interstitial spaces due to a generalized increase in capillary

FIGURE 11-21 Role of IgE antibodies and mast cells in immediate hypersensitivity. B-cell clones are converted into plasma cells, which secrete IgE antibodies on contact with the allergen for which they are specific. The Fc tail portion of all IgE antibodies, regardless of the specificity of their Fab arm regions, binds to receptor proteins specific for IgE tails on mast cells and basophils. Unlike B cells, each mast cell bears a variety of antibody surface receptors for binding different allergens. When an allergen combines with the IgE receptor specific for it on the surface of a mast cell, the mast cell releases histamine and other chemicals by exocytosis. These chemicals elicit the allergic response.

permeability. Concurrently, pronounced bronchiolar constriction occurs and can lead to respiratory failure. The person may suffocate from an inability to move air through the narrowed airways. Unless countermeasures, such as injecting a vasoconstrictor-bronchodilator drug, are undertaken immediately, anaphylactic shock is often fatal. This reaction is the reason that even a single bee sting or a single dose of penicillin can be so dangerous in people sensitized to these allergens.

IMMEDIATE HYPERSENSITIVITY AND ABSENCE OF PARASITIC WORMS

Although the immediate hypersensitivity response differs considerably from the typical IgG antibody response to bacterial infections, it is strikingly similar to the immune response elicited by parasitic worms. Shared characteristics of the immune reactions to allergens and parasitic worms include the production of IgE antibodies and increased basophil and eosinophil activity. This finding has led to the proposal that harmless allergens somehow trigger an immune response designed to fight worms. Mast cells are concentrated in areas where parasitic worms (and allergens) could contact the body. Parasitic worms can penetrate the skin or digestive tract or can attach to the digestive tract lining. Some worms migrate through the lungs during a part of their life cycle. Scientists suspect the IgE response helps ward off these invaders in the following way. The inflammatory response in the skin could wall off parasitic worms attempting to burrow in. Coughing and sneezing could expel worms that have migrated to the lungs. Diarrhoea could help flush out worms before they could penetrate or attach to the digestive tract lining. Interestingly, epidemiological studies suggest that the incidence of allergies in a country rises as the presence of parasites decreases. Thus, superfluous immediate hypersensitivity responses to normally harmless allergens may represent a pointless marshalling of a honed immune-response system “with nothing better to do” in the absence of parasitic worms.

DELAYED HYPERSENSITIVITY

Some allergens invoke delayed hypersensitivity, a T-cell-mediated immune response, rather than an immediate, B cell-IgE antibody response. Among these allergens are poison ivy

toxin and certain chemicals to which the skin is frequently exposed, such as cosmetics and household cleaning agents. Most commonly, the response is characterized by a delayed skin eruption that reaches its peak intensity one to three days after contact with an allergen to which the immune system has previously been sensitized. To illustrate, poison ivy toxin does not harm the skin on contact, but it activates T cells specific for the toxin, including the formation of a memory component. On subsequent exposure to the toxin, activated T cells diffuse into the skin within a day or two, combining with the poison ivy toxin that is present. The resulting interaction gives rise to the tissue damage and discomfort typical of the condition. The best relief is obtained from application of anti-inflammatory preparations, such as those containing cortisol derivatives.

■ Table 11-3 summarizes the distinctions between immediate and delayed hypersensitivities.

Check Your Understanding 11.8

- 1. Compare the type of immune response and immune effectors involved in immediate hypersensitivity and delayed hypersensitivity.
- 2. Discuss how the mechanism of action of IgE antibodies differs from that of IgG antibodies.

Chapter in Perspective: Focus on Homeostasis

We could not survive beyond early infancy were it not for the body’s defence mechanisms. These mechanisms resist and eliminate potentially harmful foreign agents that we continually come in contact with in our external environment and also destroy abnormal cells that often arise within the body. Homeostasis can be optimally maintained, and thus life sustained, only if the body cells are not physically injured or functionally disrupted by pathogenic

■ TABLE 11-3 Immediate versus Delayed Hypersensitivity Reactions

Characteristic	Immediate Hypersensitivity Reaction	Delayed Hypersensitivity Reaction
Time of Onset of Symptoms after Exposure to the Allergen	Within 20 minutes	Within one to three days
Type of Immune Response	Antibody-mediated immunity against the allergen	Cell-mediated immunity against the allergen
Immune Effectors Involved	B cells, IgE antibodies, mast cells, basophils, histamine, slow-reactive substance of anaphylaxis, eosinophil chemotactic factor	T cells
Allergies Commonly Involved	Hay fever, asthma, hives, anaphylactic shock in extreme cases	Contact allergies, such as allergies to poison ivy, cosmetics, and household cleaning agents

microorganisms or are not replaced by abnormally functioning cells, such as traumatized cells or cancer cells. The immune defence system—a complex, multifaceted, interactive network of leukocytes, their secretory products, and plasma proteins—contributes indirectly to homeostasis by keeping other cells alive so they can perform their specialized activities to maintain a stable internal environment. The immune system protects the other healthy cells from foreign agents that have gained entrance to the body, eliminates newly arisen cancer cells, and clears away dead and injured cells to pave the way for replacement with healthy new cells.

The skin contributes indirectly to homeostasis by serving as a protective barrier between the external environment and the rest of the

body cells. It helps prevent harmful foreign agents, such as pathogens and toxic chemicals from entering the body and helps prevent the loss of precious internal fluids from the body. The skin also contributes directly to homeostasis by helping maintain body temperature by means of the sweat glands and adjustments in skin blood flow. The amount of heat carried to the body surface for dissipation to the external environment is determined by the volume of warmed blood flowing through the skin.

Other systems that have internal cavities in contact with the external environment, such as the digestive, genitourinary, and respiratory systems, also have defence capabilities to prevent harmful external agents from entering the body through these avenues.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-47)

1. The complement system can be activated only by antibodies. (*True or false?*)
2. Specific adaptive immune responses are accomplished by neutrophils. (*True or false?*)
3. Damaged tissue is always replaced by scar tissue. (*True or false?*)
4. Active immunity against a particular disease can be acquired only by actually having the disease. (*True or false?*)
5. A secondary response has a more rapid onset, is more potent, and has a longer duration than a primary response. (*True or false?*)
6. _____ are receptors on the plasma membrane of phagocytes that recognize and bind with telltale molecular patterns present on the surface of microorganisms but absent from human cells.
7. The complement system's _____ forms a doughnut-shaped complex that embeds in a microbial surface membrane, causing osmotic lysis of the victim cell.
8. _____ is a collection of phagocytic cells, necrotic tissue, and bacteria.
9. _____ is the localized response to microbial invasion or tissue injury that is accompanied by swelling, heat, redness, and pain.
10. A chemical that enhances phagocytosis by serving as a link between a microbe and the phagocytic cell is known as a(n) _____.
11. _____, collectively, are all the chemical messengers other than antibodies secreted by lymphocytes.
12. Which statement concerning leukocytes is NOT correct?
 - a. Monocytes are transformed into macrophages.
 - b. T lymphocytes are transformed into plasma cells that secrete antibodies.
 - c. Neutrophils are highly mobile phagocytic specialists.
 - d. Basophils release histamine.
 - e. Lymphocytes arise in large part from lymphoid tissues.

13. Match the following with the answer code provided below:

- | | |
|--|--------------------------|
| ___ 1. a family of proteins that nonspecifically defend against viral infection | (a) complement system |
| ___ 2. a response to tissue injury in which neutrophils and macrophages play a major role | (b) natural killer cells |
| ___ 3. a group of plasma proteins that, when activated, bring about destruction of foreign cells by attacking their plasma membranes | (c) interferon |
| ___ 4. lymphocyte-like entities that spontaneously lyse tumour cells and virus-infected host cells | (d) inflammation |

14. Using the answer code on the right, indicate whether the numbered characteristics of the adaptive immune system apply to antibody-mediated immunity, cell-mediated immunity, or both:

- | | |
|---|---|
| ___ 1. involves secretion of antibodies | (a) antibody-mediated immunity |
| ___ 2. mediated by B cells | |
| ___ 3. mediated by T cells | (b) cell-mediated immunity |
| ___ 4. accomplished by thymus-educated lymphocytes | (c) both antibody-mediated and cell-mediated immunity |
| ___ 5. triggered by the binding of specific antigens to complementary lymphocyte receptors | |
| ___ 6. involves formation of memory cells in response to initial exposure to an antigen | |
| ___ 7. primarily aimed against virus-infected host cells | |
| ___ 8. protects primarily against bacterial invaders | |
| ___ 9. directly destroys targeted cells | |
| ___ 10. involved in rejection of transplanted tissue | |
| ___ 11. requires binding of a lymphocyte to a free extracellular antigen | |
| ___ 12. requires dual binding of a lymphocyte with both foreign antigen and self-antigens present on the surface of a host cell | |

15. Using the answer code on the right, indicate whether the numbered characteristics apply to the epidermis or dermis:

- | | |
|--|-----------------|
| ___ 1. is the inner layer of skin | (a) epidermis |
| ___ 2. has layers of epithelial cells that are | (b) dermis dead |
| ___ 3. has no direct blood supply | and flattened |
| ___ 4. contains sensory nerve endings | |
| ___ 5. contains keratinocytes | |
| ___ 6. contains melanocytes | |
| ___ 7. contains rapidly dividing cells | |
| ___ 8. is mostly connective tissue | |

Written Questions

1. Distinguish between bacteria and viruses.
2. Summarize the functions of each of the lymphoid tissues.
3. Distinguish between innate and adaptive immune responses.
4. Compare the life history of B cells and of T cells.
5. What is an antigen?
6. Describe the structure of an antibody. List and describe the five subclasses of immunoglobulins.
7. In what ways do antibodies exert their effects?
8. Describe the clonal selection theory.
9. Compare the functions of B cells and T cells. What are the roles of the two main types of T cells?
10. Summarize the functions of macrophages in immune defence.
11. What mechanisms are involved in tolerance?
12. What is the importance of class I and class II MHC glycoproteins?
13. Describe the factors that contribute to immune surveillance against cancer cells.

14. Distinguish among immunodeficiency disease, autoimmune disease, immune complex disease, immediate hypersensitivity, and delayed hypersensitivity.

15. What are the immune functions of the skin?

Quantitative Exercise (Solution in Appendix E, p. A-47)

1. As a result of the innate immune response to an infection (e.g., from a cut on the skin), capillary walls near the site of infection become very permeable to plasma proteins that normally remain in the blood. These proteins diffuse into the interstitial fluid, raising the interstitial fluid-colloid osmotic pressure. This increased colloid osmotic pressure causes fluid to leave the circulation and accumulate in the tissue, forming a welt, or wheal. This process is referred to as the *wheal response*. The wheal response is mediated in part by histamine secreted from mast cells in the area of infection. The histamine binds to receptors, called *H-1 receptors*, on capillary endothelial cells. The histamine signal is transduced via the Ca^{2+} second-messenger pathway involving phospholipase C (p. 218). In response to this signal, the capillary endothelial cells contract (via internal actin-myosin interaction), which causes a widening of the intercellular gaps (pores) between the capillary endothelial cells (p. 405). In addition, substance P (p. 150) also contributes to pore widening. Plasma proteins can pass through these widened pores and leave the capillaries. Looking at Figure 11-20, compare the magnitude of the wheal response (i.e., the extent of localized oedema) if PIF were raised (a) from 0 mmHg to 5 mmHg and (b) from 0 mmHg to 10 mmHg. In both cases, compare the net exchange pressure (NEP) at the arteriolar end of the capillary, the venular end of the capillary, and the average NEP. (Assume the other forces acting across the capillary wall remain unchanged.)

POINTS TO PONDER

(Explanations in Appendix E, p. A-47)

1. Compare the defence mechanisms that come into play in response to bacterial and viral pneumonia.
2. Why does the frequent mutation of HIV (the AIDS virus) make it difficult to develop a vaccine against this virus?

3. What impact would failure of the thymus to develop embryonically have on the immune system after birth?
4. Medical researchers are currently working on ways to “teach” the immune system to view foreign tissue as “self.” What useful clinical application will the technique have?
5. When someone looks at you, are the cells of your body that person is viewing dead or alive?

11

CLINICAL CONSIDERATION

(Explanations in Appendix E, p. A-48)

1. Christine W. has a blood disorder called *idiopathic thrombocytopenic purpura*. This is a condition in which the patient has an increased tendency to bleed due to a low platelet count. This low platelet count is caused by the generation of antibodies against platelets, which results in the phagocytosis of the platelets by macrophages in the spleen. In Christine’s case, her platelet count dropped very low and

was not responsive to treatment with steroids or immunosuppressants. It was decided that her spleen needed to be removed.

2. What are some of the major functions of the spleen?
3. How will Christine’s immune system be affected without a spleen?
4. What will happen to Christine’s platelet count after the splenectomy?

The Respiratory System

Body systems maintain homeostasis

Harry Kikstra/Getty Images

High-altitude mountaineer

Cells make up body systems

Homeostasis

The respiratory system contributes to homeostasis by obtaining O_2 from and eliminating CO_2 to the external environment. It helps regulate the pH of the internal environment by adjusting the rate of removal of acid-forming CO_2 .

Homeostasis is essential for survival of cells

Science Photo Library/Alamy Stock Photo

Alveoli

Energy is essential for sustaining such life-supporting cellular activities as protein synthesis and active transport across membranes. Cells need a continual supply of oxygen to support the metabolic reactions that produce biochemical energy—typically in the form of adenosine triphosphate (ATP; see Chapter 2)—needed for these activities. This process is known as **internal (cellular) respiration**. The carbon dioxide produced during these reactions must be eliminated from the body at the same rate as it is produced. This prevents the excessive increases in acid (necessary to maintain acid–base balance) that result from the formation of carbonic acid.

External respiration, in contrast, involves all processes that accomplish movement of oxygen from the atmosphere to the alveoli, where it diffuses into the pulmonary capillary blood. In exchange, carbon dioxide produced by the tissues diffuses from the pulmonary capillaries into the alveoli for excretion to the atmosphere. (Transportation of oxygen from the lung to the tissues and of carbon dioxide from the tissues to the lung is the responsibility of the cardiovascular system.) In no other system is the need for specialization to overcome the limitations of diffusion associated

with large multicellular organisms better illustrated than in the respiratory system.

The movement of oxygen from room air into the alveoli and carbon dioxide in the reverse direction depends on two factors: (1) the ability of the respiratory muscles to generate pressure to move air through the airways (overcoming the resistance to flow) and inflate the lung (overcoming the elastance of the lung tissue), and (2) the ability of oxygen and carbon dioxide to diffuse across the alveolar–capillary barrier. The bulk flow and diffusion of a gas are governed by a simple equation:

$$\text{flow (or diffusion)} = \text{pressure} / \text{resistance}$$

In this chapter, we discuss how this simple equation explains the flow of gas, the diffusion of oxygen and carbon dioxide, and how various pathologies illustrate these physiological principles. Before doing so, we introduce basic respiratory anatomy, lung volumes, and measurements of ventilatory function. We then examine how the pressure gradients to inflate and deflate the lungs are generated, how diffusion across the alveolar–capillary membrane is maximized, and how oxygen and carbon dioxide are transported in blood.

12

The Respiratory System

CONTENTS AT A GLANCE

- 12.1 Introduction
- 12.2 Respiratory mechanics
- 12.3 Gas exchange
- 12.4 Gas transport
- 12.5 Control of breathing

Clinical Connections

Andrea, an active, 20-year-old female, presented at hospital with shortness of breath and agitation. Her patient history reveals that she suffers from hay fever, which she controls with over-the-counter medication. She had recently moved in with a new roommate, who has two cats, and her hay fever has been worse than usual for this time of year. Her initial vital signs were a pulse of 115 beats/minute, blood pressure of 145/90 mmHg, respiratory rate of 26 breaths/minute, and oxygen saturation of 90 percent on room air. There is bilateral wheezing during expiration and increased use of accessory muscles during exhalation. Her arterial blood gas measurements were pH of 7.0, P_{AO_2} of 65, P_{CO_2} of 50, and HCO_3 of 24. A chest X-ray indicated lung hyperinflation and a pulmonary function test showed a reduced forced expiratory flow rate and a decreased FEV1 with an increased total lung capacity. Treatment with bronchodilators brought about relief of her symptoms. She was ultimately diagnosed with a cat allergy, which had progressed to allergic asthma. She was given a suitable course of treatment and advised to find a cat-free environment to live.

12.1 Introduction

The primary function of respiration—to obtain oxygen for use by the body's cells and to eliminate the carbon dioxide the cells produce—is the focus of this chapter (► Figure 12-1). The respiratory system, however, has many other functions not directly related to gas exchange (■ Table 12-1).

External respiration

External respiration refers to the entire sequence of events in the exchange of oxygen and carbon dioxide between the external environment and the cells of the body. External respiration, the primary topic of this chapter, encompasses four steps (► Figure 12-1):

1. Air is alternately moved in and out of the lungs so that air can be exchanged between the atmosphere (external environment) and air sacs (alveoli) of the lungs. This exchange is accomplished by the mechanical act of **breathing**, or **ventilation**. Ventilation is regulated
2. Oxygen diffuses from the air in the alveoli to the blood within the pulmonary capillaries; carbon dioxide diffuses in the opposite direction.
3. The blood transports oxygen from the lungs to the tissues and carbon dioxide from the tissues to the lungs.
4. Oxygen and carbon dioxide are exchanged between tissues and blood by the process of diffusion across the systemic (tissue) capillaries.

according to the body's needs for oxygen uptake and carbon dioxide removal. (See ■ Table 12-1 for exceptions.)

► **FIGURE 12-1 External and internal respiration.** External respiration encompasses the steps involved in the exchange of oxygen and carbon dioxide between the external environment and the tissues (steps 1 through 4). Internal respiration encompasses the intracellular metabolic reactions involving the use of oxygen to derive energy (ATP) from food, producing carbon dioxide as a by-product. The respiratory system does not accomplish all the steps of respiration; it is involved only with ventilation and the exchange of oxygen and carbon dioxide between the lungs and blood (steps 1 and 2). The circulatory system carries out steps 3 and 4.

TABLE 12-1 Nonrespiratory Functions of the Respiratory System

- It is a route for water loss and heat elimination. Humidification of inspired air is essential to prevent the alveolar linings from drying out. Because water has a high heat capacity (i.e., considerable energy is required to increase its temperature), heat is lost when air is expired. This is readily apparent when expired water vapour condenses on a cold day.
- It enhances venous return (see discussion of the respiratory pump, p. 418).
- It helps maintain normal acid–base balance by altering the amount of H⁺-generating carbon dioxide exhaled (p. 626).
- It enables speech, singing, and other vocalization.
- It defends against inhaled foreign matter (p. 463). The lungs, along with the gastrointestinal tract, provide a huge surface for foreign agents to enter the body, and so both systems need to be immunologically competent. The respiratory system does this not only with alveolar macrophages but also through protective reflexes such as coughing and sneezing. It has a protective lining of mucus and underlying cilia that transport mucus with any deposited material to the esophagus, where it is swallowed. In addition, the respiratory system is responsible for generating the large pressures needed for vomiting, a reflex that protects against ingestion of noxious foods.
- It removes, modifies, activates, or inactivates many biological substances passing through the pulmonary circulation. All blood returning to the heart from the tissues must pass through the lungs before returning to the systemic circulation. The lungs, therefore, are uniquely situated to act on specific substances that have been added to the blood at the tissue level before they have a chance to reach other parts of the body via the arterial system. For example, prostaglandins, a collection of chemical messengers released in many tissues to mediate particular local responses (p. 741), may spill into the blood, but they are *inactivated* during passage through the lungs so that they cannot exert systemic effects. In contrast, the lungs convert angiotensin I to angiotensin II, a hormone that plays an important role in regulating the concentration of sodium in the extracellular fluid (p. 576).
- The nose, a part of the respiratory system, serves as the organ of smell (p. 184).
- The respiratory muscles generate the large pressures needed during childbirth (parturition).
- The same respiratory muscles are used during defecation.
- The lung also provides a reservoir of blood for the left heart, helping to equalize the outputs of the left and right ventricles.

Anatomy of the respiratory system

The **respiratory system** (► Figure 12-2) consists of two components: the lungs and the chest wall. The lungs have two components: airways and alveoli. The chest wall includes other parts of the body involved in respiration: the thorax and the abdomen, which contain the muscles that generate air flow.

THE LUNGS

The lungs occupy most of the thoracic (chest) cavity; the only other structures in the chest are the heart and associated vessels, the esophagus, the thymus, and some nerves. There are two **lungs**, each divided into several lobes and each supplied by one of the bronchi. The lung tissue consists of a series of highly branched airways, alveoli, pulmonary blood vessels, and large quantities of elastic connective tissue. The upper airway contains skeletal muscles that regulate airflow by changing the diameter of the pharynx (throat) and **larynx (voice box)**, prevent aspiration of food into the lungs, and participate in vocalization. All airways, especially the smaller ones, also contain smooth muscle within their walls. The activation or relaxation of smooth muscle—resulting from changes in activity of the autonomic nervous system—affects airway dimensions and, in turn, the resistance to airflow (p. 514). In contrast, the walls of the alveoli have no muscles to either inflate or deflate them; if there were, they would interfere with diffusion. Instead, changes in lung volume (and accompanying changes in alveolar volume) result from changes in the dimensions of the

thoracic cavity due to activation of pump muscles: the diaphragm, internal and external intercostal muscles, and abdominal muscles.

AIRWAYS

The **airways** carry air between the atmosphere and the alveoli, where oxygen and carbon dioxide are exchanged. They begin at the **nasal passages (nose)** (► Figure 12-2a) that open into the pharynx, a common passageway for both the respiratory and digestive systems. Two tubes lead from the pharynx: the **trachea**, through which air is conducted to the alveoli; and the **esophagus**, the tube through which food passes to the stomach. Air normally enters the pharynx through the nose, but it can enter by the mouth as well, especially when the nasal passages are congested (you breathe through your mouth when you have a cold) and when ventilation increases during exercise. Because the pharynx serves as a common passageway for food and air, reflex mechanisms close the trachea during swallowing so that food enters the esophagus and not the airways. The esophagus stays closed except during swallowing to keep air from entering the stomach during breathing. Control of this important junction originates in the brain stem, where the breathing rhythm is generated.

The larynx is located at the entrance of the trachea. The anterior protrusion of the larynx forms the “Adam’s apple.” The **vocal folds**, two bands of elastic tissue, lie across the opening of the larynx; the laryngeal muscles control their length and shape. As air is moved past the taut vocal folds, they vibrate to produce the different sounds of speech. The lips,

► **FIGURE 12-2 Anatomy of the respiratory system.** (a) The respiratory airways. (b) Enlargement of the alveoli (air sacs) at the terminal ends of the airways. Most alveoli are clustered in grapelike arrangements at the end of the terminal bronchioles.

© 2016 Cengage

tongue, and soft palate modify the vibrations into recognizable sounds. During swallowing, the vocal folds are brought into tight apposition to close the entrance to the trachea, preventing aspiration of food.

Beyond the larynx, the trachea divides into two main branches, the right and left **bronchi**, which enter the right and left lungs, respectively. Within each lung, the bronchus continues to branch into progressively narrower, shorter, and more numerous airways, similar to the branching of a tree. The smaller branches are known as **bronchioles**; the smallest are named respiratory bronchioles because, at this stage, the walls of the airways are so thin that some gas exchange can occur. Clustered at the ends of the terminal bronchioles are the **alveoli**, the tiny air sacs where gases are exchanged between air and blood (► Figure 12-2b).

To permit flow in and out of the alveoli, the airways must remain open. The trachea and larger bronchi are fairly rigid tubes encircled by a series of cartilaginous rings that help the airways resist compression during coughing, for example. In the trachea, these rings are incomplete, resembling a horseshoe

with the two ends on the back (dorsum) joined by smooth muscle. The smaller bronchioles have no cartilage to hold them open, but their walls contain smooth muscle innervated by the autonomic nervous system; the smooth muscle is also sensitive to certain hormones and local chemicals. These factors, by varying the degree of contraction (tone) of bronchiolar smooth muscle and hence the calibre of these small terminal airways, regulate the resistance to airflow between the atmosphere and alveoli. In fact, as you will learn, regulation of airway calibre is the most important factor regulating resistance to flow (Poiseuille's law, p. 514).

The two anatomical components of the lung, airways and alveoli, have corresponding physical functions: **convection** and **diffusion**, respectively (► Figure 12-3). The balance between the volume dedicated to airways (large airways reduce resistance to flow, small ones increase it) and to alveoli (a larger surface area enhances diffusion) represents a compromise between these two functions. As described for the vascular system (Chapter 9), blood exiting the left heart travels through a single aorta that then branches into smaller and smaller blood vessels until reaching

► **FIGURE 12-3 Schematic of airways.** Movement of gas is purely convective until the gas arrives at the respiratory bronchioles, where, because of the increase in total cross-sectional area of the airways, motion of the gas molecules starts the transition from convection to diffusion. By the time gas arrives in the alveolar ducts and alveoli, the motion of gas molecules is purely diffusive.

systemic capillaries; likewise, the air entering the lung follows a similar path and with similar results. Although each successive airway is smaller, their number increases so dramatically that the total cross-sectional area of all airways at a given stage increases as gas flows into the lung. Because the flow at any given point is constant (i.e., the flow through the trachea equals the flow through all the bronchioles), this increase in total cross-sectional area means that the linear velocity of the gas slows. As a result, there is a transition from convection to diffusion, starting in the respiratory bronchioles (► Figure 12-3). By the time the gas reaches the alveoli, its motion is no longer convective (a process that requires energy produced by the muscles that generate flow) but diffusive (a process that does not require energy).

ALVEOLI

The alveoli—about 300 million of them, each about 300 μm (micrometre) in diameter—are clusters of thin-walled, inflatable, grapelike sacs at the terminal branches of the conducting airways (► Figure 12-4b) and are ideally structured for gas exchange. They

are composed of two types of epithelial cells: Type I and Type II. Alveolar walls consist of a single layer of flattened **Type I alveolar cells** (► Figure 12-4a). The walls of the dense sheetlike network of pulmonary capillaries encircling each alveolus (► Figure 12-4b) are also only one-cell thick. Thus, the interstitial space between an alveolus and the surrounding capillary network is extremely thin; only 0.5 μm separates air in the alveoli from blood in the pulmonary capillaries. (A sheet of tracing paper is about 50 times as thick as this air-to-blood barrier.) Moreover, the total alveolar surface area available for diffusion of oxygen and carbon dioxide is huge, typically 40–100 m^2 , depending on height. (If the lungs consisted of a single hollow chamber of the same dimensions rather than millions of alveoli, its surface area would be only about 0.01 m^2 .) These two factors, along with the differences in partial pressures of oxygen and carbon dioxide across this membrane (pp. 525–526), ensure that diffusion, under all but extreme environmental or pathological conditions, is both rapid and complete as blood flows through the pulmonary capillaries.

Minute **pores of Kohn** in the walls between adjacent alveoli (see ► Figure 12-2b) permit airflow between adjoining alveoli; this process is known as **collateral ventilation**. These pores are important as they allow fresh air to enter an alveolus when the terminal conducting airway is blocked because of disease.

Check Your Understanding 12.1

1. Relate the two anatomical components of the lung to their respective contributions to movement of gases.
2. Discuss how the alveolar air–pulmonary blood interface is ideally structured for gas exchange.
3. State the functions of type I alveolar cells.

THE CHEST WALL

The chest wall (**thorax**) is formed by 12 pairs of ribs, which join the **thoracic vertebrae** (backbone) posteriorly; ribs 1–7 join the **sternum** (breastbone) anteriorly. The **rib cage** protects the lungs and heart. The chest wall contains the muscles involved in generating the pressures that cause airflow. Like the lungs, it also contains considerable amounts of elastic connective tissue. At the neck, muscles and connective tissue enclose the thoracic cavity. In the absence of trauma, the only connection between the alveoli and the atmosphere is through the airways.

The main **inspiratory muscles** are the diaphragm and external intercostal muscles. The **diaphragm**, a large sheet of skeletal muscle, forms the floor of the thoracic cavity and separates it from the abdominal cavity (► Figure 12-5). The diaphragm is penetrated only by the esophagus and the blood vessels traversing the thoracic and abdominal cavities. It is innervated by the **phrenic nerves** that originate from cervical spinal cord segments 3, 4, and 5. The relaxed diaphragm has a dome shape that protrudes upward into the thoracic cavity. It is 1.7 mm thick at rest (up to 6 mm when contracting) and

FIGURE 12-4 Alveolus and associated pulmonary capillaries. (a) A schematic representation of an electron microscope view of an alveolus and surrounding capillaries. This representation is *not* to scale; the diameter of an alveolus is actually about 600 times larger than the space between the alveolus and a pulmonary capillary. A single layer of flattened Type I alveolar cells forms the alveolar walls. Type II alveolar cells in the alveolar wall secrete pulmonary surfactant. Alveolar macrophages wander within the alveolar lumen. (b) A transmission electron micrograph showing several alveoli and their surrounding capillaries. (c) Note that each alveolus is surrounded by an almost continuous sheet of blood vessels.

consists of a central part, the crus, and a costal (lateral) portion on each side. At rest, the costal parts are active, but as respiratory demands increase, additional motor units of the costal diaphragm and then the crus are recruited. At the onset of **inspiration**, the diaphragm descends (moves caudally), thereby enlarging the volume of the thoracic cavity by increasing the cavity's vertical (top-to-bottom) dimension. The abdominal wall, if relaxed, moves outward during inspiration as the descending diaphragm pushes the abdominal contents downward and forward. Fifty to 75 percent of the enlargement of the thoracic cavity during quiet inspiration is accomplished by contraction of the diaphragm.

Two sets of **intercostal muscles** lie between the ribs (*inter* means "between"; *costa* means "rib"). The **external intercostal muscles** lie over the internal intercostal muscles. Contraction

of these muscles, whose fibres run downward and forward between adjacent ribs, enlarges the thoracic cavity in both the lateral (side-to-side) and anteroposterior (front-to-back) dimensions. When the external intercostals contract, they elevate the ribs, moving the sternum upward and outward. **Intercostal nerves** (T1 to T12) activate these intercostal muscles. Many respiratory physiologists think the main result of activation of the external intercostal muscles is to stabilize the chest wall, preventing it from being sucked in during inspiration. This increases the efficiency of the diaphragm because its contraction is used to inflate the lung rather than being wasted on moving the chest wall.

The expiratory muscles include the **internal intercostal muscles** and the **abdominal muscles**, consisting of the rectus abdominis, transverse abdominis, and the external and internal

► FIGURE 12-5 Anatomy of the respiratory muscles

obliques. In humans, these are inactive at rest in healthy individuals but are recruited when ventilatory demands increase, as during exercise. They are also recruited during such protective reflexes as coughing, sneezing, and vomiting. Because these reflexes are so important, the expiratory muscles can generate much higher pressures than the inspiratory muscles. The internal intercostals are innervated by branches of the same thoracic nerves that project to the external intercostals. The abdominal muscles are innervated by nerves originating from spinal cord segments T7 through L1.

THE PLEURAL SPACE

The lung and other internal structures are covered by the visceral membrane. The inside wall of the thorax is lined by the parietal membrane. The space between these two membranes—which is very small, containing only a few millilitres of fluid—is called the **pleural space (cavity or sac)** (► Figure 12-6). The **pleural fluid**

► FIGURE 12-6 Pleural space. Schematic representation of the relationship of the pleural space to the lungs and thorax. The inside membrane of the pleural space, the *visceral pleura*, closely adheres to the surface of the lung and then reflects back on itself to form the other membrane, the *parietal pleura*, which lines the interior surface of the thoracic wall. The size of the pleural space between these two layers is grossly exaggerated here for the purpose of visualization.

Why It Matters

Pleurisy, an inflammation of the pleural membrane, is accompanied by painful breathing, because each inflation and deflation of the lungs cause a “friction rub” between the pleural and visceral membranes.

lubricates the surfaces of the two membranes as they slide past each other during breathing.

12.2 Respiratory Mechanics

As with blood flow through the circulatory system (p. 386), airflow through the airways depends on a pressure gradient, according to the equation $\text{flow} = \text{pressure}/\text{resistance}$, or $V = \Delta P/R$. The pressure gradient is used to overcome the elastance (stiffness) of the respiratory system, the resistance to airflow, and the inertia of the system. The first two account for almost all of the pressure that must be generated. For flow to occur between the airway opening (nose, mouth) and alveoli, pressure in the alveoli must be less than pressure at the mouth. For expiration to occur, pressure in the alveoli must be greater than the pressure at the mouth. To understand how our body changes alveolar pressure requires an introduction to the mechanics of the respiratory system.

Check Your Understanding 12.2

1. List the three factors opposing changes in volume of the respiratory system, and indicate their relative importance.

Pressures in the respiratory system

Four different pressures are critical to ventilation (► Figure 12-7): (1) atmospheric or barometric pressure (P_B); (2) alveolar pressure (P_A); (3) pleural pressure (P_{pl}); and (4) transpulmonary pressure (P_{tp}), which is also referred to as lung recoil pressure (P_l) (► Figure 12-8). ■ Table 12-2 explains the units used to measure these pressures.

Mechanical properties of the respiratory system

Each of the two components of the respiratory system—the lung and the chest wall—has its own pressure–volume relationship (► Figure 12-9). (Appendix G explains the derivation of the pressure–volume relationships of the lung and chest wall.) It is important for clinicians to understand the mechanical properties of these two components because the diseases that affect one or both of them impair respiratory function.

Atmospheric (barometric) pressure (P_B) is the pressure exerted by the weight of the air in the atmosphere on objects on Earth's surface. At sea level it equals 760 mmHg. This diminishes with increasing altitude as the layer of air above Earth's surface decreases in thickness. Minor fluctuations in P_B occur at any altitude because of changes in the weather.

Alveolar pressure (P_A ; also known as intrapulmonary pressure) is the pressure within the alveoli.

Pleural pressure (P_{pl}) is the pressure outside the lungs but still within the thoracic cavity; that is, the pressure within the pleural space. (It is often referred to as the intrapleural pressure; *intra* means within.) It closely approximates the **intrathoracic pressure** and, especially, the esophageal pressure, the latter being measured using a catheter passed via the patient's nose into the middle third of the esophagus. During resting breathing, P_{pl} averages $-5 \text{ cmH}_2\text{O}$. It is subatmospheric (negative) because of the mechanical properties of the lungs and the chest wall; the former wants to collapse and the latter expand, creating the negative pressure.

► **FIGURE 12-7** Pressures important in respiration

Pressure gradient across lung wall = alveolar pressure – pleural pressure. Here, $P_{lp} = 0 - (-5) = 5 \text{ cmH}_2\text{O}$.

Pressure gradient across thoracic wall = pleural pressure – atmospheric pressure. Here, $P_{tw} = -5 - 0 = -5 \text{ cmH}_2\text{O}$.

Pressures are in cmH_2O .

► **FIGURE 12-8** Transmembrane pressure gradient. In this depiction, flow is zero, and all pressures are in cmH_2O , relative to atmospheric pressure set to $0 \text{ cmH}_2\text{O}$. The pressure gradient across a structure is called the transmembrane pressure (*trans* is Latin for “across”; *mural* is the adjective of *mur*, Latin for “wall”). A transmembrane pressure difference is *always* calculated as the inside pressure minus the outside pressure. When referring to the lung, the transmembrane pressure is called the transpulmonary pressure (P_{tp}). This pressure is also the recoil pressure of the lung (P). Therefore, transpulmonary pressure = alveolar pressure – pleural pressure, or as an equation: $P_{tp} = P_A - P_{pl}$.

The line labelled P_l in ► Figure 12-9 shows the pressure–volume relationship of the lung. As lung volume increases, its recoil pressure increases from $\sim 0 \text{ cmH}_2\text{O}$ at residual volume to about $30 \text{ cmH}_2\text{O}$ at total lung capacity (p. 518). The lung therefore behaves like a balloon or a bubble, always exerting a positive (deflating) pressure.

The line labelled P_w in ► Figure 12-9 shows the pressure–volume relationship of the chest wall. It is like a spring that can be either compressed or expanded. Above approximately 65 percent of total volume (less when expressed as a percent of vital capacity; ► Figure 12-9), when it is stretched beyond its equilibrium volume, it exerts a deflating pressure. Below 65 percent, however, it is like a compressed spring, exerting negative (inflating) pressures.

The solid line labelled P_{rs} shows the pressure–volume relationship of the respiratory system. Here, the pressures represent the sums of the pressures of the lung and chest wall at any given volume. At 100 percent of the vital capacity (p. 518), both the lung and chest wall “want” to deflate, and the pressure exerted by the respiratory system is the sum of the deflationary pressures exerted by both. Conversely, at residual volume (0 percent of vital capacity), the chest wall’s tendency to inflate reflects only the passive inflationary pressure of the chest wall. At approximately 40 percent of the vital capacity, however, the net pressure exerted by the respiratory system is $0 \text{ cmH}_2\text{O}$ because, at this volume, the deflating pressure of the lung (about $+5 \text{ cmH}_2\text{O}$) is equal and opposite to the inflating pressure ($-5 \text{ cmH}_2\text{O}$) of the chest wall. This volume is the *functional residual capacity* (FRC) (p. 518) and is the volume the lungs return to at the end of a breath during resting breathing.

TABLE 12-2 Different Expressions of Units

Pressures can be expressed in many different units. Ideally, one would use those approved by the *Système Internationale* (SI)—in the case of atmospheric pressure, 1 Atm or 1000 kilopascals (kPa)—but for respiratory physiology we use traditional units based on the height of a column of mercury (mmHg) or water (cmH₂O):

- mmHg for the partial pressures of gases when discussing diffusion
- cmH₂O when discussing bulk flow (convection)

For the latter, we use cmH₂O rather than mmHg because the pressures needed to generate flow are typically small, only a few cmH₂O. For example, a pressure of 5 cmH₂O, which can easily cause a high flow, equals ~0.37 mmHg or 3.7 mmHg (1 mmHg equals 13.6 mmH₂O or 1.36 cmH₂O); 3.7 mm is too small to be measured accurately when using a mercury manometer. In addition, pressures related to convective flow are expressed *relative to atmospheric pressure*. Thus, if atmospheric pressure were 1034 cmH₂O (usually given as 760 mmHg), an alveolar pressure of 1039 cmH₂O is referred to as +5 cmH₂O, and an alveolar pressure of 1029 cmH₂O as –5 cmH₂O. (Note that “negative” pressures do not exist; they are negative only because they are less than the barometric pressure to which they are referred.)

The shape of the pressure–volume curve of the respiratory system is important. First, like all curves, it is characterized by its slope, which represents the change in volume per unit change in pressure. This slope, similar to the curve for the lung, has the units of L/cmH₂O, and is called the compliance. The compliance is greatest at functional residual capacity, the lung volume around which we breathe, and least at low or high lung volumes. Therefore, at functional residual capacity, the need to generate pressure to stretch the respiratory system is minimized, which decreases the energy (work) needed to breathe.

It is important to note that the zero pressure condition that occurs at the functional residual capacity is above the minimum

lung volume which the person can achieve upon maximal forceful expiration—that is, the residual volume. On average, the maximum volume that the lungs can hold—the total lung capacity—is about 5.7 L in healthy, young adult males and 4.2 L in females. Anatomic build (especially height), age, the distensibility of the lungs, and the presence or absence of respiratory disease all affect total lung capacity. Normally, during quiet breathing, lung volume at end-expiration is about 50 percent of the total lung capacity in a healthy, young adult. Thus, at functional residual capacity, the lungs still contain about 2.2 L of air. At rest, a typical tidal volume (p. 518) is about 0.5 L, so during quiet breathing the lung volume varies between 2.2 L at the end of expiration and

E. Agostoni and J. Mead. Statics of the Respiratory System. In: *Handbook of Physiology*. Section 3, Respiration, vol. 1, pp. 387–409 (1964). Eds W.O. Fenn and H. Rahn. Washington, DC: American Physiological Society.

FIGURE 12-9 Pressure–volume relationships of the lung, chest wall, and respiratory system. As lung volume increases, the recoil (passive) pressure of the lung (P_l), which is always positive (expiratory), also increases. In contrast, the recoil pressure of the chest wall (P_w) is most negative (inspiratory) at minimum volume, increases as volume increases, exerts no recoil pressure at approximately 60 percent of total volume, and is positive (expiratory) above this volume. The recoil pressure of the respiratory system (P_{rs}) is the sum of the pressures generated by the lung and chest wall. At functional residual capacity (FRC), the pressures of the lung and chest wall are equal and opposite; therefore, the net pressure exerted by the respiratory system is nil. Consequently, at the end of a passive expiration, the respiratory system is at FRC, approximately 50 percent of total lung capacity. This ensures that gas exchange continues during expiration. Note too that the slope of the pressure–volume relationship of the respiratory system is maximal at FRC; as a result, system compliance is maximal, which minimizes the work of breathing. For more information, see Appendix G.

2.7 L at the end of inspiration (see ▶ Figure 12-21). This presence of at least 2 L of gas in the lung even after expiration means there is sufficient oxygen in the lung to maintain its diffusion into the blood in the pulmonary capillaries, thereby preventing swings in blood oxygen levels during the respiratory cycle. During maximal expiration, lung volume can decrease to 1.2 L in males (1 L in females), but the lungs can never be completely deflated because the small airways collapse during forced expirations at low lung volumes, blocking further outflow (see ▶ Figure 12-18).

Check Your Understanding 12.3

1. Describe the respective contributions of the lung and chest wall to the generation of pressure by the respiratory system at residual volume, functional residual capacity, and total lung capacity.
2. What are the physiological benefits of breathing from functional residual capacity?

SOURCE OF THE LUNG'S ELASTIC RECOIL

The lung “wants” to collapse for two reasons: the **elastic recoil** of the tissues (pulmonary connective tissues contain large quantities of elastin fibres), and the **surface tension** of the liquid lining the inside surface of the alveoli.

Of these two factors, surface tension contributes about 70 percent of the lung's elastic recoil pressure. This was first established in the 1920s by the Swiss physiologist von Neergard who compared the pressure–volume curves of isolated lungs filled with saline and then with air (▶ Figure 12-10). (For a history of pulmonary mechanics, see Macklem, P.T. [2004]. A century of the mechanics of breathing, *American Journal of Respiratory and Critical Care Medicine*, 170: 10–15; ▶ Figure 12-11.) When the lung is filled with saline, it relies on the elastic properties of the lung and generates very little recoil pressure. In contrast, when it is inflated with air, its recoil pressure is much greater.

Why does the air-filled lung generate so much more recoil pressure than a saline-filled lung? At an air–water interface, water molecules at the surface are more strongly attracted to other surrounding water molecules than to any water molecules in the air above the surface. This is because there are far more water molecules in the water than in the water vapour above the surface. This unequal attraction, due to the polarity (unequal distribution of charge) of the water molecules, produces a force known as surface tension. Surface tension has a twofold effect. First, the liquid layer resists any force that increases its surface area; that is, it opposes expansion of the alveolus, because the surface water molecules oppose being pulled apart. Accordingly, the greater the *surface tension*, the less compliant are the lungs. Second, the surface area of the liquid tends to shrink as much as possible because the surface water molecules, being preferentially attracted to one another, try to get as close together as possible. Thus, the surface tension of the liquid lining an alveolus tends to reduce alveolar size and expel alveolar gas. This property, along with the rebound of the stretched elastin fibres, produces the lung's elastic recoil that provides the pressure for passive expiration.

▶ **FIGURE 12-10** Pressure–volume relationship of saline- and air-filled lungs. At a given volume, the saline-filled lung generates much less recoil pressure than the air-filled lung, because the former lacks an air–liquid interface and, therefore, surface tension. In an air-filled lung, surface tension accounts for most of the lung's recoil pressure; the rest comes from the elastic nature of the lung tissue. Note the space (or hysteresis) between the inflation and deflation limbs of the air-filled (but not saline-filled) lung. The hysteresis is exaggerated because this is the first inflation with air starting from a degassed state, as would occur when a baby takes its first breath. Over subsequent breaths, the inflation limb moves closer to the deflation limb.

▶ **FIGURE 12-11** Peter Macklem (1931–2011). He was one of the world's most prominent respiratory researchers (note the Order of Canada), and was still active at the time of his death in early 2011. His achievements and those of others are recounted in his excellent review of Canadian contributions to respiratory research in the *Canadian Respiratory Journal* [2007] 14: 383–92.

In emphysema, the breakdown of the alveolar walls causes both the loss of elastin fibres and the reduction in alveolar surface tension, which decrease elastic recoil. This, along with increased airway resistance, contributes to the patient's difficulty in breathing out. Moreover,

the reduced elastic recoil of the lung, in the face of unchanged outward recoil of the chest wall, means that the patient's equilibrium point—the functional residual capacity (FRC)—increases, accounting for a barrel-chested appearance in these patients.

Alveolar stability

The division of the lung into millions of alveoli provides the advantage of a huge surface area for gas exchange, but it also presents the problem of maintaining alveolar stability. Recall that the pressure generated by alveolar surface tension is directed inward. If you visualize the alveoli as spherical bubbles, according to the **law of LaPlace**, the magnitude of this collapsing pressure is directly proportional to the surface tension and inversely proportional to the radius of the bubble:

$$P = \frac{2T}{r}$$

where

- P = collapsing pressure
- T = surface tension
- r = radius of bubble (alveolus)

Because the collapsing pressure is inversely proportional to the radius, the smaller the alveolus, the smaller is its radius and the greater its tendency to collapse at a given surface tension. Accordingly, if two alveoli of unequal size but with the same surface tension are connected by the same terminal airway, the smaller alveolus—because it generates a larger collapsing pressure—will collapse and empty into the larger alveolus (► Figure 12-12a). Two factors oppose the tendency of alveoli to collapse: pulmonary surfactant and alveolar interdependence.

PULMONARY SURFACTANT

Pulmonary surfactant is a complex mixture of lipids and proteins secreted by the Type II alveolar cells (see ► Figure 12-4a). It disperses between the water molecules in the fluid lining the alveoli and lowers **alveolar surface tension**, because the cohesive force between a water molecule and an adjacent molecule of surfactant is very low. By lowering alveolar surface tension, surfactant provides two important benefits: (1) it increases pulmonary compliance, reducing

Law of LaPlace:

Magnitude of inward-directed pressure (P) in a bubble (alveolus) = $\frac{2 \times \text{Surface tension } (T)}{\text{Radius } (r) \text{ of bubble (alveolus)}}$

► **FIGURE 12-12** Role of pulmonary surfactant in counteracting the tendency for small alveoli to collapse into larger alveoli. (a) According to the law of LaPlace, if two alveoli of unequal size but the same surface tension are connected by the same terminal airway, the smaller alveolus generates a larger inward-directed pressure than the larger alveolus. In the absence of surfactant, it will collapse and empty its air into the larger alveolus. (b) Pulmonary surfactant reduces the surface tension of a smaller alveolus more than that of a larger alveolus. This reduction in surface tension offsets the effect of the smaller radius, and reduces the inward-directed pressure. Consequently, the collapsing pressures of the small and large alveoli are comparable and the small alveolus does not collapse and empty into the larger one.

Source: From Sherwood. *Human Physiology*, 8E. © 2013 Brooks/Cole, a part of Cengage, Inc. Reproduced by permission. www.cengage.com/permissions.

the work of inflating the lungs; and (2) it reduces the recoil pressure of smaller alveoli more than that of larger alveoli; this allows alveoli of different sizes to coexist, thereby keeping them open and able to participate in gas exchange. The net effect of surfactant, therefore, is to equalize the pressures within alveoli of different sizes, minimizing the tendency of small ones to empty into larger ones (► Figure 12-12b). This helps stabilize alveoli and maintains gas exchange.

ALVEOLAR INTERDEPENDENCE

The second factor that contributes to alveolar stability is the interdependence among neighbouring alveoli. Each alveolus is surrounded by other alveoli and interconnected with them by connective tissue. If an alveolus starts to collapse, neighbouring alveoli are stretched as their walls are pulled in the direction of the collapsing alveolus (► Figure 12-13a). These neighbouring alveoli then recoil in response to being stretched, and therefore exert an expanding force on the collapsing alveolus, which helps it stay open (► Figure 12-13b). This phenomenon is termed **alveolar interdependence**.

The opposing forces acting on the lung (i.e., the forces keeping the alveoli open and the countering forces that promote alveolar collapse) are summarized in ► Table 12-3.

Check Your Understanding 12.4

1. Describe the forces that keep the alveoli open and those that promote alveolar collapse.

PNEUMOTHORAX

 Normally, air does not enter the pleural cavity because there is no communication between the cavity and either the atmosphere or the alveoli. However, if the chest wall is punctured, air flows down its pressure gradient

TABLE 12-3 Opposing Forces Acting on the Lung

Forces Keeping the Alveoli Open	Forces Promoting Alveolar Collapse

Pulmonary surfactant (decreases alveolar surface tension)	Alveolar surface tension
Alveolar interdependence	

from the atmosphere into the pleural space (► Figure 12-14a). The abnormal condition of air entering the pleural space is known as **pneumothorax** (from the Greek, “air in the chest”). Both pleural and alveolar pressure now equal or actually exceed atmospheric pressure. With no opposing negative pleural pressure to keep it inflated, the lung collapses to its unstretched size (► Figure 12-14b). Likewise, with no opposing negative pleural pressure to hold it in, the thoracic wall expands to its unrestricted size (see the zero pressure point in ► Figure 12-9), but this has much less serious consequences than collapse of the lung. Pneumothorax and lung collapse can also occur if air enters the pleural cavity through a hole in the lung— produced, for example, by a disease process or by overinflation of the lung (*barotrauma*) (► Figure 12-14c). The latter reason explains why respiratory therapists and anesthetists carefully monitor the pressure and volume generated by mechanical ventilators.

Having completed our discussion of the physical properties of the respiratory system’s two components, the lung and chest wall, we can now turn to the main question: how does alveolar pressure change so that we can breathe in and out?

► FIGURE 12-13 Alveolar interdependence. (a) When an alveolus (in pink) in a group of interconnected alveoli starts to collapse, the neighbouring alveoli become stretched by the collapsing alveolus. (b) After stretching, these alveoli recoil, pulling the collapsing alveolus outward. This helps prevent the alveolus from collapsing.

► **FIGURE 12-14 Pneumothorax.** (a) *Traumatic pneumothorax*: Puncture of the chest wall permits air from the atmosphere to flow down its pressure gradient into the pleural space, abolishing the transmurial pressure gradient. (b) *Collapsed lung*: When the transmurial pressure gradient is abolished, the lung collapses, and the chest wall expands. (c) *Spontaneous pneumothorax*: A hole in the lung permits air to move down its pressure gradient and enter the pleural cavity via the lungs, abolishing the transmurial pressure gradient. As with traumatic pneumothorax, the lung collapses and the chest wall expands.

How alveolar pressure changes

For air to flow into the lung, alveolar pressure must be less than barometric (atmospheric) pressure. For air to flow out of the lung, alveolar pressure must exceed barometric pressure. Because barometric pressure is reasonably constant, the alveolar pressure must change to establish the pressure gradient needed to generate airflow. The pressure across the lung, the transpulmonary pressure (identical to the lung's recoil pressure), equals the inside (alveolar) pressure minus the outside (pleural) pressure (see ► Figure 12-7), as follows:

$$\text{lung recoil pressure} = \text{alveolar pressure} - \text{pleural pressure}$$

Because alveolar pressure needs to change in order for the lung to inflate or deflate, we rearrange this equation by placing *alveolar pressure* on the left side:

$$\text{alveolar pressure} = \text{lung recoil pressure} + \text{pleural pressure}$$

To change alveolar pressure, therefore, requires a change in the recoil pressure of the lung, the pleural pressure, or both. Because the recoil pressure of the lung depends on lung volume, in this equation we cannot change the lung volume by changing a pressure that reflects lung volume; this is a circular argument. Therefore, the pleural pressure has to change, and this happens when the muscles in the chest wall are activated. Activating the inspiratory muscles

decreases pleural pressure, whereas activating the expiratory muscles increases it.

ONSET OF INSPIRATION: CONTRACTION OF INSPIRATORY MUSCLES

Before inspiration, at the end of the preceding expiration, alveolar pressure equals atmospheric pressure, so no air flows into or out of the lungs (► Figures 12-15). As the pleural pressure decreases and the thoracic cavity enlarges, the pressure within the alveoli drops because of decompression (i.e., the same number of molecules are now present inside a larger container; see **Boyle's/Mariotte's law**, ► Figure 12-16). Because alveolar pressure is now less than atmospheric pressure, air flows down the pressure gradient, inflating the lungs (► Figure 12-15 and ► Figure 12-17), until no further gradient exists—that is, until alveolar pressure again equals atmospheric pressure. In a typical inspiratory excursion, the alveolar pressure drops only about 1 cmH₂O. (For a more detailed explanation of how this happens, see Appendix G.)

The trajectory of pleural pressure from start to end of inspiration is not linear but curved (► Figure 12-17). The “extra” pressure (hatched area) is used to overcome airflow resistance. If there were no flow resistance (as in an infinitely slow inspiration), the only pressure needed would be that needed to overcome the elastic recoil (the straight line, AC, between the start and end of inspiration).

ONSET OF EXPIRATION: RELAXATION OF INSPIRATORY MUSCLES

At the end of inspiration, the inspiratory muscles relax, decreasing their ability to expand the thorax. As a result, pleural pressure becomes less negative (i.e., more positive) (► Figure 12-15 and ► Figure 12-17). Then, because alveolar pressure is the algebraic sum of the lung recoil and pleural pressures, the alveolar pressure is now positive and expiration starts. Note that activation of the expiratory muscles is not necessary for expiration to occur; all that's required is reduction and then cessation of activity of the inspiratory muscles. Expiration stops when alveolar pressure again equals atmospheric pressure.

ROLE OF ACCESSORY INSPIRATORY MUSCLES

Deeper inspirations can be accomplished by contracting the diaphragm and external intercostal muscles more forcefully and by recruiting the previously inactive **accessory inspiratory muscles**. Contracting these accessory muscles in the neck (see ► Figure 12-5), raises the sternum and elevates the first two ribs, enlarging the upper portion of the thoracic cavity. As the volume of the thoracic cavity increases even more, making the pleural pressure and, therefore, the alveolar pressure even more negative, both inspiratory flow and tidal volume increase.

Numbers are pressures, in cmH₂O.

FIGURE 12-15 Changes in lung volume and alveolar and pleural pressures during inspiration and expiration. (a) Before inspiration, at the end of the preceding expiration: Because alveolar pressure equals atmospheric pressure, there is no flow. (b) Inspiration: As pleural pressure decreases due to inspiratory muscle contraction, alveolar pressure decreases due to decompression. This establishes a pressure gradient from atmosphere to alveoli, resulting in inspiratory flow. (c) End of inspiration: Inspiration ends when the contraction of inspiratory muscles decreases, allowing lung recoil pressure to become equal to pleural pressure. As a result, alveolar pressure again equals atmospheric pressure and flow stops. (d) Onset of expiration: Expiration starts when inspiratory muscles have stopped contracting. Lung recoil pressure is now greater than pleural pressure, resulting in a positive alveolar pressure and, therefore, expiratory flow.

SUMMARY OF INSPIRATION

Inspiration occurs when alveolar pressure is less than barometric pressure. This drop in alveolar pressure is the result of activation of the inspiratory muscles that lower pleural pressure (which, before inspiration starts, is about -5 cmH₂O). Because alveolar pressure is the algebraic sum of the pleural pressure and the elastic recoil pressure of the lung, and the lung's recoil pressure cannot change as quickly as the pleural pressure (it takes time for gas to flow into the lung, thereby increasing its recoil), alveolar pressure decreases. As a result, air flows into the lung (alveoli). As long as the inspiratory muscles contract and keep pleural pressure less (more negative) than the recoil pressure of the lung, inflation continues. Toward the end of inspiration, the activity of the inspiratory muscles declines. As a result, the recoil pressure of the lung "catches up" to the pleural pressure. When the two pressures are equal and opposite (e.g., pleural pressure = -8 cmH₂O and lung recoil pressure = $+8$ cmH₂O), inspiration stops. The "equal and opposite" situation is identical to that before inspiration started, at functional residual capacity, but the lung volume before inspiration started is greater than at the end of inspiration because the recoil pressure of the lung is greater.

For expiration to start, the cessation of inspiratory muscle activity results in pleural pressure starting to increase—that is, becomes more positive—in this case, increasing from -8 cmH₂O to -7 cmH₂O. Because the elastic recoil pressure of the lung is

Container A

Container B

Container C

Closed container with given number of gas molecules

FIGURE 12-16 Boyle's/Mariotte's law. Each container has the same number of molecules. Given the random motion of gas molecules, the likelihood of a gas molecule striking the interior wall of the container and exerting pressure varies inversely with the volume of the container at a given temperature. The gas in container B exerts more pressure than the same number of the same gas molecules in container C, but less pressure than the same number of gas molecules in container A. The relation is stated as Boyle's/Mariotte's law: $P_1V_1 = P_2V_2$. As the volume of gas increases, the pressure of the gas decreases proportionately; conversely, the pressure increases proportionately as the volume decreases.

FIGURE 12-17 Pressures, flow, and volume changes during a respiratory cycle. Before the onset of inspiration, pleural pressure (P_{pl}) is approximately $-5 \text{ cmH}_2\text{O}$, equal and opposite to the lung's recoil pressure ($+5 \text{ cmH}_2\text{O}$). Therefore, the alveolar pressure (P_A) is $0 \text{ cmH}_2\text{O}$ (relative to atmospheric), and there is no flow. As the inspiratory muscles contract, P_{pl} decreases and so does P_A (due to decompression). There is now a pressure gradient driving air from the airway opening to the alveoli. As long as P_A is less than atmospheric pressure (i.e., negative), inspiratory flow continues. As the inspiratory muscles start to relax toward the end of inspiration, lung recoil pressure (P) "catches up" to P_{pl} , and P_A returns to $0 \text{ cmH}_2\text{O}$, but this time at a more negative P_{pl} ($-8 \text{ cmH}_2\text{O}$) and, therefore, at a higher lung volume. The straight line between points A and C indicates the trajectory of P_{pl} if inspiration were infinitely slow—that is, if all the pressure required to inflate the lungs were used only to overcome elastic recoil. The hatched area between this straight line and the actual trajectory of P_{pl} during inspiration indicates the additional pressure needed to overcome flow resistance.

now greater than the pleural pressure, the alveolar pressure is positive, and expiration starts. Expiration ends when the recoil pressure of the lung again equals the pleural pressure.

ACTIVE EXPIRATION

In healthy individuals at rest, expiration is passive due to elastic recoil of the lungs. In contrast, inspiration is *always* active (i.e., requires energy expenditure), because it occurs only as a result of contraction of inspiratory muscles. **Forced or active expiration** empties the lungs more rapidly, occasionally more completely (i.e., to a lower end-expiratory lung volume). At sufficiently high levels of ventilation during exercise, the activation of expiratory muscles

can reduce the end-expiratory lung volume to below the functional residual capacity. This increases tidal volume independent of the inspiratory muscles and allows the lung volume to stay on the more compliant part of the pressure-volume curve (see Figure 12-9).

To breathe out more forcefully, alveolar pressure must be increased even more above atmospheric pressure than can be accomplished by relaxation of the inspiratory muscles and elastic recoil of the lungs (see Figure 12-9). The most important **expiratory muscles** are those of the abdominal wall. As they contract, the resulting increase in abdominal pressure becomes transferred to the pleural space, thereby increasing pleural pressure and generating a more forceful expiration (Figure 12-18). The other expiratory muscles are the internal intercostal muscles. Their contraction pulls the ribs downward and inward, flattening the chest wall and further decreasing the size of the thoracic cavity—the opposite of what results from activation of the external intercostals. Aside from decreasing the volume of the thoracic cavity, the muscles of active expiration stabilize the abdomen; this aids breathing because energy is now used to move air rather than displace the abdominal contents. This is most clearly seen during heavy physical labour and aerobic exercise.

During forceful expiration, pleural pressure becomes positive, but the lungs do not collapse because alveolar pressure increases correspondingly, according to the relationship: alveolar pressure = recoil pressure + pleural pressure. As expiratory flow occurs, however, alveolar pressure gradually decreases, because energy (pressure) is lost in overcoming flow resistance. At some point along the airways, this pressure will drop until it equals and then falls below the pressure outside the airways, the pleural pressure. At this point, the **equal pressure point**, the **transmural pressure** switches from positive (inside pressure > outside pressure) to negative (inside pressure < outside pressure), a situation in which the airway is under compression (see Figure 11-18c). How much compression occurs depends on the intrinsic strength of the airway wall (cartilage) and the degree of contraction (*tone*) of the airway smooth muscle.

Clinical Connections

Asthma is an obstructive airway disease due to bronchoconstriction of the smaller airways and an

inflammatory response in the airways that leads to an increase in mucus secretion. Patients with asthma generally have normal inhalation; however, exhalation is hindered due to the obstruction. In an effort to enhance exhalation against the obstruction, there is an increased use of accessory muscles for forced exhalation. With greater recruitment of these muscles, there is an increase in pleural pressure that causes the equal pressure point to be reached earlier in the exhalation, which further constricts the bronchioles due to compression of the lungs and results in the characteristic wheezing sound associated with asthma. Exhalation is terminated early, which causes air trapping because the next inspiration cycle begins at a higher lung volume. This air trapping further increases the amount of work needed for exhalation, and this cycle continues to worsen until the obstruction can be reduced.

Check Your Understanding 12.5

1. Explain which pressure must first change to initiate inspiration.
2. Describe the changes in pleural, transpulmonary, and alveolar pressures during inspiration and expiration at rest in a healthy individual.

Airway resistance and airflow

We have discussed airflow in and out of the lungs as a function of the magnitude of the pressure gradient between the alveoli and the atmosphere, and you have learned how this

pressure gradient is generated and used to overcome, during inspiration, the elastance of the respiratory system, especially the lung's elastic recoil. In this section, we focus on the other component of the respiratory system that needs to be overcome: airway resistance.

Resistance to flow in the airways is governed by the equation $\dot{V} = \Delta P/R$. Resistance is determined by, **Poiseuille's law**, the same equation that determines resistance to blood flow (p. 388):

$$R = 8n\ell/r^4$$

where: η = the viscosity of the fluid
 ℓ = the length of the tube
 r = the radius of the tube

Because of the fourth power, the radii of the airways are the primary factor determining resistance to flow. In our preceding discussion of pressure gradient-induced flows, we ignored airway resistance because, in a healthy respiratory system, the radii are large enough that resistance is extremely low. Therefore, only a small pressure gradient, 1–2 cmH₂O, between the alveoli and the atmosphere is usually required to generate flow in either direction.

Normally, modest adjustments in airway size can be achieved by regulating autonomic nervous system activity to suit metabolic and, therefore, ventilatory demands. Parasympathetic activity,

FIGURE 12-18 Airway collapse during forced expiration. (a) Normal, quiet expiration, during which airway resistance is low, so there is little frictional loss of pressure within the airways. Pleural pressure remains less than airway pressure throughout the airways, so they remain open. (b) In routine exercise, even though pleural pressure is elevated during the active expiration accompanying routine vigorous activity, alveolar pressure is also elevated and airway resistance is still low, so the resistance-induced drop in airway pressure does not fall below the elevated pleural pressure until gas reaches airways that are held open by cartilaginous rings. Therefore, airway collapse does not occur. (c) In forced expiration, both alveolar and pleural pressures are markedly increased. When resistive losses cause pressure in the airway to fall below the surrounding elevated pleural pressure (i.e., the transmural pressure becomes negative at the equal pressure point), the small, nonrigid airways are compressed or closed, preventing increases in expiratory flow. In healthy individuals, this dynamic compression of airways occurs only at very low lung volumes.

dominant at rest when ventilatory demands are low, promotes bronchiolar smooth muscle contraction (**bronchoconstriction**); this increases airway resistance by decreasing the radii of airways. Conversely, withdrawal of parasympathetic activity, as in exercise, causes airway smooth muscle relaxation (**bronchodilation**). Sympathetic stimulation and to a greater extent its associated hormone, epinephrine, also cause bronchodilation and decreased airway resistance via activation of β_2 -adrenergic receptors (■ Table 12-4). Therefore, during periods of sympathetic domination, when actual or potential increased demands for oxygen uptake occur, bronchodilation ensures that the pressure gradients generated by respiratory pump muscle activity can achieve maximum flows with minimal resistance. A low resistance also helps reduce the work of breathing. Because of this bronchodilator action, epinephrine or similar drugs are useful therapeutic tools to counteract airway constriction in patients with bronchial spasm.

The situation is, however, considerably more complex than this (► Figure 12-19). Airways receive a rich innervation by postganglionic parasympathetic nerve fibres originating from the vagus nerves; the release of acetylcholine causes bronchoconstriction. Tonic activity of these fibres accounts for a resting level of contraction, known as tone. In contrast, at least in humans, innervation of the airways by postganglionic sympathetic (adrenergic) fibres from the paravertebral ganglia is much less.

Dilation can be elicited in two ways by the adrenergic system: (1) directly by the terminals releasing norepinephrine, which activates β_2 -receptors on bronchial smooth muscle; or

(2) indirectly by the adrenal medulla releasing epinephrine, which is carried by the circulation to its site of action—the airway smooth muscle. (This is why people with intense reactions to allergens, such as bee venom, carry syringes loaded with epinephrine.) In addition, activation of α -adrenergic receptors located in parasympathetic ganglia may suppress parasympathetic activity, thereby decreasing tone (indicating the importance of having resting levels of tone) and causing bronchodilation.

The peptidergic system also affects airway resistance. Release of vasoactive intestinal peptide (VIP) by the inhibitory non-adrenergic-non-cholinergic parasympathetic (i-NANC) system causes dilation (possibly mediated by nitric oxide), whereas the complementary excitatory (e-NANC) system causes bronchoconstriction via the release of such tachykinins as substance P. In addition, many other bronchoconstrictor agents (histamine, thromboxane A_2 , prostaglandin F_2 , and leukotrienes) are released by mast and epithelial cells or cells recruited as part of an immunological response to allergens or infections. Given the prevalence of asthma, the amount of research on this topic—both academic and commercial/pharmaceutical—is not surprising.

Airway smooth muscle controls the resistance primarily in intrathoracic airways. Skeletal muscles in the upper airway (larynx, pharynx) also control resistance to flow, but because they are skeletal, they are not under autonomic control. Instead, they are under the control of motor neurons located in the part of the brain stem that contains the neurons that generate the respiratory rhythm (p. 542).

■ **TABLE 12-4** Factors Affecting Airway Resistance

Status of Airways	Effect on Resistance	Factors Producing the Effect
Bronchoconstriction	↓ radius, ↑ resistance to airflow	<i>Pathological factors:</i> Allergy-induced spasm of the airways caused by slow-reactive substance of anaphylaxis Histamine Physical blockage of the airways caused by excess mucus oedema of the walls Airway collapse <i>Physiological control factors:</i> Neural control: parasympathetic stimulation Local chemical control: ↓ CO₂ concentration
Bronchodilation	↑ radius, ↓ resistance to airflow	<i>Pathological factors:</i> none <i>Physiological control factors:</i> Neural control: sympathetic stimulation (minimal effect) Hormonal control: epinephrine Local chemical control: ↑ CO₂ concentration

FIGURE 12-19 Airway innervation. The lung is innervated by both branches of the autonomic nervous system. Parasympathetic neurotransmitters to airway smooth muscle include acetylcholine (ACh), vasoactive intestinal peptide (VIP), and nitric oxide (NO). The sympathetic neurotransmitter is norepinephrine (NE). Other transmitters include substance P (SP) and neurokinin A (NKA). Receptor endings located in both the epithelium and smooth muscle include slowly adapting (SAR) and rapidly adapting (RAR) receptors, along with endings of unmyelinated fibres (C-fibres). JG: jugular ganglion; NG: nodose ganglion; DRG: dorsal root ganglion.

Last, resistance can be affected by swelling of the mucosa, in the nose and elsewhere, as anyone with a “stuffy” nose can attest. Agents (sympathetic agonists) that narrow mucosal blood vessels reduce this swelling, which is why they are known as *decongestants*.

Airway resistance and chronic pulmonary diseases

Chronic pulmonary diseases are often characterized by increased resistance resulting from narrowing of the lumen of the lower airways. When resistance increases, a larger pressure gradient must be established to maintain even a normal airflow. For example, if resistance doubles due to narrowing of the airways (which, according to Poiseuille’s law, requires only a 16 percent decrease in radius), the pressure gradient must be doubled through increased activation of the respiratory pump muscles to produce the same flow. Accordingly, people with pulmonary disease work harder to breathe. Chronic (long-term) pulmonary diseases include asthma and chronic obstructive pulmonary disease (COPD).

ASTHMA

In asthma (see www.lung.ca), airway obstruction is due to (1) thickening of airway walls, brought about by inflammation

and histamine-induced oedema (p. 467); (2) plugging of the airways by excessive secretion of very thick mucus; and (3) airway hyper-responsiveness, characterized by constriction of the smaller airways due to spasm of the smooth muscle in their walls. Triggers that lead to these inflammatory changes and the exaggerated bronchoconstrictor response include repeated exposure to allergens (such as dust mites or pollen), irritants (as in cigarette smoke or pollution), and infections. In severe attacks, pronounced clogging and narrowing of the airways can prevent all airflow, leading to death. An estimated 3 million people in Canada have asthma, and the number is steadily climbing. Asthma is the most common chronic childhood disease. Scientists are unsure why the incidence of asthma is increasing.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) (the current term for emphysema and chronic bronchitis) slowly damages the airways, usually as a result of cigarette smoking. (A world authority is Dr. James C. Hogg of Vancouver, the 2013 recipient of the Gairdner Wightman Award.) The disease can also result from other airborne irritants and occupational pollutants, such as coal dust, asbestos, and silica. Combining exposure to pollutants with cigarette smoking greatly increases the likelihood of a person developing COPD.

According to the Canadian Lung Association (see www.lung.ca), approximately 600 million people worldwide have COPD, including about 1.5 million Canadians. COPD is the fourth-leading cause of death in Canada, and experts believe that, by 2020, it will be the third-largest cause of mortality worldwide, in large part because cigarette smoking is very prevalent in underdeveloped and developing countries where governments are susceptible to the influence (or lawsuits) of multinational manufacturers and dependent on taxes derived from sales of cigarettes. A good prognosis for COPD relies on early detection and diagnosis, prompt cessation of smoking when applicable, and reduction of environmental exposure to particulate pollution. Most patients demonstrate improvement in lung function at the onset of treatment, but eventually COPD progresses, and the symptoms become worse.

CHRONIC BRONCHITIS

Chronic bronchitis is a long-term inflammatory condition of the lower airways, generally triggered by frequent exposure to cigarette smoke, polluted air, or allergens. In response to the chronic irritation, the airways become narrowed by prolonged oedematous thickening of the airway linings, coupled with overproduction of thick mucus. Despite frequent coughing associated with the chronic irritation, the plugged mucus often cannot be removed, especially because the irritants immobilize the ciliary mucus escalator (p. 464). Pulmonary bacterial infections frequently occur because the accumulated mucus serves as an excellent medium for bacterial growth.

EMPHYSEMA

Emphysema is characterized by (1) collapse of the smaller airways and (2) breakdown of alveolar walls (i.e., loss of alveolar tissue, including pulmonary capillaries). This irreversible condition can arise in two ways. Most commonly, emphysema results from the excessive release of destructive enzymes, such as *trypsin*, from alveolar macrophages as a defensive mechanism in response to chronic exposure to inhaled cigarette smoke or other irritants. A protein that inhibits trypsin— α_1 -antitrypsin—normally protects the lungs from damage caused by the release of the destructive enzymes. However, excessive secretion of destructive enzymes in response to chronic irritation can overwhelm the protective capability of α_1 -antitrypsin, with the result that these enzymes destroy not only foreign materials but lung tissue as well. Loss of lung tissue leads to the breakdown of alveolar walls and collapse of small airways.

Less frequently, emphysema arises from a genetic inability to produce α_1 -antitrypsin so that the lung tissue has no protection from trypsin. The unprotected lung tissue gradually disintegrates under the influence of even small amounts of macrophage-released enzymes, even in the absence of chronic exposure to inhaled irritants. The only treatment currently available is lung transplantation.

DIFFICULTY BREATHING OUT

When pulmonary disease of any type increases airway resistance, expiration is more difficult than inspiration. The smaller airways, lacking the cartilaginous rings that hold the larger ones

open, are held open by a positive transmural pressure gradient—that is, by the negative pleural pressure. Inspiration not only increases the volume of the alveoli but also dilates the airways passively because of the greater positive transmural pressure gradient. The resulting dilation of the airways decreases flow resistance (Poiseuille's law). In a healthy individual, however, airway resistance is so low that these respiratory phase-related changes in airway resistance cannot be readily detected. When airway resistance increases substantially, however, as during an asthma attack, the difference is noticeable. Thus, a person with asthma has more difficulty expiring than inspiring, giving rise to the characteristic wheezing that happens as air is forced out through the narrowed airways.

Surprisingly, patients experiencing an acute exacerbation of asthma or COPD do not complain of difficulty breathing out; instead, they complain that they cannot get enough air in! Why? Although the initial problem is obstructive (“can’t breathe out”), it quickly becomes restrictive (“can’t breathe in”). Because the person has trouble breathing out, they do not return to the usual end-expiratory lung volume. Therefore, the next inspiration starts at a higher lung volume. This is good because airway resistance is lower at higher lung volumes. But at this elevated lung volume, the person still cannot breathe out completely. Over time, and the process can be rapid and the person hyperinflates—a phenomenon known as **dynamic hyperinflation**. But at high lung volumes, not only is the inspiratory reserve volume reduced (often to less than a litre) but so too is system compliance (see ▶ Figure 12-9). This makes inspiration difficult and uncomfortable; the patient wants to breathe in but cannot achieve a satisfactory tidal volume. The discrepancy between what is wanted and what is achieved is thought to be the basis for the debilitating sensation of **dyspnea**, or **breathlessness**, during these acute exacerbations.

Normally, the smaller airways stay open during quiet breathing and even during active expiration when pleural pressure is elevated, as during exercise (see ▶ Figure 12-18b.). In people without pulmonary disease, the smaller airways collapse and further outflow of air stops only at very low lung volumes during a maximal forced expiration (see ▶ Figure 12-22). Because the small airways collapse, the lungs can never be emptied completely, which accounts for the residual volume. By contrast, in people who have pulmonary disease, especially emphysema, the smaller airways often collapse even during expiration at rest, preventing further outflow. Such individuals breathe at higher end-expiratory lung volumes that help hold the airways open. They may also purse their lips during expiration; by limiting flow at the mouth, they shift the equal pressure point toward the mouth, and the increased pressure inside the airways helps to keep the airways open.

Lung volumes and capacities

A spirometer is a device that measures the volume of air breathed in and out; it consists of an air-filled drum floating in a water-filled chamber (▶ Figure 12-20). As a person breathes air in and out of the drum through a connecting tube, the rise and the fall of the drum, to which a pen is attached, are recorded as a **spirogram**,

► FIGURE 12-20 A spirometer

which is calibrated to measure the volume (cross-sectional area multiplied by height). Water-filled spirometers have been replaced with devices that measure flow (often using a turbine); the output signal is electronically integrated to obtain volume.

► Figure 12-21 gives an example of a spirogram for a healthy, young, adult male. Generally, the values are lower for females. The following lung volumes and lung capacities can be determined. (Note a lung capacity is the sum of two or more lung volumes.)

- **Tidal volume (V_T)**. The volume of air entering or leaving the lungs during a single breath. Average value under resting conditions = 500 mL.
- **Inspiratory reserve volume (IRV)**. The extra volume that can be maximally inspired over and above the typical resting tidal volume. Average value = 3000 mL.
- **Inspiratory capacity (IC)**. The maximum volume that can be inspired starting from the end of a normal quiet expiration ($IC = IRV + V_T$). Average value = 3500 mL.
- **Expiratory reserve volume (ERV)**. The maximum volume that can be actively expired starting from the end of a typical resting tidal volume. Average value = 1000 mL.
- **Residual volume (RV)**. The volume of air remaining in the lungs after a maximal expiration. Average value = 1200 mL. The residual volume cannot be measured directly with a spirometer, because this volume of air does not move in and out of the lungs. It can be determined indirectly, however, through gas-dilution techniques involving inspiration of a known quantity of a harmless tracer gas, such as helium.

KEY

V_T	= Tidal volume (500 mL)
IRV	= Inspiratory reserve volume (3000 mL)
IC	= Inspiratory capacity (3500 mL)
ERV	= Expiratory reserve volume (1000 mL)
RV	= Residual volume (1200 mL)
FRC	= Functional residual capacity (2200 mL)
VC	= Vital capacity (4500 mL)
TLC	= Total lung capacity (5700 mL)

► FIGURE 12-21 Subdivisions of lung volumes. Normal spirogram of a healthy, young, adult male. (The residual volume, RV, cannot be measured with a spirometer but can by other means, such as helium dilution.) Values for females are, on average, lower.

- **Functional residual capacity (FRC)**. The volume of air in the lungs at the end of a normal passive expiration ($FRC = ERV + RV$). Average value = 2200 mL.

- **Vital capacity (VC).** The maximum volume of air that can be moved out during a single breath following a maximal inspiration. The person first inspires maximally, then expires maximally ($VC = IRV + V_T + ERV$). Average value = 4500 mL.
- **Total lung capacity (TLC).** The maximum volume of air that the lungs can hold ($TLC = VC + RV$). Average value = 5700 mL.
- **Forced expiratory volume in one second (FEV_1).** The volume of air expired during the first second of a maximal expiratory effort starting from TLC. It is usually expressed as a ratio of the forced vital capacity—that is, the FEV_1/FVC —or converted to a percentage. Young, healthy people have values of 80 percent or more, but the test must be done correctly. The FEV_1/FVC decreases with age. One can estimate a person's maximum voluntary ventilation (MVV, in L/min) by multiplying the (FEV_1) by 35.

DYNAMIC LUNG FUNCTION AND RESPIRATORY DYSFUNCTION

Clinical Note As well as the measurements of their lung volumes, individuals suspected of having pulmonary problems will have their dynamic lung function assessed. Two general categories of respiratory dysfunction yield abnormal results during spirometry: *obstructive lung disease* and *restrictive lung disease* (see ▶ Figure 12-22 and ▶ Figure 12-23).

▶ Figure 12-22 illustrates a **forced vital capacity (FVC)** manoeuvre in which the person inhales maximally to total lung capacity (identical to 100 percent of the vital capacity) and then breathes out as hard, fast, and completely as possible. From this manoeuvre, considerable insight into the status of the respiratory system, especially the lungs, is obtained. The healthy person in ▶ Figure 12-22a can exhale approximately 80 percent of her vital capacity in the first second (the forced expired volume, FEV_1), but individuals with pulmonary diseases have very different results. The patient with an obstructive lung disease has a lower FEV_1 and cannot breathe out to a low lung volume because her airways collapse, trapping gas (▶ Figure 12-22b). Consequently, her FRC and residual volume (RV) are greater, but vital capacity (VC) is smaller. In contrast, the person with restrictive lung disease breathes at a lower lung volume but can still breathe out a normal or even greater than normal fraction of her vital capacity in the first second (▶ Figure 12-22c).

Another way of presenting this manoeuvre is not with a tracing of volume versus time (▶ Figure 12-22 and ▶ Figure 12-23a), in which the rate of volume change indicates flow) but with a plot of flow versus volume. The flow–volume tracings from a healthy individual, a patient with obstructive, and another with restrictive lung disease are depicted in ▶ Figure 12-23b. During the manoeuvre, expiratory flow reaches an early peak and then declines until residual volume is reached. The first part of the curve depends on the effort made and is therefore called *effort-dependent*. In contrast, the last part of the curve is *effort-independent*. In other words, even if a healthy individual tried to breathe out harder, he could not generate a higher flow. This is because a greater effort causes increased pleural pressure that compresses the smaller airways, increasing their resistance. This increase in resistance offsets the increased driving pressure.

▶ **FIGURE 12-22 Spirometry (flow versus time) tracings.** (a) The tracing from the healthy individual shows that the volume she can breathe out in the first second of a forced expiration (the FEV_1) is more than 80 percent of her vital capacity, and she can exhale to a low lung volume (the residual volume). (b) In contrast, the patient with an obstructive lung disease has a lower FEV_1 ; in other words, the slope of the flow tracing during the forced expiration is reduced. Moreover, even at rest, there is air trapping in the lung during expiration due to collapsible airways, so her functional residual capacity (FRC) and residual volume (RV) are greater, but the vital capacity (VC) is smaller. Nevertheless, total lung capacity (TLC) is normal or even elevated because it includes trapped gas. Although both VC and FEV_1 are reduced, the FEV_1 is reduced more than the forced vital capacity (FVC). As a result, the FEV_1/FVC percentage is much lower than the normal 80 percent. (c) In restrictive lung disease, the lungs are less compliant than normal. The patient breathes at a lower lung volume, has a greatly reduced VC, a normal RV, but the FEV_1/FVC percentage is normal or even elevated. Therefore, changes in FEV_1/FVC are particularly useful in distinguishing between obstructive and restrictive lung disease.

▶ **FIGURE 12-23 Derivation of expiratory flow–volume curves.** (a) Volume versus time tracing of a normal individual during a maximal forced expiration from total lung capacity. (b) At each volume, the slope (volume/time, or flow) is calculated (three such points are shown in the volume-time tracing) and plotted versus volume. Note the rapid rise to a peak flow of ~7 L/s, followed by a linear decrease in flow as lung volume decreases. In contrast, an individual with obstructive lung disease (left tracing) breathes at a higher lung volume but reaches a lower peak flow; throughout expiration, flows are much less than those in a normal individual, and the tracing is slightly concave to the x-axis (“scooping”). The person also cannot breathe out as much; that is, he has an elevated residual volume. His vital capacity is also slightly reduced. The person with a restrictive disease (right tracing) breathes at a lower lung volume, has a greatly reduced vital capacity, but can, at a given lung volume, generate expiratory flows greater than those of the healthy individual. These curves illustrate how such tests can help diagnose respiratory diseases.

Clinical Connections

Andrea's pulmonary function test would look similar to that shown in ▶ Figure 12-22b.

Recall that her forced expiratory flow rate was reduced to 25 percent of the predicted rate and that her FEV_1 was only 40 percent, instead of the expected 80 percent, of vital capacity. This spirometry tracing illustrates that patients with obstructive diseases such as asthma have a decreased ability to exhale. This causes air trapping (gas trapping; breath stacking); this is shown by increased functional residual capacity and residual volume, yet the vital capacity is smaller.

In contrast, in a person with COPD, flow again reaches an early peak, but the value is much less than that predicted for a healthy person of the same age, gender, and height. Moreover, the maximal expiratory flow rapidly decreases to a low value and stays low throughout the rest of the expiration, despite the person making a maximal effort. Although not shown, the maximum flow during this effort is the same as that used by the person at rest. Last, expiratory flow terminates prematurely, at a higher volume, because of closure of the airways. In this person, the forced vital capacity is less than predicted.

The third person has a restrictive disease. The most obvious difference between this individual and the other two is the reduced lung volume (smaller lateral dimension). The person cannot inhale as much (a smaller distance along the x -axis between the end of a normal inspiration and the end of a maximal inspiration) and, because the recoil of the lung is reduced, peak expiratory flow is less.

Check Your Understanding 12.6

1. Describe how measurements of flow and volume can be used to distinguish between obstructive and restrictive diseases.
2. Explain what happens to the lung volume of a person with an exacerbation of obstructive lung disease.

WHY WE MEASURE EXPIRATORY FLOWS

Considering that inspiration is the active, energy-consuming part of breathing, why do we measure events during *expiration* to assess pulmonary function? Indeed, to assess a person's ability to breathe, why not simply ask the person to breathe as hard and fast as possible for several minutes and measure the maximum voluntary ventilation? Aside from the difficulty of knowing whether the person is making a maximal effort, the major problem is that an increase in ventilation in the absence of an increase in carbon dioxide production means the person is hyperventilating, and the partial pressure of carbon dioxide in the arterial blood (Pa_{CO_2}) will decrease. This, in turn, will cause systemic vasoconstriction, reducing blood flow to the periphery (accounting for numbness in the extremities), including the brain (accounting for feeling "light-headed"). It is therefore difficult for a person to sustain the effort, and the procedure would not be ethical for patients.

A simple experiment can provide part of the answer to why we measure expiratory events as an index of pulmonary function. Breathe out all the way to residual volume, and then inhale as hard and as fast as you can to total lung capacity. How long did it take? Perhaps 0.5 seconds or less? Now breathe in all the way to total lung capacity, and then breathe out as hard, fast, and completely as you can to residual volume. If you did it correctly, the expiration would take at least four to six seconds. In other words, the limitation to ventilation in a healthy individual is expiratory, not inspiratory.

There are two reasons for this. First, during expiration, lung volume decreases and the radii of the airways decrease, thereby increasing flow resistance. Second, during expiration, the expiratory muscles contract and, therefore, shorten. According to the force-length relationship (Chapter 7), this reduces the ability of skeletal muscles to generate force—in the case of expiratory muscles, the ability to generate pressure. Recall that

$$\dot{V} = \Delta P/R$$

During expiration, especially a forced expiration, the ability to generate pressure decreases because of the force-length relationship, and resistance increases because of reduced lung volume and compression of the airways due to the higher pleural pressure outside the intrathoracic airways. The combination of a decreased numerator (ΔP) and an increased denominator (R) is responsible for the reduction in airflow as lung volume decreases.

During inspiration, the ability of the inspiratory muscles to generate pressure also decreases because they shorten. But this is offset by the decrease in resistance as lung volume increases. Therefore, inspiratory flow is limited not by the resistance but by the contractile properties of the inspiratory muscles.

Why not simply measure the maximal voluntary ventilation (MVV)? In fact, we do not need to perform this test. Instead, we can multiply the forced expired volume in the first second (FEV_1) of a forced vital capacity by 35 to obtain a value close to the actual MVV.

OTHER CAUSES OF RESPIRATORY DYSFUNCTION

Obstructive and restrictive diseases are not the only categories of respiratory dysfunction, and spirometry is not the only way to assess pulmonary function. Other conditions affecting respiratory function include the following:

- Diseases impairing diffusion of oxygen and carbon dioxide across the pulmonary alveolar-capillary membranes
- Reduced ventilation because of mechanical failure, as with neuromuscular diseases affecting the respiratory muscles
- Inadequate pulmonary blood flow
- Ventilation/perfusion abnormalities involving a poor matching of air to blood (and vice versa) so that gas exchange is impaired

Some lung diseases are actually a complex mixture of different types of functional disturbances. To determine what abnormalities are present, a diagnostician relies on a variety of tests in addition to spirometry, including X-rays, blood-gas measurements, and tests to measure the diffusion capacity for oxygen across the alveolar capillary membrane.

Pulmonary and alveolar ventilation

The volume of gas breathed during one minute is called the **minute ventilation**. It is calculated by multiplying the average tidal volume (V_T) over one minute by the **respiratory frequency** (f). Thus, minute ventilation (L/min) equals tidal volume (L/ breath) multiplied by respiratory rate (breaths/min). In symbols,

$$\dot{V}_E = V_T \times f$$

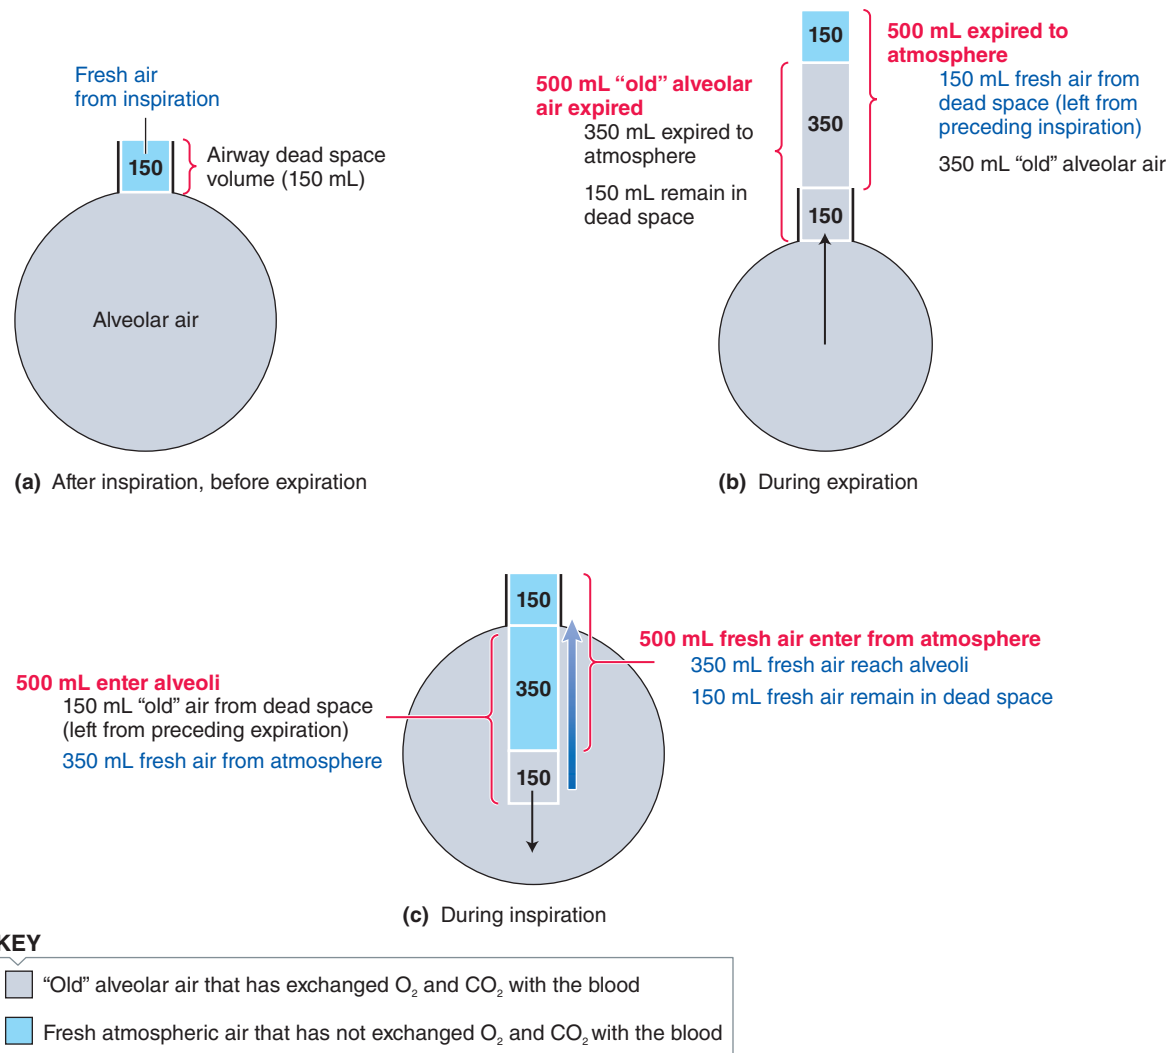

where the E after $\dot{V}$ indicates the measurement was made on expired gas. At rest, an average tidal volume is 0.5 L and the respiratory frequency is 12, so the minute ventilation is 6.0 L/min. For a brief period, a healthy, young, adult male can voluntarily increase his minute ventilation twenty-five-fold, to 150 L/min. To increase ventilation, both tidal volume and respiratory frequency increase; at the start, the tidal volume increases more than the frequency, but once a limit to tidal volume is reached (large tidal volumes increase the work of breathing because system compliance is low at high volumes),

frequency increases. But not all of this ventilation can be used for gas exchange because of the anatomic dead space.

ANATOMIC DEAD SPACE

Not all the inspired air reaches the alveoli; some remains in the conducting airways. This volume is considered anatomic dead space (V_D) because air within these conducting airways cannot participate in gas exchange. The volume of the airways in an adult averages about 150 mL. Anatomic dead space influences the efficiency of pulmonary ventilation. Although 500 mL of air move in and out with each breath, only 350 mL actually participate in gas exchange due to the anatomic dead space.

To understand how the dead space affects gas exchange, examine ▶ Figure 12-24. During inspiration, the person inspires 500 mL. Most (350 mL) enters the alveoli, but 150 mL remains in the conducting airways. Therefore, at the end of inspiration, the airways are filled with 150 mL of fresh air. During the subsequent expiration, 500 mL of air are expired. The first 150 mL

▶ **FIGURE 12-24 Effect of dead space on gas exchange.** Even though 500 mL of air moves in and out between the atmosphere and the respiratory system and 500 mL moves in and out of the alveoli with each breath, only 350 mL is actually exchanged between the atmosphere and the alveoli because of the anatomic dead space (the volume of air in the airways).

is the fresh air that stayed in the airways and never participated in gas exchange. The remaining 350 mL is gas from the alveoli. But 500 mL also had to leave the alveoli. The first 350 mL are expired to the atmosphere; the other 150 mL remain in the conducting airways.

On the next inspiration, 500 mL of gas enter the alveoli. The first 150 mL to enter the alveoli is the old alveolar air that remained in the dead space during the preceding expiration. In effect, the subject is rebreathing his own gas at the start of inspiration. The other 350 mL entering the alveoli is fresh air. But because the subject's VT is 500 mL, the last 150 mL remain in the conducting airways, to be expired without benefit of being exchanged with the blood, during the next expiration.

ALVEOLAR VENTILATION

To optimize oxygen transfer to the blood in the capillaries, we want as much as possible of the lung to be devoted to gas exchange—that is, to alveoli. But this would require the airways (which do not participate in gas exchange because their walls are too thick) to be small. But if the airways are narrow, flow resistance increases inordinately—due to the radius to the fourth power (r^4) term in Poiseuille's law (p. 514)—and the resistive work of breathing would be too high. The anatomy of the respiratory system is a compromise between airway (resistance) and alveolar (gas exchange) volumes. As just mentioned, during inspiration, some of the inspired air remains in the airways and never reaches the alveoli: the anatomic dead space. The dead space volume has important consequences for **alveolar ventilation** ($\dot{V}_A$). If the volume of gas a person breathes in with each breath (the tidal volume) is the same as the volume of the dead space, then the alveolar ventilation must be zero. In other words, all the inspired gas stays in the anatomic dead space. To have an effective alveolar ventilation (in terms of gas exchange), tidal volume must exceed dead space volume. It would seem, therefore, that the ideal breathing pattern to maximize alveolar ventilation is one in which an individual uses a slow, deep breathing pattern, when tidal volume is much greater than dead space volume. The effects of changes in tidal volume and respiratory frequency on minute and alveolar ventilation, at rest and during exercise, are shown in ■ Table 12-5.

At rest, ventilation is more effective with larger tidal volumes and lower respiratory frequencies. During exercise, and assuming dead space volume is fixed (in mL, it is approximately twice the person's weight in kg), the proportion of “wasted ventilation” ($\dot{V}_D/\dot{V}_E$) decreases, and the proportion of ventilation directed to the alveoli ($\dot{V}_A/\dot{V}_E$) increases, which makes breathing more efficient. This is because the primary way to increase ventilation is to increase the tidal volume. One cannot, however, increase tidal volume too much because that places the subject on the low compliance part of the pressure–volume curve (see ▶ Figure 12-9) and this disproportionately increases the work of breathing. As a result, after the initial increase in tidal volume, the person increases frequency as ventilatory demands continue to increase.

Work of breathing

During normal quiet breathing, the inspiratory muscles overcome two opposing forces: the elastic recoil of the lung (reflecting the elastic nature of tissues and, mainly, surface tension) and airway resistance. Moreover, expiration is passive; the energy needed to overcome flow resistance comes from the energy stored in the expanded lung (lung recoil). Normally, the lungs are highly compliant and airway resistance is low, so only about 3 percent of the total energy expended by the body is used for quiet breathing.

Note the situation in which a tidal volume (0.15 L) equal to the dead space volume (0.15 L) results in an alveolar ventilation of 0 L/min. Although even smaller tidal volumes would seem to be incompatible with gas exchange, this is not the case. It is possible—and even desirable in several clinical situations—to ventilate individuals, particularly infants, with tiny volumes but at very high frequencies (~600/min). These high frequencies enhance gas diffusion, and carbon dioxide is literally “shaken” out of the lungs. The advantage of this technique, called *high frequency oscillatory ventilation*, is that it does not produce the high pressures typically needed to inflate damaged lungs. It therefore avoids the possibility of barotrauma. Much of this work was done in the 1970s and 1980s at Toronto's Hospital for Sick Children.

■ TABLE 12-5 Effect of Changes in Tidal Volume and Frequency on Alveolar Ventilation

	V_T (L)	V_D (L)	f (bpm)	$\dot{V}_E$ (L/min)	$\dot{V}_A$ (L/min)	$\dot{V}_D/\dot{V}_E$	$\dot{V}_A/\dot{V}_E$

(For a description of the development of this technique, see “The Oscillations of HFO” by A.C. Bryan. [2001]. *American Journal of Respiratory and Critical Care Medicine*, 163: 816–17.)

An almost infinite combination of tidal volumes and respiratory frequencies can be involved in the work of breathing for a given type of alveolar ventilation (see ■ Table 12-5). However, we actually use only a limited range in the work of breathing. The combination of a low frequency and a high tidal volume is associated with a low resistive component but a high elastic component of the work of breathing (► Figure 12-25); in contrast, the combination of a high frequency and a low tidal volume is associated with a high resistive but a low elastic component of the work of breathing. In breathing, we use the particular combination of respiratory frequency and tidal volume that results in a minimal *total* of these two components. However, the range of frequencies over which we can breathe at rest and that results in the minimal work of breathing is wide: from 8 to 16 breaths per minute. At rest, we rarely use frequencies outside this range.

The work of breathing increases in four different situations:

1. When *pulmonary compliance is decreased*, such as with pulmonary fibrosis, more work is required to expand the lungs.
2. When *airway resistance is increased*, such as with COPD or asthma (especially during acute exacerbations), more work is required to achieve the greater pressures necessary to overcome increased flow resistance.
3. When *elastic recoil is decreased*, as with emphysema, passive expiration may be inadequate to expel the volume

► **FIGURE 12-25 Work of breathing.** For a given alveolar ventilation, an increase in respiratory frequency requires a concomitant decrease in tidal volume. Therefore, as respiratory frequency increases, the flow resistive component of the work of breathing increases, but the elastic work of breathing (reflecting the tidal volume) must decrease. The total work of breathing (dashed line) is the sum of the elastic and flow-resistive components. People breathe in a frequency range—a wide trough—that minimizes the work of breathing. Behavioural aspects of breathing easily override this factor, in part because the work of breathing at rest constitutes only a few percent of the total energy expenditure.

of air normally exhaled during quiet breathing. Thus, the expiratory muscles must work to aid in emptying the lungs, even at rest.

4. When there is a need for increased ventilation, such as during exercise, more work is required to generate larger tidal volumes and faster breathing.

Strenuous exercise can increase the energy cost of respiration twenty-five-fold, with the respiratory muscles accounting for 10–15 percent of total oxygen consumption, and even more in elite athletes. The oxygen consumption of the respiratory muscles during intense exercise may be so great that insufficient oxygen may be available to the exercising limb muscles. Rarely, however, in healthy individuals do the demands of the respiratory muscles for oxygen become so great that they compromise blood flow and, therefore, oxygen delivery to the exercising limb muscles (a phenomenon known as *steal*). But this situation can be exacerbated in hot and/or humid environments, when the body must direct some blood flow (cardiac output) to the skin to reduce core temperature. If there is competition by different muscle groups (respiratory, locomotive) for oxygenated blood, this will accelerate the onset of fatigue and either shorten exercise time or reduce exercise intensity.

In persons with poorly compliant lungs or chronic airflow limitation, the work of breathing—even at rest—may increase to 30 percent of the total energy expenditure. During moderate-intensity exercise, the respiratory muscles of patients with chronic airflow limitations may require 35–40 percent of the body’s oxygen consumption, severely limiting the ability of these individuals to exercise. Most recent work indicates that exercise training, including training of the respiratory muscles, can help such patients improve their quality of life. It is uncertain whether respiratory muscle training can, however, improve exercise performance in healthy individuals in whom exercise is limited by the ability of the cardiovascular system to deliver oxygen to working muscles.

Check Your Understanding 12.7

1. Explain the best way to increase alveolar ventilation during exercise. What limitations apply to your explanation?

12.3 Gas Exchange

The ultimate purpose of alveolar ventilation is to provide oxygen to the alveoli—where it is taken up by the blood—and to remove the carbon dioxide from that blood and excrete it to the atmosphere. Blood acts as a transport system for oxygen and carbon dioxide between the lungs and tissues, with the cells extracting oxygen from the blood and eliminating carbon dioxide into it.

Even those of us with normal lung function may have abnormal levels of oxygen and carbon dioxide in the blood. This can be explained by impaired diffusion of gases at the

alveolar–capillary membrane or poor matching of alveolar ventilation to perfusion. Again, an understanding of normal physiology provides insights into abnormal physiology, and vice versa.

Gas exchange involves diffusion of oxygen from the alveoli to the blood in the pulmonary capillaries and of carbon dioxide in the reverse direction. The factors determining diffusion are the *same* as those involved in convective flow: a pressure gradient (ΔP), and a resistance (R) related to the physical properties of the gas and the structures through which it diffuses. For diffusion, the pressure gradient is partial pressure, not hydraulic pressure.

Diffusion at the alveolar–capillary membrane

How much oxygen ($\dot{V}_{O_2}$) or carbon dioxide ($\dot{V}_{CO_2}$) diffuses across the alveolar–capillary membrane depends on two factors: (1) the partial pressure gradient of the gas across the membrane, and (2) the resistance to diffusion of the gas across the same membrane. For oxygen, the high end of the partial pressure gradient is set by its partial pressure in the alveoli ($P_{A_{O_2}}$), and the low end is set by its partial pressure in the pulmonary artery, which contains mixed blood ($P_{\dot{V}_{O_2}}$), because it comes from all systemic tissues. For carbon dioxide, the high end of the gradient is its partial pressure in the pulmonary arterial (mixed venous) blood ($P_{\dot{V}_{CO_2}}$), and its low end is its partial pressure in the alveoli ($P_{A_{CO_2}}$). The resistance to diffusion, in turn, depends on three factors: (1) the surface area (A) of the membrane across which diffusion occurs, (2) its thickness (T), and (3) the diffusibility (D) of the gas (reflecting its solubility and molecular weight). Because diffusibility is a constant, it can be ignored. The equations (see also Appendix H) are as follows:

$$\dot{V}_{O_2} = (P_{A_{O_2}} - P_{\dot{V}_{O_2}}) \cdot A/T$$

and

$$\dot{V}_{CO_2} = (P_{A_{CO_2}} - P_{\dot{V}_{CO_2}}) \cdot A/T$$

In summary, assuming the time available for diffusion is adequate, the *only* factors that can affect diffusion of either gas are *changes in their partial pressure gradients*, and the *surface area* and *diffusion distance* across which diffusion occurs. In the following sections, we explore how these factors affect diffusion.

Partial pressure gradients

Gas exchange at both pulmonary and tissue capillary levels involves simple passive diffusion of oxygen and carbon dioxide down **partial pressure gradients**. No active transport mechanisms exist (or are needed) for these gases. What determines these gradients?

PARTIAL PRESSURES

Atmospheric air is a mixture of gases; typical dry air contains about 79 percent nitrogen, 21 percent oxygen, and almost negligible percentages of carbon dioxide, water vapour, other gases, and pollutants. Together, these gases exert a total atmospheric pressure of 760 mmHg at sea level. This pressure is equal to the sum of the pressures contributed by each gas. Every gas molecule,

TABLE 12-6 Partial Pressures of Gases in Different Parts of the Respiratory System

	Dry Air	Inspired Gas	Alveolar Gas
P_{N_2} (mmHg)	600	563	573
P_{O_2} (mmHg)	160	150	100
P_{H_2O} (mmHg)	0	47	47
P_{CO_2} (mmHg)	0.23	0.23	40
Total (mmHg)	760	760	760

no matter its size, exerts the same pressure; for example, a molecule of nitrogen exerts the same pressure as a molecule of oxygen. The pressure exerted by a gas is directly proportional to the percentage of that gas in the mixture (**Dalton’s law**), and is therefore referred to as its **partial pressure**. Because 79 percent of the air consists of nitrogen, it is responsible for 79 percent of 760 mmHg, or 600 mmHg. Similarly, because oxygen constitutes 21 percent of the air, its partial pressure is 160 mmHg (Table 12-6). Thus, at sea level, the **partial pressure of oxygen** (P_{O_2}) in atmospheric air is normally 160 mmHg, and the **partial pressure of carbon dioxide** (P_{CO_2}) is a negligible 0.23 mmHg.

Gases dissolved in a liquid, such as blood or another bodily fluid, also exert a partial pressure. The greater its partial pressure, the more gas is dissolved. How much is dissolved also depends on the solubility of the gas in the liquid. Carbon dioxide is approximately 20 times as soluble as oxygen.

PARTIAL PRESSURE GRADIENTS

ALVEOLAR PARTIAL PRESSURES OF OXYGEN AND CARBON DIOXIDE

Alveolar air does not have the same composition as inspired air for two reasons. First, as soon as one inhales, air is saturated with water vapour (Table 12-6). Like any gas, water vapour exerts a partial pressure; at body temperature, 37°C, its partial pressure (P_{H_2O}) is 47 mmHg. Water vapour is an obligatory component of inspired gas. It dilutes the nitrogen and oxygen, thereby decreasing their partial pressures; the remaining pressure available for these gases is $760 - 47 = 713$ mmHg. This means the partial pressure of nitrogen in inspired gas ($P_{I_{N_2}}$) is 0.79×713 mmHg = 563 mmHg and that of oxygen ($P_{I_{O_2}}$) is 0.21×713 mmHg = 150 mmHg. Therefore, as a result of humidifying inspired air, P_{O_2} drops by 10 mmHg, from 160 to 150 mmHg.

The alveolar partial pressure of oxygen ($P_{A_{O_2}}$) is also lower than atmospheric P_{O_2} . This is because inspired air mixes with the large volume of unexpelled air remaining in the lungs, including the dead space, at the end of the preceding expiration (the functional residual capacity). At the end of an inspiration (at resting ventilation), less than 15 percent of the air in the alveoli is fresh

air. As a result, there is a further drop in P_{O_2} such that $P_{A_{O_2}}$ is 100 mmHg. This can be calculated using the **alveolar gas equation** (simplified here):

$$P_{A_{O_2}} = P_{I_{O_2}} - P_{A_{CO_2}}/R$$

where R is the **respiratory quotient**, that is, the ratio of metabolic carbon dioxide production to oxygen consumption ($\dot{V}_{CO_2}/\dot{V}_{O_2}$). At rest in a healthy individual with a typical Western diet, this ratio is 0.8. The effect of a ratio less than 1 is to magnify the effect of the carbon dioxide, which replaces some of the oxygen. Dividing a $P_{A_{CO_2}}$ of 40 mmHg by 0.8 gives 50 mmHg; subtracting this from the $P_{I_{O_2}}$ of 150 mmHg results in a $P_{A_{O_2}}$ of 100 mmHg (■ Table 12-6).

You might think that the P_{O_2} in the alveoli would increase during inspiration with the arrival of fresh air and then decrease during expiration. However, only small fluctuations occur, for two reasons. First, only a small proportion of the alveolar air is exchanged with each breath. The relatively small volume of inspired, high P_{O_2} air mixes quickly with the much larger volume of retained alveolar air, which has a lower P_{O_2} . Thus, the oxygen in the inspired air only slightly elevates the alveolar P_{O_2} . Second, even this potentially small elevation of P_{O_2} is diminished because of the continuous diffusion of oxygen down its partial pressure gradient from the alveoli into the blood. The oxygen arriving in the alveoli in the newly inspired air simply replaces that diffusing out of the alveoli into the pulmonary capillaries. Therefore, alveolar P_{O_2} remains relatively constant at about 100 mmHg throughout the respiratory cycle. This can be explained as follows: the arterial P_{O_2} —that is, the P_{O_2} in the blood leaving the lung—equilibrates with the alveolar P_{O_2} , so it remains fairly constant at this same value. Accordingly, the arterial P_{O_2} —that is, the P_{O_2} responsible for the diffusion of oxygen into the systemic tissues—varies only slightly during the respiratory cycle.

A similar situation exists in reverse for carbon dioxide. Produced by the tissues as a metabolic waste product, it is constantly added to the blood in the systemic capillaries. In the pulmonary capillaries, carbon dioxide diffuses down its partial pressure gradient from the blood into the alveoli and is subsequently excreted during expiration. Like the alveolar P_{O_2} , the alveolar P_{CO_2} remains fairly constant throughout the respiratory cycle but at a lower value of 40 mmHg.

Check Your Understanding 12.8

1. Describe the changes in the composition and partial pressures of nitrogen, oxygen, carbon dioxide, and water vapour as air moves from the atmosphere to the alveoli.

PARTIAL PRESSURE GRADIENTS OF OXYGEN AND CARBON DIOXIDE ACROSS THE PULMONARY CAPILLARIES

As blood passes through the lungs, it acquires oxygen and gives up carbon dioxide, due to diffusion down partial pressure gradients. Ventilation constantly replenishes alveolar oxygen and removes carbon dioxide, thereby maintaining the appropriate

partial pressure gradients. The blood entering the pulmonary capillaries via the pulmonary arteries is systemic venous blood; it therefore has a relatively low partial pressure of oxygen (the mixed venous P_{O_2} , $P_{\bar{V}_{O_2}}$) of 40 mmHg, and a relatively high mixed venous partial pressure of carbon dioxide ($P_{\bar{V}_{CO_2}}$) of 46 mmHg. As this blood flows through the pulmonary capillaries, it is exposed to alveolar air (► Figure 12-26). Because the alveolar P_{O_2} (100 mmHg) is greater than the mixed venous P_{O_2} (40 mmHg), oxygen diffuses down an initial 60 mmHg partial pressure gradient from the alveoli into the blood until no further gradient exists.

The partial pressure gradient for carbon dioxide is in the opposite direction. The mixed venous P_{CO_2} of 46 mmHg is 6 mmHg greater than the alveolar P_{CO_2} . Carbon dioxide therefore diffuses from the blood into the alveoli until blood P_{CO_2} equilibrates with alveolar P_{CO_2} at 40 mmHg.

After leaving the lungs, the arterialized blood has a P_{O_2} of 100 mmHg and a P_{CO_2} of 40 mmHg, and these are the values of the blood pumped to the systemic tissues by the left heart (► Figure 12-26).

Note that blood returning to the heart from the tissues still contains oxygen (mixed venous P_{O_2} = 40 mmHg), and blood leaving the lungs still contains carbon dioxide (arterial P_{CO_2} = 40 mmHg).

The mixed venous P_{O_2} of 40 mmHg can be expressed as mixed venous oxygen content, which is 150 mL O_2 /L of blood. Because arterial blood contains approximately 200 mL O_2 /L, this means that at rest only 50 of the 200 mL O_2 /L, or 25 percent, of the oxygen delivered to the tissues has been used. The remaining 150 mL O_2 /L represents an immediately available reserve that can be used by tissues whenever their oxygen demands increase. The carbon dioxide remaining in the arterial blood plays an important role in acid–base balance because it generates carbonic acid (see Chapter 14). Furthermore, arterial P_{CO_2} is important in stimulating respiration (discussed in Section 12.5).

The amount of oxygen taken up in the lungs matches the amount extracted and used by the tissues in steady-state conditions. (The two can differ, transiently, during sudden changes in metabolism, as occurs at the onset or cessation of exercise.) When tissues are more metabolically active, as in exercise, they extract more oxygen from the blood, reducing the mixed venous P_{O_2} to, for example, 30 mmHg. When this blood returns to the lungs, the gradient becomes 70 (100 – 30) mmHg, rather than the 60 mmHg at rest. By lowering the mixed venous P_{O_2} , the gradient for diffusion is increased. Note that while this increases the amount of oxygen transferred—because the mixed venous blood contains less oxygen—it does not increase arterial oxygen content much because the arterial oxygen content was already at or close to the maximum of 200 mL O_2 /L. (Arterial oxygen content can be increased if the concentration of haemoglobin in the blood is higher, typically by augmenting the production of red blood cells with erythropoietin; p. 438.) The larger diffusion gradient across the alveolar–capillary membrane helps ensure that diffusion is more rapid and that blood P_{O_2} equilibrates with alveolar P_{O_2} . This occurs despite there being less time available for diffusion, because blood flows more quickly through the pulmonary capillaries during exercise.

3

Across pulmonary capillaries

O₂ partial pressure gradient from alveoli to blood = 60 mmHg (100 → 40)

CO₂ partial pressure gradient from blood to alveoli = 6 mmHg (46 → 40)

Pulmonary artery
P_{VO₂} ~40 mmHg;
150 mL O₂/L blood

P_{VCO₂} ~46 mmHg;
520 mL CO₂/L blood

6

Across systemic capillaries

O₂ partial pressure gradient from blood to tissue cell = 60 mmHg (100 → 40)

CO₂ partial pressure gradient from tissue cell to blood = 6 mmHg (46 → 40)

Veins
P_{VO₂} and P_{VCO₂} vary with regional tissue metabolism

Note: blood contains only ~3 mL dissolved O₂/L at 37°C

1 The venous blood entering the lungs is low in O₂ (40 mmHg; this value decreases during exercise) and high in CO₂ (46 mmHg), due to consumption of O₂ and production of CO₂ by tissues.

2 Alveolar P_{O₂} remains high (100 mmHg) and alveolar P_{CO₂} low (40 mmHg) because only a portion of the alveolar air is replaced by fresh atmospheric air during each breath.

3 The partial pressure gradients for O₂ (100 – 40 = 60 mmHg) and CO₂ (46 – 40 = 6 mmHg) between the alveoli and pulmonary capillary blood cause O₂ to diffuse into the blood and CO₂ to diffuse into the alveoli. Diffusion continues until the blood and alveolar partial pressures become equal.

4 Blood leaving the lungs has, compared to the blood entering the lungs, a high partial pressure and content of O₂ and a low partial pressure and content of CO₂. These partial pressures and contents are identical to those delivered to the tissues.

5 The partial pressures of O₂ and CO₂ are, compared to those in arterial blood, lower and higher, respectively, in the O₂-consuming, CO₂-producing tissue cells.

6 O₂ diffuses from the arterial blood into cells to support their metabolic requirements, and metabolically produced CO₂ diffuses into the blood.

7 Having equilibrated with the tissue cells, the blood leaving the tissues is relatively low in O₂ and high in CO₂. The blood then returns to the lungs to once again replenish on O₂ and release off CO₂.

FIGURE 12-26 Oxygen and carbon dioxide exchange across pulmonary and systemic capillaries caused by partial pressure gradients

12

The other major factors influencing the high end of the gradient for diffusion of oxygen are the relative levels of ventilation ($\dot{V}$) and perfusion ($\dot{Q}$) to lung regions. (See the discussion of alveolar dead space, p. 529.) In regions with a high ratio of alveolar ventilation to perfusion (i.e., high $\dot{V}_A / \dot{Q}$), the alveolar P_{O₂} will be higher, increasing the gradient for diffusion; in regions with a low $\dot{V}_A / \dot{Q}$ ratio, the alveolar P_{O₂} will be lower, reducing the gradient.

In contrast to the 60 mmHg gradient favouring diffusion of oxygen, the gradient for the diffusion of carbon dioxide from mixed venous blood into the alveoli is only 6 mmHg (46 – 40). Carbon dioxide does not need as large a partial pressure gradient for diffusion as that for oxygen because it is approximately 20 times more soluble and, therefore, more diffusible than oxygen (see equation, p. 524). During exercise, as more carbon dioxide is released into the venous blood, its partial pressure in venous blood (the mixed venous P_{CO₂}) increases, and this

increases the gradient for its diffusion from the blood into the alveoli for excretion to the atmosphere.

Clinical Connections

Even though asthma primarily affects the bronchioles, it can also affect gas exchange at the alveoli. Normally ventilation and perfusion are matched so that adequate gas exchange can occur. However, in an obstructive disease such as asthma, inhaled air follows the path of least resistance, meaning that alveoli behind obstructed bronchioles will receive less ventilation. Consequently, there is a mismatch of ventilation and perfusion, such that the poorly ventilated areas of the lung prevent O₂ saturation of the blood returning to the systemic circulation. The result is hypoxia.

TABLE 12-7 Factors That Influence the Rate of Gas Transfer across the Alveolar–Capillary Membrane

Factor	Influence on Diffusion across the Alveolar–Capillary Membrane	Comments
Partial pressure gradients of oxygen and carbon dioxide	Diffusion ↑ as partial pressure gradient ↑	Major determinant of the rate of transfer
Surface area of the alveolar–capillary membrane	Diffusion ↑ as surface area ↑	Surface area is constant under resting conditions. Surface area ↑ during exercise as more pulmonary capillaries are recruited when cardiac output increases and the alveoli expand more as tidal volumes increase. Surface area ↓ in such pathological conditions as emphysema and lung collapse.
Thickness of the barrier separating the air and blood across the alveolar–capillary membrane	Diffusion ↓ as thickness ↑	Thickness (distance over which diffusion occurs) normally remains constant. Thickness ↑ in such pathological conditions as pulmonary oedema, pulmonary fibrosis, and pneumonia. But it ↓ in exercise as previously closed pulmonary capillaries are recruited (opened) by the increase in pulmonary arterial pressure.
Diffusion coefficient (solubility of the gas in the membrane)	Diffusion ↑ as diffusion coefficient ↑. For a given gas, however, the diffusion coefficient is constant.	Diffusion coefficient for carbon dioxide is 20 times that for oxygen, offsetting the smaller partial pressure gradient for carbon dioxide; therefore, approximately equal amounts of carbon dioxide and oxygen diffuse across the membrane.

Other factors

According to **Fick's law of diffusion**, the rate of diffusion of a gas also depends on the surface area and thickness of the membrane through which the gas is diffusing and on the diffusion coefficient of the particular gas (Table 12-7). In healthy individuals at rest, these other factors are relatively constant. But there are circumstances when they change, affecting the rate of gas transfer in the lungs.

EFFECT OF SURFACE AREA AND MEMBRANE THICKNESS ON GAS EXCHANGE

At rest, some pulmonary capillaries, especially those at the apex (top) of the lung, are closed because the low blood pressure in the pulmonary circulation cannot keep them open. During exercise, however, cardiac output increases and this increases pulmonary arterial pressure. This increased pressure opens (recruits) many of the previously closed pulmonary capillaries, thereby increasing the surface area (A) available for gas exchange. Moreover, recruiting previously closed pulmonary capillaries now means that a given molecule of oxygen may not have to diffuse as far to reach the blood, effectively reducing diffusion distance (T). In addition, alveolar membranes are stretched more during exercise because of the larger tidal volumes, thereby increasing the alveolar surface area and decreasing the thickness (T) of the membrane. Collectively, these changes improve gas exchange during exercise.

This recruitment of pulmonary capillaries to enhance gas exchange is very important during exercise. In the pulmonary capillaries, the equilibration of P_{O_2} and P_{CO_2} in the blood with those in the alveoli is dependent not only on the pressure gradients and the

surface area (p. 524) but also on the duration of exposure of the capillary blood to alveolar gas. This is called the **capillary transit time** (Figure 12-27). At rest, blood remains in the pulmonary capillaries for approximately 0.75 seconds; hence, the capillary transit time is 0.75 seconds. This is approximately triple the time needed for equilibration of P_{O_2} and much more than that needed for equilibration of P_{CO_2} . During maximal aerobic exercise, however, the capillary transit time is reduced to about 0.4 seconds. This is still enough time to allow equilibration of P_{O_2} and P_{CO_2} because the partial pressure gradients are maintained or even increased and because alveolar surface area increases. Indeed, equilibration of the two gases may occur in as little as 0.25 seconds—and elite endurance athletes may push this limit of pulmonary diffusion even further.

The capillary transit time is a major reason why exercise at altitude, especially very high altitude, is so difficult. The lower atmospheric pressure reduces the alveolar P_{O_2} , which is the high end of the gradient for diffusion. Although the low end of the gradient—the mixed venous P_{O_2} —also decreases due to a combination of exercise and altitude, this is not enough to compensate. During extreme exercise, the arterial P_{O_2} will not equilibrate with the alveolar P_{O_2} . At very high altitudes, such as near (8400 m) the peak of Everest (8848 m), the arterial P_{O_2} of four climbers averaged 25 mmHg, and arterial P_{CO_2} averaged 13 mmHg; arterial oxygen content was about 146 mL O_2 /L (Grocott et al. [2009]. *New England Journal of Medicine*, 360: 140–9). As we shall see, this arterial oxygen content is much higher than predicted by the oxygen dissociation curve (see Figure 12-32), and the reasons why are explored in Section 11.4.

► **FIGURE 12-27 Dynamics of diffusion of oxygen across the alveolar-capillary membrane.** At sea level (black line), diffusion of oxygen is complete (i.e., the blood in the pulmonary capillary attains a partial pressure of oxygen equivalent to that in the alveoli) within approximately 0.25 seconds, leaving a “safety margin” of about 0.5 seconds. If diffusion is impaired (dashed line), equilibration still occurs before the red blood cells reach the end of the capillary, but only at rest. If the time available for diffusion decreases, for example, due to an increase in cardiac output, the person with normal diffusion is unaffected (equilibration still occurs), but the person with diffusion impairment will experience a drop in arterial P_{O_2} (desaturation). At altitude (red line), the driving pressure for diffusion—the alveolar P_{O_2} —is reduced because of the fall in barometric pressure. This reduces the rate of oxygen diffusion, but in the healthy person equilibration is still complete (albeit at a lower alveolar P_{O_2}). In the patient with impaired diffusion, however, equilibration does not occur even at rest and is severely compromised during exercise.

Several pathological conditions can markedly reduce pulmonary surface area and, in turn, decrease diffusion. Most notably, in *emphysema*, surface area is reduced because many alveolar walls, with their capillaries, are lost, resulting in larger but fewer chambers (► Figure 12-28). Loss of surface area is

likewise associated with collapsed regions of the lung (**atelectasis**) and also results when part of the lung is surgically removed—for example, in treating lung cancer. Compared to carbon dioxide, oxygen has lower solubility and, therefore, diffusibility (see p. 529), so reductions in pulmonary surface area decrease the diffusion of oxygen more than that of carbon dioxide.

Inadequate gas exchange can also occur when the thickness of the barrier separating the air and blood is pathologically increased. This decreases the rate of gas transfer because a gas takes longer to diffuse. Thickness increases in (1) *pulmonary oedema*, when excess interstitial fluid accumulates between the alveoli and pulmonary capillaries due to pulmonary inflammation or left-sided congestive heart failure (p. 370); (2) *pulmonary fibrosis*, which involves replacement of delicate lung tissue with thick, fibrous tissue in response to certain chronic irritants; and (3) *pneumonia*, which is characterized by inflammation-induced accumulation of fluid within or around the alveoli. Most commonly, pneumonia is due to bacterial or viral infection of the lungs, but it may also arise from accidental *aspiration* (breathing in) of food, vomitus, or chemical agents.

In a diseased lung in which diffusion is impeded because of a reduction in surface area or a thickening of the alveolar-capillary membrane, oxygen transfer is usually more seriously impaired than transfer of carbon dioxide, because of oxygen’s lower diffusibility (reduced solubility). By the time the blood reaches the end of a pulmonary capillary, P_{CO_2} is more likely than P_{O_2} to have equilibrated with its counterpart in the alveolar compartment because carbon dioxide diffuses more rapidly. In less stressful conditions, diffusion of both gases may be adequate at rest, but during exercise, when pulmonary transit time is decreased, the P_{O_2} at the end of the pulmonary capillary may be less than the P_{O_2} in the alveolus, indicating failure of equilibration.

► **FIGURE 12-28 Comparison of normal and emphysematous lung tissue.** (a) Photomicrograph of lung tissue from a healthy individual. Each of the smallest clear spaces is an alveolar lumen. (b) Photomicrograph of lung tissue from a patient with emphysema. Note the loss of alveolar walls in the emphysematous lung tissue, resulting in larger but fewer alveoli. Alveolar capillaries are also lost.

EFFECT OF DIFFUSION COEFFICIENT ON GAS EXCHANGE

The rate of gas transfer is directly proportional to the diffusion coefficient (D), a constant directly related to the solubility of a particular gas in the lung tissues (mostly water) and inversely proportional to its molecular weight. The diffusion coefficient for carbon dioxide is 20 times that of oxygen because carbon dioxide is much more soluble in tissues. The rate of diffusion of carbon dioxide across the respiratory membranes is therefore approximately 20 times more rapid than that of oxygen per mmHg. The lower diffusion coefficient of oxygen is partially offset by its greater partial pressure gradient (alveolar – mixed venous = $100 - 40 = 60$ mmHg), compared to that for carbon dioxide (mixed venous – alveolar = $46 - 40 = 6$ mmHg).

1. List and explain the importance of the factors that determine the diffusion of oxygen and carbon dioxide across the alveolar–capillary membrane.

ALVEOLAR DEAD SPACE

Not all alveoli participate equally well in gas exchange. We have assumed that all the atmospheric air entering the alveoli participates in the exchange of oxygen and carbon dioxide with pulmonary blood. However, gas exchange can only occur when gas “meets” blood. Ideally, ventilation should match perfusion and vice versa. Because, however, not all alveoli are ventilated and perfused equally, gas exchange is less than perfect. At one extreme, some alveoli (or lung regions) are perfused but not ventilated; they are called **shunts**. At the other extreme, some lung regions are ventilated but not perfused; their alveoli cannot participate in gas exchange and are referred to as **alveolar dead space**. In healthy people, alveolar dead space is small and of little importance, but it can increase to lethal levels in several types of pulmonary disease. The combination of anatomic and alveolar dead space is referred to as the **physiological dead space**.

Let’s now examine why alveolar and, therefore, physiological dead space, are minimal in healthy individuals.

Regional control of ventilation and perfusion

In our discussion of the role of airway resistance during inspiration and expiration, we referred to the overall resistance of all the airways. However, the resistance of individual airways supplying a specific region can be adjusted independently in response to regional changes in P_{CO_2} . Similarly, the resistance of individual blood vessels supplying a region is influenced by the regional P_{O_2} . This situation is analogous to the control of systemic arterioles. Recall that overall systemic arteriolar resistance (i.e., total peripheral resistance) is an important determinant of the blood flow through the systemic circulatory system (p. 401). Yet the radii of individual arterioles supplying various tissues can be

adjusted locally to match the tissues’ differing metabolic needs (p. 398). In the lung, this regional control can be modelled using a simple analogy: a sink.

EFFECT OF OXYGEN

The oxygen delivered by ventilation to a lung region is analogous to the water flowing into a sink (▶ Figure 12-29). When you open the faucet (increasing ventilation), delivering more water (oxygen), the water level (the P_{O_2}) rises in the sink (lung region); when you close the faucet, the water level (and P_{O_2}) falls. How fast the oxygen (water) is removed (emptied) from the lung region depends on its perfusion; this is modelled by the degree of opening of the sink’s drain. Unlike a sink’s drain, however, the lung region has a built-in control to regulate the opening of the drain. If ventilation to the lung region is inadequate, the regional P_{O_2} falls. This low P_{O_2} (hypoxia) causes constriction of the vascular smooth muscle of the blood vessels (vasoconstriction) supplying that lung region. This is analogous to partially closing the sink’s drain. As a result, the regional P_{O_2} rises. And because all of the blood ejected from the right ventricle must go to the lungs, this means that the perfusion to the hypoxic lung region has been diverted to other, better ventilated (nonhypoxic) regions.

Does the reverse happen? In other words, does an increase in regional ventilation and the resulting increase in regional P_{O_2} cause vasodilation of the blood vessels supplying that region? The evidence for this effect is weaker. As already discussed, the alveolar P_{O_2} in a normal person at sea level is approximately 100 mmHg. The only way to exceed this value is to increase

▶ **FIGURE 12-29 Regional alveolar gas pressures: Oxygen and hypoxic vasoconstriction.** The level of water in a sink is determined by how fast water is delivered to the sink through the faucet and how fast it is taken away through the drain. Similarly, the level (partial pressure) of oxygen in a given lung region—the regional alveolar P_{O_2} —is determined by how much oxygen is delivered by the ventilation to that region and how much oxygen is taken up by the blood flowing to that region. Unlike a sink, the lung region can regulate its perfusion. If regional alveolar P_{O_2} falls, the resulting hypoxia causes vasoconstriction to that region, thereby diverting blood to other, presumably better ventilated (nonhypoxic), regions.

ventilation disproportionate to metabolic demands (i.e., hyperventilation) and thereby decrease alveolar (and arterial) P_{CO_2} . According to the alveolar gas equation (p. 525), this will increase the alveolar P_{O_2} . This effect, however, is modest, perhaps 20 mmHg at the most. The other way to increase alveolar P_{O_2} is artificial: inhalation of supplemental oxygen. This, however, is not a circumstance that would drive the evolution of a mechanism to cause vasodilation in response to high alveolar P_{O_2} . Consequently, the response to higher levels of regional alveolar P_{O_2} should really be considered a reduction of any prevailing vasoconstriction rather than an actual vasodilation.

EFFECT OF CARBON DIOXIDE

The carbon dioxide delivered by perfusion (output of the right ventricle) to a lung region is also analogous to the water flowing into a sink (► Figure 12-30); how fast carbon dioxide (water) is removed depends on the ventilation (degree of opening of the drain). When you open the faucet—thereby increasing perfusion and therefore delivery of carbon dioxide, which reflects metabolic production of carbon dioxide $\dot{V}_{\text{CO}_2}$ —the water level (P_{CO_2}) rises in the sink (lung region); when you close the faucet, the water level P_{ACO_2} falls. This same sink (lung region) has a built-in control to regulate the opening of the drain. If perfusion to the lung region is low, the regional P_{CO_2} falls. This low P_{CO_2} (hypocapnia) constricts the smooth muscle of the airways (bronchoconstriction) supplying that lung region. As a result, ventilation of that region decreases, returning P_{CO_2} toward its control level. Because all the ventilation goes to the lungs, any ventilation of

an underperfused region is diverted to other better perfused regions. Conversely, an increase in perfusion to a region increases regional P_{CO_2} ; this causes dilation of the regional airways, leading to increased regional ventilation and, as a result, a return of P_{CO_2} back toward control levels.

The two mechanisms for matching airflow and blood flow function simultaneously, so normally very little air or blood is wasted in the lung (► Figure 12-31). In this way, local control mechanisms operate to match ventilation and perfusion in a particular region so as to optimize overall gas exchange.

Check Your Understanding 12.10

1. Explain how changes in the partial pressures of oxygen and carbon dioxide in the lung operate to optimize the matching of regional alveolar ventilation to regional alveolar perfusion.

GAS EXCHANGE ACROSS THE SYSTEMIC CAPILLARIES

Just as they do at the pulmonary capillaries, oxygen and carbon dioxide move between the systemic capillary blood and the tissue cells by simple diffusion down partial pressure gradients (see ► Figure 12-26). The arterial blood that reaches the systemic capillaries is essentially the same blood that left the lungs in the pulmonary veins, because the only two places in the entire circulatory system at which gas exchange can take place are the pulmonary capillaries and the systemic capillaries. The arterial P_{O_2} is 100 mmHg, and the arterial P_{CO_2} is 40 mmHg, the same as the alveolar P_{O_2} and P_{CO_2} .

P_{O_2} AND P_{CO_2} GRADIENTS ACROSS THE SYSTEMIC CAPILLARIES

Cells constantly consume oxygen and produce carbon dioxide through oxidative metabolism. Cellular P_{O_2} averages about 40 mmHg, and P_{CO_2} about 46 mmHg; these values are highly variable depending on the tissue and the level of cellular metabolic activity. Oxygen moves by diffusion down its partial pressure gradient from the entering systemic capillary blood ($P_{\text{O}_2} = 100$ mmHg) into the adjacent cells until equilibrium is reached. Therefore, the P_{O_2} of venous blood leaving the systemic capillaries is equal to the tissue P_{O_2} , an average of 40 mmHg.

The reverse situation exists for carbon dioxide. Carbon dioxide rapidly diffuses out of the cells ($P_{\text{CO}_2} = 46$ mmHg) into the entering capillary blood ($P_{\text{CO}_2} = 40$ mmHg) and down the partial pressure gradient created by its ongoing production. Transfer of carbon dioxide continues until blood P_{CO_2} equilibrates with tissue P_{CO_2} . Accordingly, blood leaving the systemic capillaries, pumped by the right ventricle into the pulmonary capillaries, has an average of 46 mmHg.

Actually, the partial pressures of the systemic blood gases never completely equilibrate with tissue P_{O_2} and P_{CO_2} . Because the cells are constantly consuming oxygen and producing carbon dioxide, tissue P_{O_2} is always slightly less than the P_{O_2} of the blood leaving the systemic capillaries, and the tissue P_{CO_2} is always slightly exceeds the systemic venous P_{CO_2} .

► **FIGURE 12-30 Regional alveolar gas pressures: Carbon dioxide and bronchoconstriction/bronchodilation.** The regional alveolar P_{CO_2} is determined by how much carbon dioxide is delivered by the perfusion to that region and how much carbon dioxide is excreted via its ventilation. If regional alveolar P_{CO_2} falls, the resulting hypocapnia causes bronchoconstriction to that region, thereby diverting ventilation to other lung regions with higher alveolar P_{CO_2} . Conversely, if regional alveolar P_{CO_2} rises, the resulting hypercapnia causes bronchodilation in that region, thereby reducing flow resistance and increasing regional ventilation to eliminate more carbon dioxide.

FIGURE 12-31 Two-compartment model of the lung. Top panel shows a perfect lung receiving 4 L/min of air and 4 L/min of blood, 2 L/min of air and blood to each of the two lung regions, A and B. The left middle panel shows a reduction of ventilation ($\dot{V}$) to 1 L/min to region A; at constant total ventilation, ventilation to region B increases to 3 L/min. Thus, region A is underventilated and region B is overventilated. As a result (bottom left), there is regional vasoconstriction, reducing perfusion to region A. Because cardiac output does not change, this means that perfusion is diverted to the better ventilated region B. The right middle panel illustrates a reduction in perfusion to region A to 1 L/min; at constant cardiac output, perfusion to region B increases to 3 L/min. Thus, region A is underperfused, and region B is overperfused. As a result (bottom right), there is hypercapnia-induced bronchodilation of region B, thereby increasing ventilation to the better perfused region. Not shown here are hypocapnia-induced bronchoconstriction of region A on the left and region B on the right. In all cases, local controls help match ventilation ($\dot{V}_A$) to perfusion ($\dot{Q}$), and vice versa, thereby preventing extremes of $\dot{V}_A / \dot{Q}$.

As a tissue's metabolism increases, its P_{O_2} falls and its P_{CO_2} rises. Because this increases the partial pressure gradients for diffusion, more oxygen diffuses from the blood into the tissue and more carbon dioxide diffuses out of the tissue before blood P_{O_2} and P_{CO_2} equilibrate with those in the tissue. Therefore, the amount of oxygen transferred to the cells and the amount of carbon dioxide carried away from the cells both depend on the rate of cellular metabolism.

NET DIFFUSION OF OXYGEN AND CARBON DIOXIDE BETWEEN THE ALVEOLI AND TISSUES

Net diffusion of oxygen occurs first between the alveoli and blood and then between the blood and tissues, because of the partial pressure gradients of oxygen created by its continuous replenishment by alveolar ventilation and its continuous uptake by cells. Net diffusion of carbon dioxide occurs in the reverse direction, first between the tissues and blood and then between the blood and alveoli, because of the partial pressure gradients of carbon dioxide created by its continuous production in the cells and its continuous removal from the lung by alveolar ventilation (see ▶ Figure 12-26).

We now examine how oxygen and carbon dioxide are transported in the blood between the alveoli and tissues.

12.4 Gas Transport

Oxygen acquired by the blood in the lungs must be transported to the tissues. Conversely, carbon dioxide produced by cells must be transported to the lungs for elimination.

Blood, oxygen, and haemoglobin

Oxygen is present in the blood in two forms: one physically dissolved and the other chemically bound to haemoglobin (see ■ Table 12-8).

PHYSICALLY DISSOLVED OXYGEN

Very little oxygen dissolves in plasma water because oxygen is poorly soluble. At a normal arterial P_{O_2} of 100 mmHg, only

TABLE 12-8 Methods of Gas Transport in the Blood

Gas	Method of Transport in Blood	Percentage Carried in This Form
Oxygen	Physically dissolved	1.5
	Bound to haemoglobin	98.5
Carbon Dioxide	Physically dissolved	5–10
	Bound to haemoglobin	5–10
	As bicarbonate (HCO ₃ ⁻)	80–90

3 mL of oxygen can dissolve in 1 L of blood. At a resting cardiac output of 5 L/min, only 15 mL of O₂/min can dissolve. Under resting conditions, however, the body consumes 250 mL O₂/min. If oxygen were carried only in dissolved form, the cardiac output needed to sustain resting metabolic activity would therefore have to be 83.3 L/min (250 mL O₂/min divided by 3 mL O₂/L blood), and this assumes that all the oxygen would be extracted from the blood. It should be obvious that the cardiovascular system cannot accommodate a twenty-five-fold increase in consumption during strenuous exercise. To do so requires an additional mechanism for transporting oxygen to the tissues: haemoglobin (Hb). Haemoglobin transports 98.5 percent of the oxygen carried by the blood. Because *the oxygen bound to haemoglobin does not contribute to the P_{O₂} of the blood*, the P_{O₂} of the blood provides no information about its oxygen content. This is critical in understanding the difference between saturation and content.

OXYGEN BOUND TO HAEMOGLOBIN

Haemoglobin, an iron-bearing protein molecule contained within the red blood cells, can form an easily reversible combination with oxygen (p. 436). When not combined with oxygen, haemoglobin is referred to as **reduced haemoglobin (deoxyhaemoglobin)**; when combined with oxygen, it is called **oxyhaemoglobin (HbO₂)**:

We need to answer several questions about the role of haemoglobin in oxygen transport. What determines whether oxygen and haemoglobin are combined or dissociated (separated)? Why does haemoglobin combine with oxygen in the lungs and release it at the tissues? How can a variable amount of oxygen be released at the tissues, depending on the level of tissue activity? How can we talk about oxygen transfer between blood and surrounding tissues in terms of the partial pressure gradients of oxygen when 98.5 percent of the oxygen is bound to haemoglobin and thus does not contribute to the P_{O₂} of the blood?

P_{O₂} and haemoglobin saturation

Each of the four atoms of iron within the heme portions of a haemoglobin molecule can combine with an oxygen molecule, so each haemoglobin molecule can carry up to four oxygen molecules. As a result, the actual reactions are as follows:

These sequential reactions account for the sigmoid shape of the oxygen dissociation curve (▶ Figure 12-32).

Haemoglobin is considered fully saturated when all the haemoglobin present is carrying its maximum oxygen load. The **percent haemoglobin (% Hb) saturation**, a measure of the extent to which the available haemoglobin is combined with oxygen, can vary from 0 to 100 percent.

The most important factor determining the % Hb saturation is the P_{O₂} of the blood, which is determined by how much oxygen is physically dissolved. According to the **law of mass action**, if the concentration of one substance involved in a reversible reaction is increased, the reaction is driven toward the opposite side. Conversely, if the concentration of one substance is decreased, the reaction is driven toward the side of that concentration. Applying this law to the reversible reaction involving haemoglobin and oxygen (Hb + O₂ ⇌ HbO₂), when blood P_{O₂} increases, as in the pulmonary capillaries, the reaction is driven toward the right, increasing the formation of HbO₂ (increased % Hb saturation). When blood P_{O₂} decreases, as in the systemic capillaries, the reaction is driven toward the left, and oxygen is released from haemoglobin as HbO₂ dissociates (decreased % Hb saturation). Thus, because of the difference in P_{O₂} at the lungs and other tissues, haemoglobin acquires oxygen in the lungs, where ventilation is continually providing fresh supplies of oxygen, and releases it to the tissues, which are constantly consuming oxygen.

OXYGEN-HAEMOGLOBIN DISSOCIATION CURVE

The relationship between blood P_{O₂} and % Hb saturation is not linear, a feature of great physiological importance. Doubling the P_{O₂} does not double the % Hb saturation. Rather, the relationship between these variables follows a sigmoid-shaped curve, the **O₂-Hb dissociation (or saturation) curve** (▶ Figure 12-32). Over the P_{O₂} range of 0 to 60 mmHg, a small change in P_{O₂} causes a large change in the % Hb saturation, as shown by the steep lower part of the curve. In contrast, at the upper end, between a blood P_{O₂} of 60 and 100 mmHg, the curve flattens to a plateau. Over this 40 mmHg range, a rise in P_{O₂} produces only a small increase in the % Hb saturation. Both portions of the curve, the lower steep part and the upper plateau, are physiologically significant.

SIGNIFICANCE OF THE PLATEAU PORTION OF THE O₂-HB CURVE

The plateau is present over the blood P_{O₂} range that exists in the pulmonary capillaries where haemoglobin acquires oxygen. The systemic arterial blood leaving the lungs, having equilibrated

► **FIGURE 12-32 Oxygen-haemoglobin (O₂-Hb) dissociation (saturation) curve.** Relation between (a) % Hb saturation and (b) oxygen content (or concentration) versus P_{O_2} . The relationship between these two variables is depicted by a sigmoid-shaped curve with a steep portion between 0 and 60 mmHg and a plateau above a P_{O_2} of 60 mmHg. A reduction by half of the number of red blood cells or the concentration of haemoglobin in the red blood cells (anaemia) does not affect the position of the curve (blue line) when the y-axis is (a) % Hb saturation because only the percent, not the absolute number, of binding sites occupied by oxygen is measured. When the y-axis is (b) content (or concentration), however, the anaemia curve is reduced by half.

with alveolar P_{O_2} , normally has a P_{O_2} of 100 mmHg. According to the O₂-Hb dissociation curve, the haemoglobin of blood at a P_{O_2} of 100 mmHg is 97.5 percent saturated. Therefore, haemoglobin in the systemic arterial blood is normally almost completely saturated.

If the alveolar P_{O_2} and, consequently, the arterial P_{O_2} fall below normal, the plateau ensures that the Hb saturation does not decrease greatly until the P_{O_2} falls below 60 mmHg, at which point haemoglobin is still about 90 percent saturated. Conversely, if the blood P_{O_2} is greatly increased above 100 mmHg—say, to 600 mmHg by breathing pure oxygen—the oxygen content of the blood increases very little because it was already almost completely saturated. What little increase in content does occur is due to the extra oxygen dissolved in blood. Therefore, in the P_{O_2} range between 60 and 600 mmHg or even higher, there is only a 10 percent difference in the amount of oxygen carried by haemoglobin. In this way, the plateau portion of the O₂-Hb curve provides a good margin of safety in the oxygen-carrying capacity of the blood.

Arterial P_{O_2} may be reduced by pulmonary diseases accompanied by inadequate ventilation or defective gas exchange, or by circulatory disorders that result in inadequate blood flow to the lungs. It may also fall in healthy people under two circumstances: (1) at high altitudes, where the P_{O_2} of the inspired air is reduced because of the lower atmospheric pressure; or (2) in oxygen-deprived environments at sea level, such as if someone were accidentally locked in an air-tight vault. Unless the arterial P_{O_2} becomes markedly reduced (falls below 60 mmHg) in either pathological conditions or abnormal

circumstances, near-normal amounts of oxygen can still be carried to the tissues.

SIGNIFICANCE OF THE STEEP PORTION OF THE O₂-HB CURVE

The steep portion of the curve between 0 and 60 mmHg occurs in the blood P_{O_2} range that exists at the systemic capillaries, where oxygen is unloaded from haemoglobin. In the systemic capillaries, the blood equilibrates with the surrounding tissue cells at an average (but highly variable) P_{O_2} of 40 mmHg. Note in ► Figure 12-32 that at a P_{O_2} of 40 mmHg, the % Hb saturation is 75 percent. The blood arrives in the tissue capillaries at a P_{O_2} of 100 mmHg and with 97.5 percent Hb saturation. Because haemoglobin is 75 percent saturated at a P_{O_2} of 40 mmHg in the systemic capillaries, nearly 25 percent of the HbO₂ must dissociate, yielding reduced haemoglobin and oxygen. This released oxygen is free to diffuse down its partial pressure gradient from the red blood cells through the plasma and interstitial fluid into the tissue.

The normal 60 mmHg drop in P_{O_2} from 100 to 40 mmHg in the systemic capillaries causes unloading of about 25 percent of the oxygen combined with haemoglobin, sufficient to sustain resting metabolism. But an additional drop in P_{O_2} of only 20 mmHg from 40 mmHg unloads an additional 45 percent of the total oxygen because this change in partial pressure occurs over the steep portion of the curve. In this range, only small decreases in systemic capillary P_{O_2} are required to unload considerable oxygen to meet increased metabolic demands. During strenuous exercise, for example, as much as 85 percent of the

oxygen may be released to muscle. Even more oxygen can be made available to actively metabolizing cells, such as exercising muscles, by circulatory and respiratory adjustments that increase perfusion to active tissues.

The steep part of the oxygen dissociation curve has another important consequence. At high altitude, the low barometric pressure reduces the inspired P_{O_2} . At sufficiently high altitudes, this results in arterial hypoxaemia that activates the carotid chemoreceptors; their activation increases ventilation. This means that if metabolism does not change (i.e., the person is still at rest), more carbon dioxide is expired, causing a fall in the arterial P_{CO_2} and, as a result, an increase in the alveolar and therefore arterial P_{O_2} (alveolar gas equation; p. 525). Although this increase may be only a few mmHg on the steep part of the curve, this small increase can cause a significant increase in arterial oxygen content.

The function of the steep portion of the oxygen dissociation curve may, on the basis of the previous paragraph, appear obvious—that is, augment unloading of oxygen to metabolically active tissues or augment arterial oxygen content as a result of altitude-induced hyperventilation. However, recall that oxygen diffuses to tissues down a partial pressure gradient. Over the steep part of the curve, the high end of the gradient decreases, and this would reduce the gradient that favours diffusion. Why would evolution conserve an oxygen dissociation curve that reduces the driving pressure for diffusion into cells over such a critical range? The answer is that the oxygen dissociation curve, as depicted, applies to conditions in the lung, where the P_{O_2} determines the saturation or content of the arterial blood. In tissues, however, oxygen is consumed, and this means the oxygen content determines the local arterial P_{O_2} . When oxygen content becomes the independent variable and P_{O_2} the dependent variable, a different interpretation is apparent (► Figure 12-33): as oxygen is consumed and the saturation drops, the systemic P_{O_2} does not fall as much (reduced slope). In other words, the shape of the curve preserves the P_{O_2} , thereby maintaining the partial pressure gradient for diffusion.

Haemoglobin and oxygen transfer

There is more to say about the role of haemoglobin in gas exchange. In our discussion of oxygen being driven from the alveoli to the blood by a P_{O_2} gradient, we ignored the oxygen bound to haemoglobin because blood P_{O_2} depends entirely on the *dissolved* oxygen. However, haemoglobin plays a crucial role in permitting the transfer of large quantities of oxygen to the tissues before blood P_{O_2} equilibrates with the surrounding tissues (► Figure 12-34).

ROLE OF HAEMOGLOBIN AT THE ALVEOLAR LEVEL

Haemoglobin acts as a storage depot for oxygen, removing it from solution as soon as it enters the blood from the alveoli. Because only dissolved oxygen contributes to the P_{O_2} , the oxygen stored in haemoglobin cannot contribute to blood P_{O_2} . When systemic venous blood enters the pulmonary capillaries, its P_{O_2} is considerably lower than alveolar P_{O_2} , so oxygen immediately diffuses into the blood, raising blood P_{O_2} . As soon as

► **FIGURE 12-33** Another approach to the oxygen dissociation curve. Here, the axes have been reversed from those shown in Figure 12-32. In tissues, oxygen is consumed, and, therefore, saturation becomes the independent variable. So when the oxygen dissociation curve is plotted with percentage saturation on the x-axis and P_{O_2} on the y-axis, a fall in saturation (i.e., uptake of oxygen by the tissues) does not cause as large a drop in P_{O_2} , thereby preserving the partial pressure responsible for diffusion of oxygen into the cells.

the blood P_{O_2} increases, the percentage of haemoglobin that can bind with oxygen likewise increases, as indicated by the oxygen dissociation curve. Consequently, most of the oxygen that has diffused into the blood combines with haemoglobin and no longer contributes to blood P_{O_2} . As oxygen is removed from solution by combining with haemoglobin, blood P_{O_2} falls to about the same level it was when the blood entered the lungs, even though the oxygen content of the blood has increased. Because blood P_{O_2} is still less than alveolar P_{O_2} , oxygen continues to diffuse from the alveoli into the blood, only to bind to more haemoglobin.

Even though we described this process as a series of steps, the net diffusion of oxygen from alveoli to blood occurs continuously until haemoglobin becomes as completely saturated with oxygen as it can be at that particular P_{O_2} . At a normal P_{O_2} of 100 mmHg, haemoglobin is 97.5 percent saturated. Thus, by binding oxygen, haemoglobin keeps blood P_{O_2} low, preserving the partial pressure gradient so that oxygen continues to diffuse from the alveolar gas into the blood. Not until haemoglobin is maximally saturated for that P_{O_2} does all the oxygen transferred into the blood remain dissolved and directly contribute to the P_{O_2} . Only now does blood P_{O_2} rapidly equilibrate with alveolar P_{O_2} and bring further oxygen transfer to a halt—but this point is not reached until haemoglobin is already loaded with oxygen to the maximum extent possible. Once blood P_{O_2} equilibrates with alveolar P_{O_2} , no further transfer of oxygen occurs, no matter how little or how much total oxygen has already been transferred.

FIGURE 12-34 Haemoglobin facilitates transfer of oxygen by acting as a storage depot to keep P_{O_2} low. (a) In the hypothetical situation in which no haemoglobin is present in the blood, the alveolar P_{O_2} and the pulmonary capillary blood P_{O_2} are at equilibrium. (b) Haemoglobin has been added to the pulmonary capillary blood. As the Hb starts to bind with oxygen, it removes oxygen from solution. Because only dissolved oxygen contributes to blood P_{O_2} , the blood P_{O_2} remains below that of the alveoli, even though the same number of oxygen molecules are present in the blood as in (a). By binding some of the dissolved oxygen, Hb favours the net diffusion of more oxygen down its partial pressure gradient from the alveoli to the blood. (c) Haemoglobin is fully saturated with oxygen, and the alveolar and blood P_{O_2} are at equilibrium again. The blood P_{O_2} resulting from dissolved oxygen is equal to the alveolar P_{O_2} , despite the fact that the total oxygen content in the blood is much greater than in (a), in which blood P_{O_2} was equal to alveolar P_{O_2} in the absence of Hb.

ROLE OF HAEMOGLOBIN AT THE TISSUE LEVEL

The reverse situation occurs at the tissue level. Because the P_{O_2} of blood entering the systemic capillaries is considerably higher than the P_{O_2} of the surrounding tissue, oxygen immediately diffuses from the blood into the tissues, lowering blood P_{O_2} . When blood P_{O_2} falls, haemoglobin must unload some stored oxygen. As the oxygen released from haemoglobin dissolves in the blood, blood P_{O_2} increases and once again exceeds the P_{O_2} of the surrounding tissues. This favours further movement of oxygen out of the blood, although the arterial oxygen content has already fallen. Only when haemoglobin can no longer release any more oxygen into solution (when Hb is unloaded to the greatest extent possible for the P_{O_2} existing at the systemic capillaries) can blood P_{O_2} fall as low as that in surrounding tissue. At this time, further transfer of oxygen stops. Haemoglobin, because it stores a large quantity of oxygen that can be freed by a slight reduction in P_{O_2} at the systemic capillary level, permits the transfer of much more oxygen from the blood into the cells than would be possible in its absence.

Haemoglobin is crucial for oxygen transport. Because oxygen bound to haemoglobin does not contribute to the blood P_{O_2} , it keeps the blood P_{CO_2} low and thereby maintains the partial pressure gradient needed to ensure transfer of oxygen from alveolar gas to blood until haemoglobin is saturated and the P_{O_2} in the blood equilibrates with the P_{O_2} in the alveoli. This ensures that enough oxygen (its concentration, or content, as distinct from its partial pressure) is transported to the tissues to meet resting and increased metabolic demands. If haemoglobin levels fall to half of normal, as in a severely anaemic patient (p. 441), the oxygen-carrying capacity of the blood falls by 50 percent, even

though the arterial P_{O_2} is still the normal 100 mmHg, and the Hb is 97.5 percent saturated. An oximeter (a device that measures oxygen saturation) reading of 97.5 percent tells you only what percentage of the binding sites on haemoglobin are occupied by oxygen; it does *not* indicate how many binding sites are available (i.e., the concentration of Hb in the blood) or the arterial oxygen content. Similarly, if the P_{O_2} of a blood sample is 100 mmHg, this reveals nothing about the concentration (or content) of oxygen in the blood; a P_{O_2} of 100 mmHg is just as compatible with a concentration of 200 mL O_2 /L blood (the maximum) as it is with 3 mL O_2 /L blood (the minimum). In summary, an oximeter cannot detect anaemia.

Unloading of oxygen

Even though the main factor determining % Hb saturation is the P_{O_2} of the blood, other factors affect the affinity, or bond strength, between haemoglobin and oxygen. Accordingly, they shift the oxygen dissociation curve (i.e., change the % Hb saturation at a given P_{O_2}).

Both disease and exercise influence the oxygen dissociation curve. The by-products associated with energy turnover during exercise are heat, carbon dioxide, and lactic acid. All three enhance the release of oxygen from haemoglobin; that is, at a given P_{O_2} , haemoglobin holds less oxygen. Another factor that affects the dissociation of oxygen from haemoglobin is the pH. One of the forms in which carbon dioxide is transported in the plasma is as a bicarbonate ion (HCO_3^-), while it goes through the carbonic anhydrase–carbonic acid cycle. As bicarbonate is produced, a hydrogen ion (H^+) is released as a by-product.

Additionally, in muscle, lactic acid is produced because some of the energy turnover is anaerobic. This increased production of lactic acid is associated with the release of H^+ . The intensity of exercise dictates the amount of lactic acid produced. Thus, higher-intensity work increases the amount of lactic acid produced (and associated H^+). As the concentration of H^+ increases, the pH decreases (increased acidity); this, in turn, enhances the dissociation of oxygen from haemoglobin, a phenomenon known as the **Bohr effect**.

BOHR EFFECT

Both carbon dioxide (Haldane effect, p. 536) and the H^+ component of acids can combine reversibly with haemoglobin at sites other than those binding oxygen. The result is a change in the molecular shape (conformation) of haemoglobin that reduces its affinity for oxygen. Note that the % Hb saturation refers only to the extent to which haemoglobin is combined with oxygen, not the extent to which it is bound with carbon dioxide, H^+ , or other molecules. Indeed, the % Hb saturation decreases when carbon dioxide and H^+ bind with haemoglobin, because their presence on haemoglobin facilitates release of oxygen.

In cells, oxygen is used for energy production, and carbon dioxide and lactic acid are produced as by-products. The H^+ that accumulates because of increases in lactic acid (generated during anaerobic metabolism), and HCO_3^- production lowers the blood pH and enhances the dissociation of oxygen. This is particularly important for metabolically active cells, such as muscle during exercise.

Haemoglobin binds with most of the H^+ that accumulates within the erythrocytes when carbonic acid dissociates into H^+ and HCO_3^- . As with carbon dioxide, reduced haemoglobin has a greater affinity for H^+ than oxygenated haemoglobin. Therefore, oxygen unloading facilitates the pickup by haemoglobin of carbon dioxide-generated H^+ . Because only free, dissolved H^+ contributes to the acidity of a solution, the venous blood would be considerably more acidic than the arterial blood if haemoglobin did not bind most of the H^+ generated at the tissue level. Haemoglobin is therefore an important buffer.

The Bohr effect acts in reverse at the alveoli. The carbonic anhydrase-carbonic acid reaction reverses in the pulmonary capillaries. This reversal in turn decreases the amount of carbonic acid (H_2CO_3), bicarbonate HCO_3^- , and hydrogen ion (H^+), thereby increasing pH and decreasing the dissociation of oxygen, which facilitates its loading onto haemoglobin. Thus, the Bohr effect, as represented by the sigmoidal shape of the oxygen dissociation curve (▶ Figure 12-35), does not influence the combination of oxygen with haemoglobin in the lung during exercise. However, at the tissue level, the Bohr effect acts in an opposite

▶ **FIGURE 12-35** Effect of P_{CO_2} , increased, H^+ , temperature, and 2,3-bisphosphoglycerate on the oxygen dissociation curve. Increased P_{CO_2} , acid, temperature, and 2,3-bisphosphoglycerate, as occurs in red blood cells, shift the curve to the right. Because less oxygen can bind to haemoglobin at a given P_{O_2} , more oxygen is unloaded from haemoglobin for use by the tissues.

fashion. In skeletal muscle during exercise, the ability of haemoglobin to bind oxygen is reduced by about 10–15 percent; as a result, more oxygen is available to the tissue, facilitating aerobic metabolism.

Other factors that influence the binding of oxygen to haemoglobin are carbon dioxide, acidity, temperature, and 2,3-bisphosphoglycerate; they will be examined separately. The oxygen dissociation curve you are already familiar with (see ▶ Figure 12-32) is a typical sigmoid-shaped curve at normal arterial P_{CO_2} and acidity levels, normal body temperature, and normal 2,3-bisphosphoglycerate concentration.

HALDANE EFFECT

An increase in P_{CO_2} shifts the oxygen dissociation curve to the right (▶ Figure 12-35) and vice versa. The % Hb saturation still depends on the P_{O_2} , but for any given P_{O_2} , less oxygen binds to haemoglobin as the P_{CO_2} increases, and more oxygen binds to haemoglobin as the P_{CO_2} decreases. This effect is important, because the P_{CO_2} of the blood increases in the systemic capillaries as carbon dioxide diffuses down its gradient from the cells into the blood. The presence of this additional carbon dioxide in the blood in effect decreases the affinity of haemoglobin for oxygen, so haemoglobin unloads even more oxygen at the tissue level than it would if the reduction in P_{O_2} in the systemic capillaries were the only factor affecting % Hb saturation. Note, too, that this effect of carbon dioxide is lost at high P_{O_2} (as when supplemental oxygen is provided), but this beneficial effect is not needed since arterial oxygen content is high.

EFFECT OF TEMPERATURE ON % HB SATURATION

In a similar manner, a rise in temperature shifts the oxygen dissociation curve to the right, resulting in more unloading of

oxygen at a given P_{O_2} . An exercising muscle or other actively metabolizing tissue produces heat. The local rise in temperature enhances oxygen release from haemoglobin for use by more active tissues.

COMPARISON OF THESE FACTORS AT THE TISSUE AND PULMONARY LEVELS

As you just learned, increases in carbon dioxide, acidity, and temperature at the tissue level—all of which are associated with increased cellular oxygen consumption—enhance the effect of a drop in P_{O_2} in facilitating the release of oxygen from haemoglobin. These effects are largely reversed in the lung, where the extra acid-forming carbon dioxide is blown off and the local environment is cooler. (Although body temperature is 37°C , regional differences occur; working muscle can be as warm as 40°C .) Appropriately, therefore, haemoglobin has a higher affinity for oxygen in the pulmonary capillaries, enhancing the effect of the high P_{O_2} on the uptake of oxygen by haemoglobin.

EFFECT OF 2,3-BISPHOSPHOGLYCERATE ON % HB SATURATION

The preceding changes take place in the *environment* of the red blood cells, but a factor *inside* the red blood cells, **2,3-bisphosphoglycerate (BPG)**, can also affect the degree of binding of oxygen to haemoglobin. This erythrocyte constituent, which is produced during red blood cell metabolism, can bind reversibly with haemoglobin and reduce its affinity for oxygen, just as carbon dioxide and H^+ do. Thus, an increased level of BPG, like the other factors, shifts the curve to the right, enhancing oxygen unloading as blood flows through tissues.

The production of BPG by red blood cells gradually increases whenever haemoglobin in the arterial blood is chronically undersaturated—that is, when arterial oxygen saturation is below normal (hypoxemia). This condition may occur in people living at high altitudes or in those suffering from certain types of circulatory or respiratory diseases or anaemia. By helping unload oxygen from haemoglobin at the tissue level, increased BPG helps maintain oxygen availability for tissue use despite chronic reductions in arterial oxygen content.

However, unlike the other factors—which normally are present only at the tissue level and thus shift the curve to the right only in the systemic capillaries, where the shift is advantageous in unloading oxygen—BPG is present in the red blood cells and, accordingly, shifts the curve to the right to the same degree in both the tissues and the lungs. As a result, BPG decreases the ability to load oxygen in the lung, which is the negative aspect of its increased production.

Haemoglobin and carbon monoxide

Carbon monoxide (CO) and oxygen compete for the same binding sites on haemoglobin, but haemoglobin's affinity for carbon monoxide is 240 times greater than that for oxygen. The combination of carbon monoxide and haemoglobin is known as **carboxyhaemoglobin (HbCO)**. Because of this much greater affinity, even small amounts of carbon monoxide can occupy a

disproportionately large share of haemoglobin's binding sites, making haemoglobin unavailable for oxygen transport. Even though the Hb concentration and P_{O_2} are normal (because only dissolved oxygen is responsible for the P_{O_2} , and the presence of carbon monoxide does not affect how much oxygen dissolves in the plasma), the oxygen content of the blood is seriously reduced. In addition, carbon monoxide also shifts the oxygen dissociation curve to the left. As a result, a much greater drop in P_{O_2} is required to unload oxygen to the tissues, increasing the likelihood of cellular anoxia.

Fortunately, carbon monoxide is not a normal constituent of inspired air. It is a poisonous gas produced during the incomplete combustion (burning) of carbon products, such as gasoline, coal, wood, and tobacco. Carbon monoxide is especially dangerous because it is so insidious. If it is produced in a closed environment and its concentration continues to increase (e.g., in a parked car with the motor running and windows closed), it can reach lethal levels without a person ever being aware of the danger. People cannot detect carbon monoxide because it is odourless, colourless, tasteless, and nonirritating. Furthermore, a person with carbon monoxide poisoning has no sensation that arterial oxygen levels are low and makes no attempt to increase ventilation, even though the cells are anoxic (lack oxygen). (For a history of the treatment of carbon monoxide poisoning, and how an effective treatment was replaced by a less effective one that is still in use, see J.A. Fisher et al. [2011]. *Experimental Physiology*, 96: 1262–69.)

Carbon dioxide

When arterial blood flows through the tissue capillaries, carbon dioxide diffuses down its partial pressure gradient from the cells into the blood. Carbon dioxide is transported in the blood in three ways (see ▶ Figure 12-36 and also ■ Table 12-7):

1. *Physically dissolved.* As with dissolved oxygen, the amount of carbon dioxide physically dissolved in the blood depends on the P_{CO_2} . Because carbon dioxide is more soluble than oxygen, a greater proportion of the total carbon dioxide (compared to oxygen) is physically dissolved in the blood. Even so, only 5–10 percent of the blood's total carbon dioxide content is carried this way at the normal systemic venous P_{CO_2} of 46 mmHg.
2. *Bound to haemoglobin.* Another 5–10 percent of the carbon dioxide combines with haemoglobin to form **carb-amino haemoglobin (HbCO₂)**. Carbon dioxide binds with the globin portion of haemoglobin, unlike oxygen that combines with the heme portions. Reduced haemoglobin (i.e., haemoglobin without oxygen) has a greater affinity for carbon dioxide than does oxygenated haemoglobin. The unloading of oxygen from haemoglobin in the tissue capillaries therefore facilitates the uptake of carbon dioxide by haemoglobin.
3. *As bicarbonate.* By far the most important means of carbon dioxide transport is as **bicarbonate (HCO₃⁻)**, with

80–90 percent of the carbon dioxide converted into bicarbonate by the following chemical reaction, which takes place inside red blood cells:

In the first step, carbon dioxide combines with water to form **carbonic acid** (H_2CO_3). This reaction occurs very slowly in plasma, but it proceeds swiftly inside red blood cells because of the presence of the enzyme carbonic anhydrase, which catalyzes (accelerates) the reaction. As is characteristic of acids, some of the carbonic acid molecules spontaneously dissociate into hydrogen ions (H^+) and bicarbonate ions (HCO_3^-). The one carbon atom and two oxygen atoms of the original carbon dioxide molecule are therefore present in the blood as an integral part of bicarbonate. This is beneficial because bicarbonate is more soluble than carbon dioxide in blood.

CHLORIDE SHIFT

As this reaction proceeds, bicarbonate and hydrogen ions start to accumulate inside red blood cells in the systemic capillaries. The red blood cell membrane has a bicarbonate–chloride (HCO_3^- – Cl^-) carrier that passively facilitates the diffusion of these ions in opposite directions across the membrane. The membrane is relatively impermeable to H^+ . Consequently, HCO_3^- ,

but not H^+ , diffuses down its concentration gradient out of the erythrocytes into the plasma. Because bicarbonate is a negatively charged ion, its efflux—unaccompanied by a comparable outward diffusion of positively charged ions—creates an electrical gradient (p. 38). Chloride ions (Cl^-), the dominant plasma anions, diffuse into the red blood cells down this electrical gradient and restore electrical neutrality. This inward shift of chloride in exchange for the efflux of carbon dioxide–generated bicarbonate ion is known as the **chloride (Hamburger) shift**.

REVERSE HALDANE EFFECT

Removing oxygen from haemoglobin increases the ability of haemoglobin to bind carbon dioxide and the carbon dioxide–generated H^+ ; this is known as the **Haldane effect**. The Haldane and Bohr effects work in synchrony to facilitate the liberation of oxygen and the uptake of carbon dioxide and carbon dioxide–generated H^+ at the tissue level. The reduced haemoglobin transports the bound carbon dioxide back to the lungs, where it is excreted (► Figure 12-36).

There is also a phenomenon known as the **reverse Haldane effect**. Increases in arterial P_{O_2} , as occur during inhalation of supplementary oxygen, reduce or prevent haemoglobin from binding the carbon dioxide released from tissues. As a result, carbon dioxide must be carried back to the lungs primarily as

CA = Carbonic anhydrase

► **FIGURE 12-36 Carbon dioxide transport in the blood.** Carbon dioxide diffusing from tissues is transported in the blood to the lungs in three ways: (1) physically dissolved; (2) bound to haemoglobin (Hb); and (3) as bicarbonate ion (HCO_3^-). Haemoglobin is present only in the red blood cells, as is carbonic anhydrase, the enzyme that catalyzes the production of (HCO_3^-). The H^+ generated during the production of (HCO_3^-) also binds to Hb. Bicarbonate moves by facilitated diffusion down its concentration gradient out of the red blood cell into the plasma, and chloride (Cl^-) moves by means of the same passive carrier into the red blood cell down the electrical gradient created by the outward diffusion of (HCO_3^-). The reactions that occur at the tissue level are reversed in the lung.

bicarbonate and dissolved carbon dioxide. The increase in P_{CO_2} would be of no consequence except that some researchers believe the increase in P_{CO_2} at the site of the central chemoreceptors (p. 547), is responsible for the increase in ventilation associated with breathing supplemental oxygen, not a decrease, as commonly thought. This causes *hypocapnia*, something that may have serious consequences for the delivery of oxygen to tissues (see Why It Matters, p. 541).

Check Your Understanding 12.11

1. Compare the transport of oxygen and carbon dioxide in the blood.

Abnormal blood-gas levels

■ Table 12-9 provides a glossary of terms used to describe various states associated with respiratory abnormalities.

ABNORMALITIES IN ARTERIAL P_{O_2}

The term **hypoxia** refers to the condition of insufficient oxygen at the cellular level. There are four general categories of hypoxia:

1. *Hypoxic hypoxia* is characterized by a low arterial blood P_{O_2} accompanied by inadequate Hb saturation. It is caused by (a) inadequate gas exchange, typified by a normal alveolar P_{O_2} but a reduced arterial P_{O_2} ; or (b) exposure to high altitude or to a suffocating environment where atmospheric P_{O_2} is reduced so that alveolar and arterial P_{O_2} are likewise reduced.
2. *Anaemic hypoxia* is a reduced oxygen-carrying capacity of the blood. It can result from (a) a decrease in the number of circulating red blood cells, (b) an inadequate amount of Hb within the red blood cells, or (c) carbon monoxide poisoning. In all cases of anaemic hypoxia, the arterial P_{O_2} is normal, but the oxygen content of the arterial blood is lower than normal because less haemoglobin is available to carry oxygen.
3. *Circulatory (or stagnant) hypoxia* arises when too little oxygenated blood is delivered to the tissues. Circulatory hypoxia to a limited area can result from a local vascular spasm, blockage, or injury. Alternatively, circulatory hypoxia may be general, from congestive heart failure or circulatory shock. In this case, the arterial P_{O_2} and oxygen content are typically normal, but too little oxygenated blood reaches the cells.
4. In *histotoxic hypoxia*, oxygen delivery to the tissues is normal, but the cells cannot use the oxygen available to them. The classic example is *cyanide poisoning*. Cyanide blocks cellular enzymes essential for internal respiration.

Hyperoxia, an above-normal arterial P_{O_2} , cannot occur when a person is breathing air at sea level. However, breathing supplemental oxygen can increase alveolar and, consequently, arterial P_{O_2} . Because more of the inspired gas is oxygen, the P_{O_2} is greater; as a

result, more oxygen dissolves in the blood before arterial P_{O_2} equilibrates with alveolar P_{O_2} . Even though arterial P_{O_2} increases, the total blood oxygen content does not increase significantly because haemoglobin is nearly fully saturated at a normal arterial P_{O_2} . In certain pulmonary diseases in which the patient has a reduced arterial P_{O_2} , however, breathing supplemental oxygen can help establish a larger alveoli-to-blood partial pressure gradient, improving arterial P_{O_2} . Far from being advantageous, in contrast, a markedly elevated arterial P_{O_2} can be dangerous. If the arterial P_{O_2} is too high, **oxygen toxicity** can occur. Even though the total oxygen content of the blood

■ TABLE 12-9 Mini-Glossary of Clinically Important Respiratory States

Apnea	Transient cessation of breathing
Asphyxia	Oxygen starvation of tissues, caused by a lack of oxygen in the air, respiratory impairment, or inability of the tissues to use oxygen; always accompanied by a rise in carbon dioxide levels
Cyanosis	Blueness of the skin resulting from insufficiently oxygenated blood in the arteries
Dyspnea	Difficult or laboured breathing
Eupnea	Normal breathing
Hypercapnia	(or hypercarbia) Excess carbon dioxide in the arterial blood
Hyperpnea	Increased pulmonary ventilation that matches increased metabolic demands (carbon dioxide production), as in exercise
Hyperventilation	Increased pulmonary ventilation in excess of metabolic requirements, resulting in decreased arterial P_{CO_2} and respiratory alkalosis
Hypocapnia	Below-normal P_{CO_2} in the arterial blood
Hypoventilation	Underventilation in relation to metabolic requirements, resulting in increased arterial P_{CO_2} and respiratory acidosis
Hypoxaemia	Below normal P_{O_2} in the arterial blood
Hypoxia	Insufficient oxygen at the cellular level
Anaemic hypoxia	Reduced oxygen-carrying capacity of the blood
Circulatory hypoxia	Inadequate oxygenated blood delivered to tissues; also called <i>stagnant hypoxia</i>
Histotoxic hypoxia	Inability of the cells to use available oxygen
Hypoxic hypoxia	Low arterial P_{O_2} accompanied by inadequate Hb saturation
Respiratory arrest	Permanent cessation of breathing (unless clinically corrected)
Suffocation	Oxygen deprivation as a result of an inability to breathe

is only slightly increased, exposure to a high P_{O_2} can damage some cells due to the production of reactive oxygen species and free radicals that can damage membranes. In particular, brain damage and blindness-causing damage to the retina are associated with oxygen toxicity. In addition, through mechanisms still being investigated, a high P_{O_2} increases vascular resistance in many organs. If perfusion decreases more than arterial oxygen content increases, regional delivery of oxygen may actually decrease even though the patient is breathing or being ventilated with 100 percent oxygen. Therefore, oxygen must be administered cautiously; it is not needed, and may even be dangerous, in individuals who are not hypoxic.

ABNORMALITIES IN ARTERIAL P_{CO_2}

Because of carbon dioxide's high solubility and, therefore, diffusibility, it is not readily affected by changes in the resistance (R) term of the equation for diffusion. The alveolar P_{CO_2} is, however, directly related to the metabolic production of carbon dioxide and inversely related to the alveolar ventilation, as described by the alveolar ventilation equation: $P_{A_{CO_2}} = k \times \dot{V}_{CO_2} / \dot{V}_A$ (where k , a constant, is 863 mmHg; see Quantitative Exercises, p. 553). Thus, at a given metabolism, the greater the alveolar ventilation, the lower is the alveolar P_{CO_2} , and vice versa.

The term **hypercapnia** (sometimes called *hypercarbia*) refers to excess carbon dioxide in arterial blood; it is caused by **hypoventilation** (ventilation inadequate to meet metabolic needs for oxygen delivery and carbon dioxide removal). With most pulmonary diseases, carbon dioxide accumulates in arterial blood concurrently with an oxygen deficit, because the exchanges of both gases between lungs and atmosphere are equally affected (► Figure 12-37). However, when a decrease in arterial P_{O_2} is due to reduced pulmonary diffusing capacity—as in pulmonary oedema or emphysema—oxygen transfer suffers more than that of carbon dioxide, because oxygen is 20 times less diffusible than carbon dioxide. As a result, in these circumstances hypoxic hypoxia occurs much more readily than hypercapnia. (This can also occur in cases of ventilation/perfusion mismatch in the lung.)

Hypocapnia (or *hypocarbia*), below-normal arterial P_{CO_2} levels, results from **hyperventilation**, a condition in which alveolar ventilation is greater than that needed to excrete metabolically produced carbon dioxide. Hyperventilation can be triggered by anxiety, fever, and aspirin poisoning. It also occurs during high levels of exercise when there is a shift to anaerobic metabolism. Alveolar P_{O_2} increases during hyperventilation as more fresh oxygen is delivered to the alveoli from the atmosphere than the blood extracts from the alveoli for tissue consumption, and arterial P_{O_2} increases correspondingly (► Figure 12-37). However, because haemoglobin is almost fully saturated at the normal arterial P_{O_2} , very little additional oxygen is added to the blood. Nor can the P_{O_2} increase very much; it can never exceed the partial pressure of inspired oxygen (about 150 mmHg, at sea level). Except for the small, extra amount of dissolved oxygen, blood oxygen content in a normal person remains essentially unchanged during hyperventilation.

Increased ventilation is not synonymous with hyperventilation. Increased ventilation that matches an increased metabolic demand, such as that which occurs during exercise, is termed **hyperpnea**. (Recall that increased ventilation

© 2016 Cengage

► **FIGURE 12-37** Effects of hyperventilation and hypoventilation on arterial P_{O_2} and P_{CO_2} . Alveolar and arterial P_{CO_2} at a given carbon dioxide production ($\dot{V}_{CO_2}$) are inversely related to alveolar ventilation, as indicated by the alveolar ventilation equation. From the change in alveolar P_{CO_2} , one can compute the alveolar P_{O_2} using the alveolar gas equation (p. 525). Doubling alveolar ventilation cannot double alveolar P_{O_2} to 200 mmHg because the upper limit of alveolar P_{O_2} is the inspired P_{O_2} , approximately 150 mmHg at sea level.

that exceeds metabolic demand is called hyperventilation.) During exercise below the threshold at which the exercising muscles switch to anaerobic metabolism, alveolar and arterial P_{O_2} and P_{CO_2} remain constant, with the increased alveolar ventilation matching the increased oxygen consumption and carbon dioxide production. Above the anaerobic threshold, the increased production of acid (lactic acid) causes alveolar ventilation to exceed that required for excretion of carbon dioxide, and the person becomes hypocapnic.

CONSEQUENCES OF ABNORMALITIES IN ARTERIAL BLOOD GASES

The consequences of reduced oxygen availability to tissues during hypoxia are apparent. The cells need adequate oxygen to sustain energy-generating metabolism. The consequences of abnormal levels of carbon dioxide in the blood are less obvious. Changes in blood concentration of carbon dioxide primarily affect acid–base balance. Hypercapnia elevates production of carbonic acid. The subsequent generation of excess H^+ produces a condition termed *respiratory acidosis*. Conversely, less-than-normal amounts of H^+ are generated through carbonic acid formation in conjunction with hypocapnia. The resultant condition is called *respiratory alkalosis* (Chapter 14). (To learn about the effects of altitude and exercise training at high altitude, see Chapter 14, Integration of Human Physiology.)

Oxygen is the most commonly administered drug—and it is a drug—in the world. It is given to patients who have, or are suspected of having, hypoxic or anoxic tissues. Some of the most common clinical situations are acute exacerbations of chronic obstructive pulmonary disease, myocardial infarctions (heart attacks), and strokes. Many of these patients are not, however, hypoxic, based on measurements of arterial oxygen saturation using an oximeter: a small device typically placed over a finger or earlobe. Guidelines for emergency medical personnel typically stipulate that, regardless of the oximeter reading, patients be given oxygen by facemask or nasal tubes.

Is there any evidence that oxygen is clinically beneficial in these nonhypoxemic patients? Surprisingly, the answer is no. Instead, control trials, in which patients are randomly assigned to treatment groups and the outcomes later evaluated “blind” (i.e., without knowing the group to which the patient was assigned) demonstrate either that the extra oxygen provides no benefit or that those given oxygen have greater mortality than those given less oxygen or even air.

The reasons for the worse outcomes are uncertain but there are two main possibilities. The first is that the high levels of oxygen cause the formation of reactive oxygen species that damage membranes and interfere with cellular function, and may even activate processes that lead to cell death (apoptosis). The other major possibility, and one that predates the first, is that oxygen increases vascular resistance in many tissues, including the brain and heart. Although the relative contributions of the possible mechanisms (e.g., interference by reactive oxygen species with endothelial nitric oxide, hyperoxia-induced hypocapnia) may be controversial, the physiological reasoning is incontrovertible.

A nonhypoxemic patient is, by definition, almost fully saturated and has, therefore, a near-maximum concentration of oxygen in the blood (200 mL O₂/L blood). Breathing 100 percent oxygen, therefore, cannot increase haemoglobin saturation; the only way to increase arterial oxygen content is by increasing the amount of oxygen dissolved in the blood. But because oxygen is relatively insoluble, breathing 100 percent

oxygen will provide no more than an 8 percent increase in content. In contrast, breathing 100 percent oxygen commonly provokes decreases of cerebral or coronary blood flow of 20 percent or more. If the perfusion decreases more than the oxygen concentration increases, a paradox results: breathing 100 percent oxygen actually decreases oxygen delivery to tissues. Although the arterial P_{O_2} may increase to as much as 600 mmHg during inhalation of oxygen, this increased driving pressure for diffusion is of limited value if perfusion (which transports the amount of oxygen that cells need to consume) is inadequate.

Even before these recent (as late as 2013) findings of the effects of administration of oxygen to nonhypoxemic adults appeared, a major change in the guidelines about the use of oxygen for resuscitating newborns had occurred. Administering 100 percent oxygen to newborns in difficulty (a low Apgar [Appearance, Pulse, Grimace, Activity, Respiration] score—introduced by Virginia Apgar, an American physician who founded the discipline of neonatology) delays the onset of spontaneous breathing and generally results in worse outcomes. Some have linked the administration of oxygen to neurological disorders, but this is contentious. Readers interested in this fascinating story, and the difficulties overcoming the inherent bias in favour of oxygen, can start by checking the scientific literature for publications by the Norwegian neonatologist, O.D. Saugstad (see also [2010]. *Lancet*, 376[9757]: 1970–71).

When there is clear evidence of hypoxia, either at the systemic or tissue level, oxygen is a lifesaver. One example is the use of high-pressure (hyperbaric) oxygen for treating gangrene or foot ulcers in people with diabetes. However, individuals promoting the use of hyperbaric chambers often claim unproven benefits on the grounds that hyperbaric oxygen delivers more oxygen to tissues. It is true that the arterial P_{O_2} can be as high as 2000 mmHg, but this does not ensure that more oxygen is actually delivered—and it is uncertain that this would be beneficial—because they fail to take into account that a high P_{O_2} reduces perfusion. As is true for any drug, oxygen has its uses, but it must not be used indiscriminately.

Check Your Understanding 12.12

1. Describe the effects of changes in alveolar ventilation on the contents and partial pressures of oxygen and carbon dioxide in arterial blood.

12.5 Control of Breathing

Like the heartbeat, breathing must occur in a continuous, cyclic pattern to sustain life. Just as the heart rhythmically contracts and relaxes to alternately pump blood from the heart and fill it again, the inspiratory muscles rhythmically contract and relax to alternately fill the lungs with air and empty them. Both these

activities are accomplished automatically, without conscious effort. However, the underlying mechanisms and control of these two systems differ markedly.

Respiratory centres in the brain

Whereas the heart can generate its own rhythm by means of its intrinsic pacemaker activity, the respiratory muscles, being skeletal muscles, contract only when stimulated. The rhythmic pattern of breathing is established by their cyclic neural activation. The neuronal discharges that establish breathing rhythm, and reflexively adjust the level of ventilation to match uptake of oxygen to removal of carbon dioxide, originate in the respiratory control centres in the brain (specifically the medulla), not in the lungs or respiratory muscles. This contrasts with the

heart, where external input is not needed to initiate a heartbeat, but rather external input can modify the rate and strength of cardiac contraction. Furthermore, unlike cardiac activity, which is not subject to voluntary control, respiratory activity can be voluntarily modified to accomplish speaking, singing, whistling, playing a wind instrument, or holding one's breath while swimming.

COMPONENTS OF NEURAL CONTROL OF RESPIRATION

Neural control of respiration involves three distinct components: (1) generation of the alternating inspiratory/expiratory rhythm, (2) regulation of the level of ventilation (i.e., the rate and depth of breathing) to match metabolism, and (3) modification of respiratory activity to serve other purposes. The latter modifications may be either voluntary, as in speech, or involuntary, as in cough or sneeze.

Respiratory control centres in the brain stem generate the rhythmic pattern of breathing. The primary respiratory control centre, the *medullary respiratory centre*, consists of several aggregations of cells within the medulla that generate output to the respiratory muscles. (These observations about the location of the neurons are based on recordings from animals.) In addition, other respiratory centres are present in the pons, a more rostral region of the brain stem. These centres influence output from the medullary respiratory centre. Following is a description of how these various regions interact to establish respiratory rhythmicity.

INSPIRATORY AND EXPIRATORY NEURONS IN THE MEDULLARY CENTRE

We rhythmically breathe in and out during quiet breathing because of alternate contraction and relaxation of the inspiratory muscles—the diaphragm and external intercostal muscles—which are supplied by the phrenic nerve and intercostal nerves, respectively. The cell bodies of the axons projecting to these muscles are located in the spinal cord. When activated, they stimulate motor units of the inspiratory muscles, causing inspiration; when inactive, the inspiratory muscles relax, and expiration takes place. These spinal motor neurons receive inputs originating from pre-inspiratory neurons (i.e., neurons that do not project directly to the muscles) of the medullary respiratory centre.

The **medullary respiratory centre** consists of two clusters known as the *dorsal respiratory group* and the *ventral respiratory group*. The **dorsal respiratory group (DRG)** contains primarily *inspiratory neurons* whose descending fibres terminate on the spinal motor neurons that supply the inspiratory muscles. When neurons in the DRG fire, inspiration occurs; when they cease firing, expiration occurs. Expiration ends when synaptic input to the inspiratory neurons is again sufficient to bring them to threshold and make them discharge. Many neurons of the DRG project to neurons of the ventral respiratory group (VRG); if these projections are their only ones, they are referred to as *respiratory interneurons* because their connections remain within the respiratory control centres. They may also project to neurons in the VRG via collaterals from their axons that project to inspiratory motor neurons in the spinal cord.

The **ventral respiratory group (VRG)** is composed of *inspiratory neurons* and *expiratory neurons*, some of which are inactive during resting breathing. Many neurons that discharge in phase with inspiration, especially those in the nucleus ambiguus, are actually inspiratory motor neurons because they project directly to the many skeletal muscles, including the tongue, that widen (abduct) the upper airway (larynx and oropharynx) and reduce resistance to flow during inspiration.

Neurons that discharge in phase with expiration (defined as the absence of activity of the inspiratory muscles) are premotor expiratory neurons and expiratory motor neurons. The former project to motor neurons in the spinal cord that innervate the expiratory pump muscles (abdominal and internal intercostal muscles). The latter innervate muscles that narrow (adduct) the upper airway. Many neurons in this region are recruited by increased input from neurons of the DRG during periods of increased ventilatory demand, and this accounts for the recruitment of expiratory pump muscles when expiration becomes active.

GENERATION OF RESPIRATORY RHYTHM

Until recently, the DRG was generally thought to generate the basic rhythm of ventilation. Then, the generation of respiratory rhythm was attributed to pacemaker-like neurons in the **pre-Bötzinger complex**, a region located near the rostral end of the VRG. The issue of whether or not neurons in this complex display pacemaker activity is contentious. To be a true pacemaker, a cell has to display rhythmic changes in membrane potential in the absence of synaptic input, and this has not always been observed. (Moreover, the first preparations in which activity was recorded from these neurons were probably hypoxic, if not anoxic; the respiratory activity more closely resembled gasping, not normal breathing.) The most recent data indicate that respiratory rhythm arises from synaptic interactions between multiple structures, specifically the VRG, the Bötzing and pre-Bötzing complexes, and the pons. There may well be a pacemaker component in the pre-Bötzing complex, but it is one in which its state is determined by inputs from other structures.

Influences from higher centres

It is a truism that every neuron in the brain is connected, inevitably, with every other neuron. It is therefore not surprising that structures elsewhere in the brain stem affect respiratory pattern. In the 1920s, an English investigator, Thomas Lumsden, observed that destruction of certain areas in the pons dramatically altered breathing pattern in anesthetized cats. One area, called the **apneustic centre** (from the Greek, “to hold one's breath”) was associated with prolonged and deep inspirations; another, called the **pneumotaxic centre** (from the Greek, “to regulate respiratory rate”) stopped inspiration and caused prolonged expirations. These terms—apneustic and pneumotaxic—are still used by some investigators, but they have little physiological meaning because they describe breathing patterns only rarely observed, as during pathological conditions such as coma. More importantly, although lesions of these areas cause abnormal breathing patterns while the experimental animals are anesthetized, their breathing appears normal after recovery from the anesthetic.

DISCHARGE PATTERNS OF RESPIRATORY NEURONS AND MOTOR NEURONS

Respiratory neurons in the brain stem can be characterized by their different discharge patterns, as defined by timing and discharge frequency. In terms of timing, many neurons fire only during one phase (i.e., during inspiration or expiration); others fire only during a particular phase (e.g., during late inspiration) or during the transition between phases. In terms of discharge patterns, common ones include augmenting (i.e., discharge frequency starts at a low value and increases during the time the neuron is active), decrementing (i.e., high initial onset frequency that decreases thereafter), or plateau (rapid increase to a peak followed by a steady discharge until firing ceases). Many investigators have modelled these discharge patterns to reveal how the interconnections between these various neuronal types can generate the oscillating pattern of discharge that defines respiration.

These discharge patterns can be most readily understood by linking them to the functions of the respiratory muscles that generate pressure and those that regulate resistance of the upper airway. During inspiration, the elastic recoil of the respiratory system, especially the lung, increases (see ▶ Figure 12-10). To overcome this increasing recoil, the discharge of inspiratory pump muscles increases (▶ Figure 12-38). By both increasing the frequency of discharge and recruiting previously inactive motor neurons during an inspiration, inspiratory muscles generate more pressure to overcome the elastic recoil. These inspiratory motor neurons all stop firing at the end of inspiration regardless of when they started to fire during inspiration.

The discharge pattern of expiratory motor neurons can be similarly understood in terms of their function. During resting breathing, expiratory flow is generated through passive recoil;

as a result, expiratory motor neurons are often inactive. (This does not mean that expiratory premotor neurons in the brain stem are inactive; they may be discharging at levels too low to activate the motor neurons to which they project. And expiratory interneurons—those that project to other neurons participating in the generation of respiratory rhythm—are still active.) But when ventilation increases in response to metabolic or other demands, expiratory motor neurons are recruited; in addition to the pressure generated by elastic recoil, this increases expiratory flow. Unlike inspiratory motor neurons, however, expiratory motor neurons often stop discharging during the expiratory phase before the onset of the next inspiration because the last part of expiration can include, especially at rest, an expiratory pause.

The discharge patterns of motor neurons that adjust the calibre of the upper airway differ markedly from those providing input to the muscles that generate airflow. During inspiration, motor neurons innervating the upper airway abductors often start to fire before those innervating the inspiratory pump muscles, rapidly reach a peak discharge frequency, and maintain this level of activity until the end of inspiration. This pattern results in a rapid opening of the upper airway that keeps it open during inspiration, thereby decreasing flow resistance and, consequently, the energy expended to generate inspiratory flow.

At high levels of ventilatory demand, as in exercise, some of these motor neurons become tonically (continuously) active, keeping the airways open and helping to reduce flow resistance during both phases of respiration. In contrast, motor neurons innervating upper airway muscles that are active during expiration often display activity at low ventilatory levels—especially at the start of expiration—then a decrease in activity during the expiratory phase. This results in narrowing of the upper airway, increasing flow resistance and impeding expiratory flow, especially at the start of expiration. This helps maintain lung volume and gas exchange. As ventilatory demands increase, however, their activity decreases, ensuring that the upper airway is dilated and therefore offers minimal resistance to flow.

In summary, the discharge patterns of the motor neurons innervating the respiratory muscles—pump muscles (flow generation) and airway muscles (control of flow resistance)—are appropriate for their respective functions.

▶ **FIGURE 12-38 Phrenic motor neuron discharge patterns.** Traces, from top down: a small filament from the phrenic nerve with activity of two distinct motor axons (Phr unit); the smoothed (integrated) activity of the contralateral whole phrenic nerve (IPhr); and the raw activity of the contralateral phrenic nerve (Phr). During inspiration in a decerebrate cat, the amplitude of the discharge of all phrenic motor neurons (which innervate motor units of the diaphragm) increases in a ramplike pattern. This is due to both an increase in the discharge frequency of individual motor axons and the recruitment of additional motor axons throughout inspiration. Later-recruited motor axons innervate larger motor units that generate more force. The increased discharge overcomes the increased elastic recoil of the lung as lung volume increases.

Check Your Understanding 12.13

1. Describe the differences in discharge patterns between motor neurons innervating pump muscles (e.g., diaphragm) and motor neurons innervating muscles controlling the diameter of the upper airway
2. How are these discharge patterns affected by increases in the chemical drive to breathing?

Control of respiratory pattern

Two main types of receptors, mechanical and chemical, control respiratory pattern and, therefore, the level of ventilation.

MECHANORECEPTORS

Any receptor that detects a change in pressure, flow, or displacement of a structure in the respiratory system is a *mechanoreceptor*. These receptors are found in both components of the respiratory system, the lung and chest wall.

PULMONARY RECEPTORS

The lungs contain some of the best-studied mechanoreceptors in physiology, in part because their reflex effects can be easily measured and because the effects of their activation can be readily eliminated by section of the vagus nerves (cranial nerve X), the nerves carrying their afferents to the brain stem. They include slowly and rapidly adapting receptors (with myelinated afferents) and C-fibres (with unmyelinated afferents). (See > Figure 12-19.)

- **Slowly adapting receptors:** **Slowly adapting receptors**, the endings of which are located in the smooth muscle of the airways respond to changes in lung volume (actually, changes in transmural pressure). Inflation of the lung activates them, if previously inactive, or increases their discharge if they were already active. As their name implies, they maintain their discharge frequency if lung inflation is sustained. They are the receptors responsible for one of the best known reflexes, the Breuer–Hering reflex.
- **Rapidly adapting receptors:** **Rapidly adapting receptors**, in contrast, have endings in the airway epithelia, primarily in larger airways. In response to chemical or mechanical stimuli, they exhibit a rapid burst of high frequency action potentials that quickly adapts (ceases). They used to be called irritant receptors because they could be activated by such stimulants as smoke or histamine. Their activation can lead to airway narrowing and cough, part of a protective reflex that limits inhalation of irritants into the lung. Their activation can also elicit mucus production that helps eliminate inhaled particles. Also, because they respond to deflation of lung regions, they initiate sighs, which help open regions of the lung that are in the process of closing (atelectasis) and thereby help maintain gas exchange.
- **C-fibres (J receptors):** The endings of these receptors are close (or juxtaposed; J) to the pulmonary capillaries. As such, they can detect increases in pulmonary arterial pressure and exudation of fluid into the interstitial space (i.e., pulmonary oedema). They also respond to chemical stimuli, such as capsaicin (the pungent extract of chili peppers), that signal inflammation. When activated, they cause bronchoconstriction and rapid shallow breathing (tachypnea) typical of dyspnea. Their activation also causes inhibition of spinal motor neurons; this would reduce motor activity associated with exercise and, hence, the need to increase cardiac output to the pulmonary circulation.

BREUER–HERING REFLEX

The first description of a negative biological feedback loop was made in the 1860s by Joseph Breuer (the student) and Ewald Hering (the professor) in Austria. In rabbits, they observed that inflation of the lungs inhibited inspiration and prolonged

expiration, whereas deflation had the opposite effects. (They could easily monitor the rabbit's breathing by watching the opening and closing of its nostrils.) They referred to this phenomenon as *selbststeuerung* (German for “self-steering”). In hundreds of subsequent studies, researchers have confirmed these findings, in ever greater detail, in anaesthetized animals. In brief, the discharge of brain stem inspiratory neurons activates inspiratory motor neurons, causing lung inflation. Inflation activates the pulmonary slowly adapting receptors. The discharge of their afferents, in the vagus nerve projecting to the medulla, activates neurons in the brain stem that inhibit inspiratory premotor neurons, thereby stopping inspiration. This is *the* classic negative feedback loop.

This feedback loop controls the depth and duration of inspiration in spontaneously breathing *anaesthetized* animals. These studies show that more feedback from slowly adapting receptors is required to terminate inspiration soon after the onset of inspiration, but less feedback is required as inspiration continues. The central (brain stem respiratory centre) threshold, in terms of feedback from slowly adapting receptors, for terminating inspiration therefore falls as inspiration proceeds. Thus, large tidal volumes are associated with short inspiratory durations, and small tidal volumes are associated with longer inspiratory durations. Studies in human infants also suggest that this reflex is operative.

There is, however, little evidence that the Breuer–Hering reflex operates in *conscious* animals and, especially, in conscious humans. Indeed, in conscious adults, the longer the inspiration (within limits), the larger is the tidal volume. If one adds carbon dioxide to the inspire, this relation still holds, but the relation is steeper. That is, for a given duration of inspiration, a larger tidal volume is achieved due to an increased flow. This is consistent with carbon dioxide increasing the drive to breathe (i.e., production of a greater inspiratory flow). The Breuer–Hering reflex does appear to operate at higher tidal volumes, when inspiration becomes more difficult because the system is less compliant.

The Breuer–Hering reflex may, however, operate *during* inspiration as opposed to terminating inspiration. In lightly anaesthetized animals, activity in the phrenic nerves (that innervate the diaphragm) is greater during unimpeded inspirations than during inspiratory phases when lung inflation is prevented. In other words, the slowly adapting receptors provide *positive feedback* during inspiration. The probable explanation is that increased activity (higher discharge frequencies of already active motor units and recruitment of previously inactive ones) is needed to overcome progressively greater elastic recoil as lung volume increases. If the level of anesthesia is slightly increased, this effect disappears, accounting for the failure to observe this phenomenon in earlier studies in more deeply anesthetized animals.

CHEST WALL RECEPTORS

- **Diaphragm:** The diaphragm contains relatively few receptors—spindles and Golgi tendon organs—with myelinated afferents, and the effects of their activation are poorly understood. The lack of these receptors, so prevalent in limb muscles, may reflect the fact that the diaphragm's role

is largely limited to respiration and such protective reflexes as coughing, sneezing, and vomiting. During these reflexes, these receptors may act to limit its contraction and, therefore, the high intrathoracic and abdominal pressures that are generated. In contrast, the diaphragm has many receptors with small myelinated and unmyelinated afferents, the receptors of which respond to local metabolic conditions (*metaboreceptors*). Their activation may elicit a reflex inhibition of the diaphragm, via either spinal or supraspinal interneurons, thereby reducing its activity and the production of catabolites. Their activation may also contribute to the sense of dyspnea.

- Rib cage:** Unlike the diaphragm, the muscles of the chest wall, especially the intercostal muscles, are richly supplied with muscle spindles and, to a lesser degree, Golgi tendon organs. What is unclear, however, is their role in respiration. The spindles are identical to those in limb muscles and are therefore able to detect discrepancies between expected outcome (shortening of the intrafusal fibres due to activation of the γ efferents) and achieved outcome (shortening of the extrafusal fibres via α efferents). A discrepancy, such as a smaller increase in chest wall distension than expected, would cause the spindle receptor to discharge, eliciting a reflex increase in a efferent activity in an attempt to “unload” the spindle. Some researchers believe that this failure to meet contractile expectations—in this case, a person’s awareness of not getting the anticipated tidal volume—is the underlying cause of breathlessness (dyspnea). This is plausible, but recall that the intercostals and abdominal muscles are not only respiratory muscles; they also have an important role in posture or stabilization of the thorax during such movements as lifting a heavy object. Therefore, the spindles could also have a role in postural adjustments.

CHEMICAL CONTROL

VENTILATION ADJUSTMENT

No matter how much oxygen is extracted from the blood or how much carbon dioxide is added to it at the tissue level, the P_{O_2} and P_{CO_2} of the arterial blood are held remarkably constant, indicating that arterial blood-gas tensions are precisely regulated.

Arterial blood gases are maintained within the normal range by varying the rate and depth of breathing (and so too is alveolar ventilation) to match the body’s metabolism (oxygen uptake and carbon dioxide production). If more oxygen and carbon dioxide are extracted from and unloaded to the alveoli, respectively, because of increased tissue metabolism, alveolar ventilation increases to maintain arterial blood gases within a normal range.

The medullary respiratory centres receive many inputs. One of the most important is information about the chemical composition of the blood. The two most obvious signals to increase ventilation are a decreased arterial P_{O_2} and an increased arterial P_{CO_2} . Intuitively, you would suspect that if oxygen levels in the arterial blood declined or if carbon dioxide accumulated, ventilation would be stimulated to obtain more oxygen or to eliminate excess carbon dioxide. These two factors do indeed influence the magnitude of ventilation, but not to the same degree nor through the same pathway(s). Also, a third chemical factor, H^+ , influences the level of respiratory activity. Next we examine the role of each of these important chemical factors in the control of ventilation (see ■ Table 12-10).

DECREASED ARTERIAL P_{O_2}

Arterial levels of oxygen are monitored by **peripheral chemoreceptors**, the **carotid bodies** and **aortic bodies**, which lie at the forks of the left and right common carotid arteries and in the arch of the aorta, respectively (► Figure 12-39). These chemoreceptors respond to specific changes in the chemical content of the arterial blood that bathes them. (They should not be confused with the carotid sinus and aortic arch baroreceptors, located in the same vicinity, which help regulate systemic arterial blood pressure (p. 419). Those interested in a more detailed description of the versatility of both sets of chemoreceptors, and the role of ATP, should consult work by Colin Nurse at McMaster University (Piskuric & Nurse [2013]. *Journal of Physiology*, 591: 415–22).

EFFECT OF A LARGE DECREASE IN P_{O_2} ON THE PERIPHERAL CHEMORECEPTORS

In terms of respiratory control, the carotid chemoreceptors are more important than the aortic chemoreceptors. This is

■ TABLE 12-10 Influence of Chemical Factors on Respiration

Chemical Factor	Effect on the Carotid Chemoreceptors	Effect on the Central Chemoreceptors
↓ $P_{A_{O_2}}$	Activated only when arterial $P_{O_2} < 60$ mmHg; an emergency mechanism	Directly depresses central chemoreceptors and respiratory centre when < 60 mmHg, but may activate other neurons in brain stem
↑ $P_{A_{CO_2}}$ (= ↑ H^+ in brain ECF)	Weakly stimulates; sensitizes receptors to hypoxia	Strongly stimulates; is the dominant control of ventilation (levels > 70 – 80 mmHg depress the respiratory centre and central chemoreceptors)
↑ arterial $[H^+]$	Stimulates; important in acid–base balance; sensitizes receptors to hypoxia	Does not affect; cannot penetrate blood–brain barrier

► **FIGURE 12-39** Discharge patterns of pump and airway muscles

because the former respond to changes in arterial P_{O_2} , whereas the latter respond to changes in arterial oxygen content. The reasoning is as follows: increases and decreases in alveolar ventilation increase and decrease, respectively, the alveolar P_{O_2} . Assuming equilibration between alveolar and arterial pressures, this means that alveolar ventilation controls arterial P_{O_2} . But the carotid chemoreceptors are relatively insensitive to modest decreases in arterial P_{O_2} until the P_{O_2} falls below 60 mmHg, the level at which desaturation starts to fall to levels that could impair oxygenation of peripheral tissues. When arterial P_{O_2} does fall below 60 mmHg, the receptors are activated and reflexively increase ventilation and, therefore, alveolar P_{O_2} . Activating the carotid chemoreceptors at P_{O_2} $s > 60$ mmHg is unnecessary because an increase in alveolar P_{O_2} would not increase arterial oxygen content much more since the blood is already well saturated.

In contrast, the aortic chemoreceptors respond not to arterial P_{O_2} but to arterial oxygen content. When content falls, their activation causes an increase not in ventilation but in cardiac output, thereby increasing systemic oxygen delivery (the product of arterial oxygen content and cardiac output: $\text{mL } O_2 / \text{L blood} \times \text{L blood/min} = \text{mL } O_2 / \text{min}$).

You can appreciate the distinction between the two stimuli by considering an individual with anaemia. This person has a normal arterial P_{O_2} but a reduced arterial oxygen content. Consequently, there is no need for a reflex increase in ventilation. An increase would marginally increase arterial P_{O_2} but would not increase content; only correction of the anaemia would do that. An anaemic person would, however, benefit from an increased cardiac output because this compensates for the reduced arterial oxygen content, thereby maintaining oxygen delivery to the periphery.

In summary, the two sets of peripheral arterial chemoreceptors work together, when needed, to ensure adequate oxygen delivery to the tissues. The carotid chemoreceptors respond to and control arterial P_{O_2} and therefore arterial oxygen content, by adjusting ventilation. The aortic chemoreceptors respond to decreases in arterial oxygen content and adjust cardiac output to maintain oxygen delivery to the tissues.

DIRECT EFFECT OF A LARGE DECREASE IN P_{O_2} ON THE RESPIRATORY CENTRES

In general, hypoxia depresses cellular activity, particularly the maintenance of ionic gradients. Were it not for the intervention of the peripheral chemoreceptors when the arterial P_{O_2} falls below 60 mmHg, a vicious cycle ending in cessation of breathing would ensue. Direct depression of the respiratory centre by a markedly low arterial P_{O_2} would further reduce ventilation, leading to an even greater fall in arterial P_{O_2} that would depress the respiratory centre even more until ventilation ceased and death occurred. (This is an example of positive feedback; most positive feedbacks destabilize a system, resulting in a bad outcome.)

Until recently, the only cells thought capable of responding to hypoxia were the carotid chemoreceptors. Although most cells in the brain decrease their metabolic activity during exposure to hypoxia, some neurons in the caudal hypothalamus and rostral ventrolateral medulla of rats increase their activity during hypoxia. Nevertheless, in animals lacking feedback from the periphery (cut vagus and carotid sinus nerves), progressive hypoxia depresses inspiratory activity, so the hypoxia-induced activation of these neurons has little effect.

There is another related issue. Newborn animals are extremely resistant to hypoxia; they can recover completely from prolonged anoxia or asphyxiation that would kill an adult. This feature has obvious evolutionary value during and immediately after birth until breathing starts.

CARBON DIOXIDE-GENERATED H^+

In contrast to arterial P_{O_2} , which does not contribute to the minute-to-minute regulation of ventilation, arterial P_{CO_2} is the most important factor regulating ventilation under resting conditions. This role is appropriate because changes in alveolar ventilation have an immediate and pronounced effect on arterial (see alveolar ventilation equation, p. 540). Even slight alterations from normal in arterial P_{CO_2} induce significant reflex changes in ventilation. An increase in arterial P_{CO_2} stimulates the respiratory centre, and the resulting increase in ventilation promotes elimination of the excess carbon dioxide to the atmosphere. Conversely, a fall in arterial P_{CO_2} reduces respiratory drive and, therefore, ventilation; as a result, metabolically produced carbon dioxide accumulates, returning to P_{CO_2} normal.

EFFECT OF INCREASED P_{CO_2} ON THE CENTRAL CHEMORECEPTORS

Surprisingly, given the key role of arterial P_{CO_2} in regulating respiration, no important receptors monitor arterial P_{CO_2} *per se*. The carotid bodies respond weakly to changes in arterial P_{CO_2} , so they play only a minor role in reflexively stimulating ventilation

in response to an elevation in arterial P_{CO_2} . However, they do sensitize the carotid chemoreceptors to hypoxia, such that for a given arterial P_{O_2} , the response is greater during hypercarbia. More important in linking changes in arterial P_{CO_2} to compensatory adjustments in ventilation are the **central chemoreceptors**, located in the medulla near the respiratory centres. Originally, these receptors were thought to lie on or just beneath the ventral surface of the medulla, but later work indicates that they are present in many areas of the brain stem, often close to capillaries in regions containing neurons that generate the respiratory rhythm. These central chemoreceptors do not monitor carbon dioxide itself; however, they are sensitive to carbon dioxide-induced changes in H^+ concentration in the brain extracellular fluid that bathes them.

Movement of materials across the brain capillaries is restricted by the blood–brain barrier (p. 100). Because this barrier is readily permeable to carbon dioxide, any increase in arterial P_{CO_2} causes a similar rise in brain extracellular fluid P_{CO_2} as carbon dioxide diffuses down its partial pressure gradient from the cerebral capillaries into the brain extracellular fluid. The increased P_{CO_2} within the brain extracellular fluid correspondingly raises the concentration of H^+ according to the law of mass action as it applies to this reaction: $\text{CO}_2 + \text{H}_2\text{O} \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}^+ + \text{HCO}_3^-$. An elevation of H^+ concentration in the brain extracellular fluid directly stimulates the central chemoreceptors, which in turn increase ventilation by stimulating the respiratory centre through synaptic connections (► Figure 12-40). As the excess carbon dioxide is subsequently blown off, the arterial P_{CO_2} and the P_{CO_2} and H^+ concentration of the brain extracellular fluid return to normal. Conversely, a decline in arterial P_{CO_2} below normal is paralleled by a fall in P_{CO_2} and H^+ in the extracellular fluid; the result of this is a central chemoreceptor-mediated decrease in ventilation. As carbon dioxide produced by cell metabolism is consequently allowed to accumulate, arterial P_{CO_2} and P_{CO_2} and H^+ of the brain extracellular fluid return toward normal.

Unlike carbon dioxide, H^+ cannot readily permeate the blood–brain barrier, so H^+ in the plasma cannot gain access to the central chemoreceptors. Accordingly, the central chemoreceptors respond only to H^+ generated within the brain extracellular fluid itself as a result of the entry of carbon dioxide. Thus, the major mechanism controlling ventilation under resting conditions is specifically aimed at regulating H^+ concentration in the brain extracellular fluid, which in turn directly reflects the arterial P_{CO_2} . Unless there are extenuating circumstances, such as reduced availability of oxygen in the inspired air, arterial P_{O_2} is coincidentally maintained at its normal value by receptors responding to brain extracellular fluid H^+ .

The powerful influence of the central chemoreceptors on the respiratory centre is responsible for your inability to hold your breath for more than about a minute. While you hold your breath, metabolically produced carbon dioxide continues to accumulate in your blood and then to build up the $P_{\text{CO}_2} / \text{H}^+$ concentration in your brain extracellular fluid. Finally, the increased H^+ stimulus to respiration becomes so powerful that central chemoreceptor excitatory input overrides the voluntary inhibition of breathing. This happens long before arterial P_{O_2} falls to the threateningly low levels that trigger the carotid chemoreceptors. Therefore, you cannot deliberately hold your breath long enough to create a dangerously high level of carbon dioxide or low level of oxygen in the arterial blood.

But activation of the central chemoreceptors is not the sole determinant of breath-hold duration. If, for example, a person at the breakpoint of a breath-hold is allowed to inhale a gas mixture that does not improve the blood gases, the person can continue to hold his or her breath. Moreover, blowing air in through the mouth and out through the nostrils while breath-holding also allows the breath-hold to continue; the sensation of airflow through the nose apparently fools people into believing they are breathing. Consider the experimental situation in which a person agrees be paralyzed except for an arm used to signal the experimenter (the arm is spared because a tourniquet prevents its paralysis). This paralyzed person can hold his or her breath

► FIGURE 12-40 Effect of increased arterial P_{CO_2} on ventilation

much longer than others who can voluntarily breathe. These results indicate that unrewarded breathing efforts, particularly contractions of the diaphragm, are a source of sensory input that causes the person to stop the breath-hold. The relevance of these experiments is that they provide information related to the sensation of breathlessness (dyspnea), a debilitating symptom in many people with respiratory diseases.

DIRECT EFFECT OF A LARGE INCREASE IN P_{CO_2} ON THE RESPIRATORY CENTRES

In contrast to the normal reflex stimulatory effect of the increased P_{CO_2} - H^+ mechanism on respiratory activity, very high levels of carbon dioxide directly depress the entire brain, including the respiratory centre, just as very low levels of oxygen do. Up to a P_{CO_2} of 70–80 mmHg, progressively higher P_{CO_2} levels induce correspondingly more vigorous respiratory efforts in an attempt to blow off the excess carbon dioxide. A further increase in P_{CO_2} beyond 70–80 mmHg, however, does not increase ventilation more, but actually depresses (hyperpolarizes) respiratory neurons. For this reason, carbon dioxide must be removed and oxygen supplied in closed environments, such as closed-system anesthesia machines, submarines, or space capsules.

Surprisingly, however, high levels of carbon dioxide are not lethal if the P_{O_2} is adequate. There are reports of individuals who have, accidentally, experienced extremely high levels of arterial P_{O_2} (supercarbia) but have recovered with no neurological deficits. The likely explanation is that the body can limit the intracellular acidosis by transferring bicarbonate from the extracellular space into the cell.

LOSS OF SENSITIVITY TO P_{CO_2} WITH LUNG DISEASE

During prolonged hypoventilation caused by certain types of chronic lung disease, an elevated P_{CO_2} occurs simultaneously with a reduced P_{O_2} . In most cases, the elevated P_{CO_2} (acting via the central chemoreceptors) and the reduced (acting via the peripheral chemoreceptors) are *synergistic*; that is, the combined stimulatory effect on respiration exerted by these two inputs together is greater than the sum of their independent effects.

However, some patients with severe chronic lung disease lose their sensitivity to an elevated arterial P_{CO_2} . Chronic retention of carbon dioxide results in an increased generation of hydrogen ions in the brain extracellular fluid, which is eventually neutralized by the influx of bicarbonate across the blood–brain barrier. The additional bicarbonate combines with the excess H^+ , removing it from solution so that it no longer contributes to the free H^+ concentration. As a result, the H^+ concentration in the brain extracellular fluid returns to normal, although P_{CO_2} in the arterial blood and brain extracellular fluid remains high. Because the central chemoreceptors respond to H^+ , not P_{CO_2} , there is no reflex stimulation of the respiratory centres. Consequently, the drive to eliminate carbon dioxide is blunted in such patients; that is, their level of ventilation is low considering their high arterial P_{CO_2} . In these patients, the hypoxic drive to ventilation is the primary respiratory stimulus, whereas in normal individuals the arterial

P_{CO_2} is the dominant factor governing the level of ventilation. Paradoxically, administering oxygen to such patients to relieve the hypoxia can markedly depress ventilation. This leads to acute worsening of carbon dioxide retention because it removes the stimulus to breathe. In addition, administration of oxygen also worsens the mismatching of ventilation to perfusion ($\dot{V}_A/\dot{Q}$ see ▶ Figure 12-31) due to the release of hypoxic vasoconstriction. This increases perfusion to alveoli that are relatively underventilated, thereby leading to an increase in arterial P_{CO_2} . Last, the higher P_{O_2} displaces carbon dioxide (reverse Haldane effect) from haemoglobin, increasing arterial P_{CO_2} . Thus, supplemental oxygen must be administered cautiously to patients with chronic pulmonary diseases.

Acid–base balance

Changes in arterial H^+ concentration cannot influence the central chemoreceptors because H^+ does not readily cross the blood–brain barrier. However, the carotid chemoreceptors do respond to fluctuations in arterial H^+ concentration, in contrast to their weak sensitivity to changes in arterial P_{CO_2} and their unresponsiveness to arterial P_{O_2} until it falls below approximately 60 mmHg.

Any change in arterial P_{CO_2} brings about a corresponding change in the H^+ concentration of the blood as well as of the brain extracellular fluid. These carbon dioxide–induced changes of H^+ in the arterial blood are detected by the peripheral chemoreceptors; the result is a reflex increase in ventilation in response to increased arterial H^+ concentration (decreased pH) and a reflex decrease in response to a decreased arterial H^+ concentration (increased pH). However, these changes in ventilation mediated by the carotid chemoreceptors are far less important than the powerful central chemoreceptor mechanism(s) that adjust ventilation in response to changes in carbon dioxide–generated H^+ concentration.

The peripheral chemoreceptors do play a major role in adjusting ventilation in response to alterations in arterial H^+ concentration unrelated to fluctuations in P_{CO_2} . In many situations, even though P_{CO_2} is normal, arterial H^+ concentration is changed by the addition or loss of noncarbonic acids from the body. For example, arterial H^+ concentration increases during diabetes mellitus because of the addition of excess H^+ -generating keto acids to the blood. A rise in arterial H^+ concentration reflexly stimulates ventilation by means of the carotid chemoreceptors. Conversely, the carotid chemoreceptors reflexly suppress respiratory activity in response to a fall in arterial H^+ concentration resulting from nonrespiratory causes. (Nonrespiratory causes of a change in H^+ are generally referred to as *metabolic*—that is, metabolic acidosis and, rarely, metabolic alkalosis.) Changes in ventilation by this mechanism are extremely important in regulating the body's acid–base balance because they determine how much of the carbon dioxide generated by H^+ is eliminated. The resulting adjustment in the amount of H^+ added to the blood from carbon dioxide can compensate for the metabolic-induced abnormality in arterial H^+ concentration that first elicited the respiratory response. (See Chapter 14 for further details.)

Check Your Understanding 12.14

1. List the potential factors determining the level of breathing at rest, and explain why one is likely the most important.

Effect of exercise on ventilation

Alveolar ventilation may increase up to twentyfold during heavy exercise (90 to 195 L/min) to keep pace with the increased demand for oxygen uptake and carbon dioxide elimination. (Table 12-11 highlights changes in oxygen- and carbon dioxide-related variables during exercise.) The cause of increased ventilation during exercise is still largely speculative. Although it would seem logical that decreased arterial P_{O_2} and increased arterial P_{CO_2} and H^+ would account for the increase in ventilation, this does not appear to be the case.

- Despite the marked increase in oxygen use during exercise, arterial P_{O_2} does not decrease but remains normal or may actually increase slightly, because the increase in alveolar ventilation keeps pace with or even slightly exceeds the elevated rate of oxygen consumption.

- Likewise, despite the marked increase in carbon dioxide production during exercise, arterial P_{CO_2} does not increase but remains normal or even decreases slightly, because the extra carbon dioxide produced is removed as rapidly or even more rapidly by the increase in ventilation.
- During mild or moderate exercise, H^+ concentration does not increase because H^+ -generating carbon dioxide is held constant. During heavy exercise, H^+ concentration does increase somewhat due to the release of H^+ -generating lactic acid into the blood by anaerobic metabolism in the exercising muscles. Even so, the elevation in H^+ concentration resulting from lactic acid formation is not enough to account for the large increase in ventilation that accompanies exercise. This anaerobic production of H^+ is, however, sufficient to cause an increase in alveolar ventilation disproportionate to the production of carbon dioxide; as a result, the person actually hyperventilates (defined as a decrease in arterial P_{CO_2}), and this is responsible for the increase in arterial P_{O_2} during exercise above the anaerobic threshold.

Some investigators argue that the constancy of the three chemical regulatory factors during exercise shows that ventilatory responses to exercise are actually controlled by these

TABLE 12-11 Oxygen- and Carbon Dioxide-Related Variables during Exercise

Oxygen- or Carbon Dioxide-Related Variables	Change	Comment
Oxygen Use	Marked ↑	Active muscles oxidize nutrient molecules more rapidly to meet ↑ energy needs.
Carbon Dioxide Production	Marked ↑	More actively metabolizing muscles produce more carbon dioxide.
Alveolar Ventilation	Marked ↑	By mechanisms not completely understood, alveolar ventilation keeps pace with or even slightly exceeds the increased metabolic demands during exercise.
Arterial P_{O_2}	Normal or slight ↑ } Normal or slight ↓ }	Despite a marked ↑ in oxygen use and carbon dioxide production during exercise, alveolar ventilation keeps pace with or even slightly exceeds the elevated rates of oxygen consumption and carbon dioxide production.
Arterial P_{CO_2}		
Oxygen Delivery to Muscles	Marked ↑	Although arterial P_{CO_2} remains normal, oxygen delivery to muscles is greatly ↑ by the ↑ blood flow to exercising muscles, accomplished by ↑ cardiac output coupled with local vasodilation of arterioles in active muscles.
Oxygen Extraction by Muscles	Marked ↑	↑ use of oxygen ↓ the P_{O_2} at the tissue level, which results in more oxygen unloading from haemoglobin; this is enhanced by ↑ P_{CO_2} , and ↑ H^+ and ↑ temperature.
Carbon Dioxide Removal from Muscles	Marked ↑	↑ blood flow to exercising muscles removes the excess carbon dioxide produced by these more actively metabolizing tissues.
Arterial H^+ Concentration		
Mild-to-Moderate Exercise	Normal	Because carbonic acid-generating carbon dioxide is held constant in arterial blood, arterial H^+ concentration does not change.
Heavy Exercise	Modest ↑	In heavy exercise, when muscles resort to anaerobic metabolism, lactic acid is added to the blood.

factors—particularly by P_{CO_2} , because it is normally the dominant variable controlled at rest. According to this reasoning, how else could alveolar ventilation be increased in exact proportion to carbon dioxide production, thereby keeping the P_{CO_2} constant? This proposal, however, cannot account for the observation that during heavy exercise, alveolar ventilation often increases more than carbon dioxide production increases, thereby actually causing a slight decline in P_{CO_2} . Also, ventilation increases abruptly at the onset of exercise (within seconds), long before changes in arterial blood gases could influence the respiratory centre (which requires a matter of minutes).

Other factors that may increase ventilation during exercise

A number of other factors, including the following, play a role in the ventilatory response to exercise:

1. *Reflexes originating from body movements.* Joint and muscle receptors (mechanoreceptors) excited during muscle contraction reflexly stimulate the respiratory centre, abruptly increasing ventilation. Golgi tendon organs, muscle spindles, and skeletal joint receptors send afferent signals to the sensory cortex, which then relays the information to the respiratory centre. Even passive movement of the limbs (e.g., someone else alternately flexing and extending a person's knee) may increase ventilation several fold through activation of these receptors, although no actual exercise is occurring. Thus, the mechanical events of exercise are believed to play an important role in coordinating respiratory activity with the increased metabolic requirements of the active muscles.
2. *Increase in body temperature.* Much of the energy generated during muscle contraction is converted to heat rather than to actual mechanical work. Heat-loss mechanisms, such as sweating, frequently cannot keep pace with the increased heat production that accompanies increased physical activity, so body temperature often rises slightly during exercise (p. 711). Because raised body temperature stimulates ventilation, this exercise-related heat production undoubtedly contributes to the respiratory response to exercise. For the same reason, increased ventilation often accompanies a fever.
3. *Epinephrine release.* The adrenal medullary hormone epinephrine also stimulates ventilation. The level of circulating epinephrine rises during exercise in response to the sympathetic nervous system discharge that accompanies increased physical activity.
4. *Impulses from the cerebral cortex.* Especially at the onset of exercise, the motor areas of the cerebral cortex are believed to simultaneously stimulate the medullary respiratory neurons and activate the motor neurons of the exercising muscles. This is similar to the cardiovascular

adjustments initiated by the motor cortex at the onset of exercise. In this way, the motor control region of the brain elicits increased ventilatory and circulatory responses to support the increased physical activity it is about to orchestrate. These anticipatory adjustments are feedforward regulatory mechanisms; that is, they occur *before* any homeostatic factors actually change. This contrasts with the more common case in which regulatory adjustments to restore homeostasis take place *after* a factor has become altered.

Experiments in animals show that stimulation of a region of the brain that elicits locomotion also increases ventilation. But if an experimenter paralyzes the animal (and places it on mechanical ventilation), the same stimulation now elicits activity in the nerves projecting to the leg muscles and to the diaphragm. This activation occurs in the absence of any movement and, therefore, of any feedback from the periphery.

None of these factors or combinations of factors fully explains the abrupt and profound effect exercise has on ventilation, nor can they completely account for the high degree of correlation between respiratory activity and the body's needs for gas exchange during exercise.

Apnea and dyspnea

Apnea is the transient interruption of ventilation, with breathing resuming spontaneously. If breathing does not resume, the condition is called **respiratory arrest**. Because ventilation normally decreases and the central chemoreceptors are less sensitive to the P_{CO_2} drive during sleep, especially paradoxical sleep (p. 134), apnea (known as **sleep apnea**) is most likely to occur during this time.

DYSPNEA

People who have dyspnea have the subjective sensation that they are not getting enough air; that is, they feel short of breath. *Dyspnea* (also called *breathlessness*) is the anguish associated with the unsatiated desire for more adequate ventilation. It often accompanies the laboured breathing characteristic of obstructive lung disease or the pulmonary oedema associated with congestive heart failure. In contrast, during exercise, a person can breathe very hard without experiencing dyspnea, because such exertion is not accompanied by a sense of anxiety over the adequacy of ventilation. Surprisingly, dyspnea is not directly related to chronic elevation of arterial P_{CO_2} or reduction of P_{O_2} . The subjective feeling of air hunger may occur even when alveolar ventilation and the blood gases are normal. Some people experience dyspnea when they *perceive* that they are short of air, even though this is not actually the case, such as in a crowded elevator. A generally accepted theory, first advanced by E.J.M. Campbell (1925–2004) at McMaster University, is that the discrepancy between the respiratory drive—the “want”—and the tidal volume achieved—the “get”—accounts for the disabling sensation of dyspnea.

Many people with chronic obstructive pulmonary disease (COPD) experience dyspnea, especially when they increase their ventilation during exercise. Because expiration is difficult (the obstruction), they do not have time to breathe out completely to functional residual capacity, even to the elevated functional residual capacity characteristic of people with COPD. Consequently, they inhale more air than they exhale and, over time, they increase their end-expiratory lung volume, a process referred to as *dynamic hyperinflation* (p. 517). This limits how much they can inspire because the inspiratory reserve volume (the difference between total lung capacity and end-inspired lung volume) decreases. Thus, despite the disease being one that limits expiration, these people complain of an inability to breathe in adequately, especially during exercise or acute exacerbations of COPD. A fall in the inspiratory reserve volume below a certain value, typically about 0.8 L, is associated with the onset of severe dyspnea. One of the world's leading researchers in this area is Denis O'Donnell at Queen's University, Kingston, Ontario.

Chapter in Perspective: Focus on Homeostasis

The respiratory system contributes to homeostasis by obtaining oxygen from, and eliminating carbon dioxide to, the external environment. All cells ultimately need an adequate supply of oxygen to use in oxidizing nutrient molecules to generate ATP. Adult brain cells that depend on a continual supply of oxygen die if deprived of oxygen for more than four minutes. Even cells that can resort to anaerobic metabolism for energy production, such as strenuously exercising muscles, can do so only transiently by incurring an oxygen deficit that ultimately must be made up during the period of excess post-exercise oxygen consumption.

As a result of these energy-yielding metabolic reactions, the body produces large quantities of carbon dioxide that must be eliminated. Because carbon dioxide and water form carbonic acid, adjustments in the rate of carbon dioxide elimination by the respiratory system are important in regulating acid-base balance in the internal environment.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-48)

- Breathing is accomplished by alternate contraction and relaxation of muscles within the lung tissue. (*True or false?*)
- Normally the alveoli empty completely during maximal expiratory efforts. (*True or false?*)
- Alveolar ventilation does not always increase when pulmonary ventilation increases. (*True or false?*)
- Oxygen and carbon dioxide have equal diffusion coefficients. (*True or false?*)
- Haemoglobin has a higher affinity for oxygen than for any other substance. (*True or false?*)
- Rhythmicity of breathing is brought about by pacemaker activity displayed by the respiratory muscles. (*True or false?*)
- The expiratory neurons send impulses to the motor neurons controlling the expiratory muscles during normal quiet breathing. (*True or false?*)
- The three forces that tend to keep the alveoli open are _____, _____, and _____.
- The two forces that promote alveolar collapse are _____ and _____.
- _____ is a measure of the magnitude of change in lung volume accomplished by a given change in the transmural pressure gradient.
- _____ is the phenomenon of the lungs snapping back to their resting size after having been stretched.
- _____ is the erythrocytic enzyme that catalyzes the conversion of CO_2 into HCO_3^- .
- Which reaction takes place in the pulmonary capillaries?

- Indicate the oxygen and carbon dioxide partial pressure relationships important in gas exchange by circling > (*greater than*), < (*less than*), or = (*equal to*) as appropriate in each of the following statements:
 - P_{O_2} in blood entering the pulmonary capillaries is (>, <, or =) P_{O_2} in the alveoli.
 - P_{CO_2} in blood entering the pulmonary capillaries is (>, <, or =) P_{CO_2} in the alveoli.
 - P_{O_2} in the alveoli is (>, <, or =) P_{O_2} in blood leaving the pulmonary capillaries.
 - P_{CO_2} in the alveoli is (>, <, or =) P_{CO_2} in blood leaving the pulmonary capillaries.
 - P_{O_2} in blood leaving the pulmonary capillaries is (>, <, or =) P_{O_2} in blood entering the systemic capillaries.
 - P_{CO_2} in blood leaving the pulmonary capillaries is (>, <, or =) P_{CO_2} in blood entering the systemic capillaries.
 - P_{O_2} in blood entering the systemic capillaries is (>, <, or =) P_{O_2} in the tissues.
 - P_{CO_2} in blood entering the systemic capillaries is (>, <, or =) P_{CO_2} in the tissues.
 - P_{O_2} in the tissues is (>, <, or approximately =) P_{O_2} in blood leaving the systemic capillaries.
 - P_{CO_2} in the tissues is (>, <, or approximately =) P_{CO_2} in blood leaving the systemic capillaries.
 - P_{O_2} in blood leaving the systemic capillaries is (>, <, or =) P_{O_2} in blood entering the pulmonary capillaries.
 - P_{CO_2} in blood leaving the systemic capillaries is (>, <, or =) P_{CO_2} in blood entering the pulmonary capillaries.

15. Using the answer code on the right, indicate which chemoreceptors are being described:

- | | |
|--|---|
| ___ 1. stimulated by an arterial P_{O_2} of 80 mmHg | (a) peripheral chemoreceptors |
| ___ 2. stimulated by an arterial P_{O_2} of 55 mmHg | (b) central chemoreceptors |
| ___ 3. directly depressed by an arterial of 55 P_{O_2} mmHg | (c) both peripheral and central chemoreceptors |
| ___ 4. weakly stimulated by an elevated arterial P_{CO_2} | (d) neither peripheral nor central chemoreceptors |
| ___ 5. strongly stimulated by an elevated brain ECF H^+ concentration induced by an elevated arterial P_{CO_2} | |
| ___ 6. stimulated by an elevated arterial H^+ concentration | |

Written Questions

1. Distinguish between internal and external respiration. List the steps in external respiration.
2. Describe the two anatomical components of the respiratory system. What is the site of gas exchange?
3. Describe the two physical processes involved in ventilation/gas exchange.
4. Compare atmospheric, alveolar, and pleural pressures.
5. Why are the lungs normally stretched even during expiration?
6. Explain why air enters the lungs during inspiration and leaves during expiration.
7. Why does a forced maximal expiration take much longer than a forced maximal inspiration?
8. Why is inspiration normally active and expiration normally passive?
9. Why does airway resistance become an important determinant of flow in chronic obstructive pulmonary disease?
10. Explain pulmonary elasticity in terms of compliance and elastic recoil.
11. State the source and function of pulmonary surfactant.
12. Define the various lung volumes and capacities.
13. Compare pulmonary ventilation and alveolar ventilation. What is the consequence of anatomic and alveolar dead space?
14. What determines the partial pressures of a gas in air and in blood?
15. List how oxygen and carbon dioxide are transported in blood.
16. What is the primary factor that determines the percent haemoglobin saturation? What is the significance of the plateau and the steep portions of the O_2 -Hb dissociation curve?
17. How does haemoglobin promote the net transfer of oxygen from the alveoli to the blood?

18. Explain the Bohr and Haldane effects.

19. Define the following: *hypoxic hypoxia*, *anemic hypoxia*, *circulatory hypoxia*, *histotoxic hypoxia*, *hypercapnia*, *hypocapnia*, *hyperventilation*, *hypoventilation*, *hyperpnea*, *apnea*, and *dyspnea*.
20. Distinguish between the DRG and the VRG.
21. What brain region establishes the rhythmicity of breathing?
22. Describe the functional significance of the discharge properties of motor neurons of inspiratory pump muscles and of the skeletal muscles of the upper airway.

Quantitative Exercises (Solutions in Appendix E, p. A-48)

1. The two curves in > Figure 12-37 show partial pressures for oxygen and carbon dioxide at various alveolar ventilations. These curves can be calculated from the following two equations:

$$P_{A_{O_2}} = P_{I_{O_2}} - (\dot{V}_{O_2} / \dot{V}_A) \times 863 \text{ mmHg}$$

$$P_{A_{CO_2}} = (\dot{V}_{CO_2} / \dot{V}_A) \times 863 \text{ mmHg}$$

2. In these equations, $P_{A_{O_2}}$ equals the partial pressure of oxygen in the alveoli; $P_{A_{CO_2}}$ equals the partial pressure of carbon dioxide in the alveoli; $P_{I_{O_2}}$ equals the partial pressure of oxygen in the inspired air; $\dot{V}_{O_2}$ equals the rate of oxygen consumption by the body; $\dot{V}_{CO_2}$ equals the rate of carbon dioxide production by the body; $\dot{V}_A$ equals the alveolar ventilation; and 863 mmHg is a constant that accounts for atmospheric pressure and temperature.
3. John is training for a marathon tomorrow and just ate a meal of pasta (assume this is pure carbohydrate, which is metabolized with an R of 1). His alveolar ventilation ($\dot{V}_A$) is 3.0 L/min, and he is consuming oxygen at a rate of 300 mL/min. What is his $P_{A_{CO_2}}$?
4. Assume you are flying in an airplane that is cruising at 5500 m (18 000 ft.), where the pressure outside the plane is 380 mmHg.
 - a. Calculate the P_{O_2} in the air outside the plane, ignoring water vapour pressure.
 - b. If the plane depressurized, what would be your $P_{A_{O_2}}$? Assume that the ratio of your oxygen consumption ($\dot{V}_{O_2}$) to ventilation does not change (i.e., equals 0.06), and note that under these conditions the constant in the equation that accounts for atmospheric pressure and temperature decreases from 863 to 431.5 mmHg.
 - c. Calculate your $P_{A_{CO_2}}$, assuming that your carbon dioxide production ($\dot{V}_{CO_2}$) and alveolar ventilation ($\dot{V}_A$) remained unchanged at 200 mL/min and 4.2 L/min, respectively.
5. A student has a tidal volume of 350 mL. While breathing at 12 breaths/min, her alveolar ventilation ($\dot{V}_A$) is 80 percent of her minute ventilation ($\dot{V}_E$). What is the volume of her anatomic dead space?

POINTS TO PONDER

(Explanations on p. A-48)

1. Why is it important that airplane interiors are maintained at, for example, a pressure equivalent to that at an altitude of 2100 m when the plane is at an altitude of 12 000 m? Explain the physiological value of using oxygen masks when the pressure in the airplane interior cannot be maintained.
2. Would hypercapnia accompany the hypoxia produced in each of the following situations? Explain why or why not.
 - a. cyanide poisoning
 - b. pulmonary oedema
 - c. restrictive lung disease
 - d. high altitude
 - e. severe anaemia
 - f. congestive heart failure
 - g. obstructive lung disease
3. If a person lives 1.6 km above sea level in Denver, Colorado, where the atmospheric pressure is 630 mmHg,

what would the P_{O_2} of the inspired air be once it is humidified in the upper airway?

4. Based on what you know about the control of respiration, explain why it is dangerous to voluntarily hyperventilate to lower the arterial P_{O_2} before going underwater. The purpose of the hyperventilation is to stay under longer before P_{O_2} rises above normal and drives the swimmer to surface for a breath of air.
5. If a person whose alveolar membranes are thickened by disease has an alveolar P_{O_2} of 100 mmHg and an alveolar P_{CO_2} of 40 mmHg, which of the following values of systemic arterial blood gases are most likely?

$$P_{O_2} = 105 \text{ mmHg}, P_{CO_2} = 35 \text{ mmHg}$$

$$P_{O_2} = 100 \text{ mmHg}, P_{CO_2} = 40 \text{ mmHg}$$

$$P_{O_2} = 90 \text{ mmHg}, P_{CO_2} = 45 \text{ mmHg}$$

6. If the person is administered 100 percent oxygen, will the arterial P_{O_2} increase, decrease, or remain the same? Will the arterial P_{CO_2} increase, decrease, or remain the same?

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-49)

1. Keith M., a former heavy cigarette smoker, has severe emphysema. How does this condition affect his airway resistance? How does this change in airway resistance influence Keith's inspiratory and expiratory efforts? Describe how his respiratory muscle activity and

intra-alveolar pressure changes compare with normal to accomplish a normal tidal volume. How would his spirogram compare with that of a normal individual? What influence would Keith's condition have on gas exchange in his lungs? What blood-gas abnormalities are likely present? Would it be appropriate to administer oxygen to Keith to relieve his hypoxia?

Normal: Exercise

When exercise begins, are the cardiovascular (e.g., heart rate, blood pressure, and cardiac output) and respiratory (e.g., tidal volume and breathing frequency) systems coordinated to meet the increased metabolic needs of the skeletal muscles? Do these two systems respond independently or together? If they respond together, is there a common control system? The answers to these questions have taken many years to unravel (Johansson J.E. [1895]. *Scandinavian Archives of Physiology*, 5: 20–66) and continue to be studied. However, it is generally agreed that these two systems respond as one (the cardiorespiratory system), and are under a common control—central command. We now explore the reasoning behind the concept of central command.

Evidence of Cardiorespiratory Integration during Exercise

There is a parallel between an increase in ventilation and cardiac output and an increase in oxygen uptake, which suggests a common control system and integrated response. The integrators consist of motor and sensory areas of the brain, with the brain stem linking respiratory and cardiovascular controls. Neural outflow from the motor cortex initiates exercise as well as changes in respiration and cardiovascular function; this ties together all three systems: skeletal muscle, respiratory, and cardiovascular. This activation is a feedforward process.

Central command is demonstrated by the fact that the ventilatory and cardiac responses are similar over a range of submaximal exercise intensities. Both ventilation and cardiac output increase abruptly at the onset of exercise, followed by a more gradual increase over the next one to three minutes, until a steady state is achieved between minutes three and five. How quickly a steady state is attained in a healthy individual depends on exercise intensity, movement economy, and fitness level. *Economy* is considered the amount of energy required to exercise at a specific intensity. If one person uses less energy while exercising at the same intensity as another person, the person using less energy is said to be more economical (their economy is greater), or efficient. At the termination of exercise, ventilation and cardiac output both rapidly decline in the first minute, followed by a more gradual decline over the next several minutes.

The cardiorespiratory adjustments to exercise result from the integration of both neural and humoral factors (i.e., blood and body fluid-borne factors), but the neural component is more important to overall control and integration. Signals from the brain to the active muscles—the motor outflow called central command—pass through the reticular activating system of the medulla, and this command signal from the motor cortex activates (irradiates) the respiratory and cardiovascular control centres in the medulla. The theory of central command gained

momentum through research conducted by August Krogh and Johannes Lindhard ([1913–14]. *Journal of Physiology*, 47: 112–36), who believed that the exercise-induced rise in heart rate and ventilation was produced by irradiation (neural impulses) from the motor cortex. More specifically, the supraspinal centres believed to be involved in central command are the primary motor cortex, posterior hypothalamus, subthalamus, and mesencephalon. We next examine these neural elements more closely.

The Central and Peripheral Neural Elements

During exercise, there is a major neural outflow to the skeletal, cardiovascular, and respiratory systems. Central command produces descending neural activation of motor nerves, causing muscular contraction and movement and also stimulation of the supraspinal centres responsible for autonomic nervous system (ANS) outflow to the periphery. As the muscle contractions associated with exercise begin, descending signals from supraspinal centres—in conjunction with afferent neural feedback from activated proprioceptors (e.g., muscle spindles), chemoreceptors, baroreceptors, and metaboreceptors—act to control and modulate the cardiorespiratory system in relation to muscle activation and exercise intensity.

Supraspinal activation of the ANS increases heart rate and myocardial contractility (facilitating the Frank–Starling mechanism); vasodilates peripheral muscle arterioles; and vasoconstricts nonworking vasculature (e.g., in the stomach). However, central command has little direct influence on the sympathetic nervous system (SNS) and primarily acts through withdrawal of parasympathetic tone. Thus, the initial increase in heart rate occurs via the withdrawal of parasympathetic (vagal) tone. Sympathetic activity is influenced more by neural reflexes (e.g., baroreceptors) during exercise. The activation (irradiation) hypothesis of central command is considered a feedforward mechanism, which accelerates the cardiorespiratory variables until they are turned off or modified by feedback.

Afferent feedback from proprioceptors (e.g., muscle spindles) in the active skeletal muscles is relayed via spinal afferents to central command. This verifies that exercise has begun and skeletal muscle metabolism has increased, which changes the chemical milieu of muscle, interstitial fluid, and blood. The central (throughout the medulla) and peripheral (aortic and carotid bodies) chemoreceptors, along with metaboreceptors in skeletal muscles respond to changes in the levels of carbon dioxide and H^+ , by-products of metabolism, thereby providing feedback for modulation of central command; this feedback is likely one of the most important modifiers of cardiorespiratory function.

The arterial P_{O_2} and P_{CO_2} are typically within normal range below the anaerobic threshold, and during this time the central chemoreceptors dominate. The central chemoreceptors

are protected by the blood–brain barrier, but recall that carbon dioxide can readily cross the blood–brain barrier and act on the chemoreceptors by increasing the local concentration of H^+ . During submaximal steady-state exercise, respiration is adjusted in parallel to skeletal muscle production of carbon dioxide.

In contrast, this is not the case during transitions from rest to exercise and during intense (but still submaximal) exercise when the peripheral chemoreceptors and muscle metaboreceptors are stimulated. The basis for this stimulation of ventilation is unclear because, below the anaerobic threshold, arterial P_{O_2} and P_{CO_2} do not change. (Note, however, that taking a blood sample to measure P_{O_2} and P_{CO_2} eliminates any respiration-related oscillations in P_{O_2} and P_{CO_2} ; if the receptors are sensitive to the rate of change of P_{O_2} and P_{CO_2}/H^+ during the respiratory cycle, and these changes are faster and larger during exercise, then we could not, on the basis of a blood sample drawn over several seconds, detect their contributions to the increase in ventilation.) Exercising muscles release potassium (K^+) that activates the peripheral chemoreceptors; K^+ could therefore be an important factor contributing to the increase in ventilation. Above the anaerobic threshold, the production of metabolic acids (e.g., lactic acid) stimulates the peripheral chemoreceptors. As a result, the subject hyperventilates; arterial P_{O_2} increases and P_{CO_2} decreases, blunting the response to metabolic acids. The peripheral chemoreceptors provide feedback to the respiratory centres to increase respiration. Activated central and peripheral chemoreceptors and/or muscle metaboreceptors communicate with central command to modulate respiration. In essence, chemoreceptors provide feedback for control of breathing (rate and depth of respiration) by central command, as they detect mismatches between respiration and muscular work.

Similarly, activation of the baroreceptors provides afferent feedback to central command to modify heart rate, on a beat-to-beat basis, and vascular resistance through the SNS. Recall that baroreceptors are mechanoreceptors that sense change in pressure within the walls of the vessels. Changes in pressure in the aortic arch and carotid sinus are detected by mechanoreceptors and signal central command to adjust cardiac vagal tone and SNS outflow accordingly, which change heart rate and the diameters of the arterioles that determine peripheral resistance. Likewise, the cardiopulmonary baroreflex senses changes in blood volume and filling pressure in the pulmonary arteries and veins. Again, afferent feedback to central command allows for the appropriate modification of vagal tone and SNS outflow to adjust heart rate and the diameters of arterioles, which increases or decreases blood pressure.

Note that systolic and arterial pulse pressures increase during rhythmical dynamic exercise (e.g., running), and there is an adjustment of the baroreflex to accommodate the higher pressure. This is accomplished by resetting the baroreflex to regulate arterial blood pressure at a higher operating point (new set point) during exercise. If the set point of the baroreflex were not increased, the ANS could not make the necessary cardiovascular adjustments; instead, the baroreceptors would attempt to reduce cardiac output, heart rate, and blood pressure, all of which would oppose the needed responses to exercise. The resetting of the arterial baroreflex is believed to be accomplished by central command.

It can be difficult to definitively distinguish between the central and peripheral neural contributions to the cardiorespiratory

response to exercise. However, many animal and human studies of these responses to exercise support the theory of central command initiating and coordinating the cardiorespiratory responses to exercise, with the peripheral elements providing information to central command to modify its control.

Peripheral Humoural Elements

The humoural factors that influence skeletal muscle blood flow, cardiac output, and ventilation are metabolic vasodilators (e.g., ADP) and hormones (e.g., epinephrine). The focus here will be on the metabolic vasodilators that influence muscle metaboreceptors. Carbon dioxide has already been mentioned and will not be discussed further. Accordingly, the focus of this section is on the response of skeletal muscle metaboreceptors to chemical factors other than carbon dioxide.

The muscle metaboreceptors are local sensors that monitor chemical changes. For example, if oxygen delivery to the quadriceps muscle is inadequate at the onset of exercise, the concentrations of chemical factors (e.g., AMP and ADP) increase in the quadriceps muscle, interstitial fluid, and blood, causing local vasodilation. Local interstitial factors thought to influence metaboreceptor activity include adenosine, AMP, ADP, Pi, H^+ , lactic acid, bradykinin, prostaglandins, K^+ , and nitric oxide (NO); however, adenosine is considered a weak vasodilator. These interstitial factors stimulate the nerve endings surrounding the skeletal muscle fibres; activation of their afferents influences the ANS.

The local changes are relayed to central command and modify ANS activity. The resulting increase in SNS outflow vasoconstricts blood vessels in nonworking tissue but vasodilates those in working tissue. Some experimental evidence even suggests that the resulting increase in SNS outflow from the stimulation of muscle metaboreceptors increases heart rate via β -adrenergic modulation. Nevertheless, increased vasodilation associated with stimulation of metaboreceptors is specific to the site of working muscle, making this response local. The end result ensures sufficient delivery of oxygen to active muscle tissue, while reducing delivery of oxygen to tissues not essential to exercise.

The preceding discussion supports the concept that at the onset of exercise, neural outflow from central command increases, and this activates the cardiorespiratory system. Feedback from central and peripheral chemoreceptors, metaboreceptors, baroreceptors, and peripheral proprioceptors help match cardiorespiratory output and muscle perfusion with exercise intensity and the mass of muscle activated. This matching supports the delivery of blood, oxygen, and other nutrients (e.g., glucose) to the working limb muscles and the removal of metabolic by-products (e.g., H^+).

Abnormal: Obstructive Sleep Apnea (OSA)

Obstructive sleep apnea (OSA) is a disease that illustrates the interactions between the respiratory and cardiovascular systems. Although the problem is respiratory—cessation of breathing for a few seconds or up to a minute as many as 500 times a night—the pathological consequences are primarily cardiovascular.

OSA occurs in approximately 4 percent of males and 2 percent of females. Snoring, a frequent precursor to OSA, is even more common. Contributing factors include age and obesity, mostly because the extra weight, especially in the neck, predisposes the upper airway to collapse. This effect is exacerbated when the neural drive to the muscles in the upper airway that dilate it during inspiration decreases during sleep. As a result, the increased inspiratory efforts can suck the upper airway closed, an effect exacerbated by surface tension between the opposing walls of the collapsed airway.

The Effects of OSA

The effects of OSA have profound effects on health. Each episode of OSA-induced asphyxia (particularly the hypoxia) stimulates the sympathetic nervous system, activating the heart and vascular smooth muscle at a time when oxygen delivery to tissues decreases because of the asphyxia. This is especially stressful to the heart because even at rest it consumes approximately 70 percent of the oxygen delivered to it. Therefore, unless blood flow to the heart increases, there is a risk that it will receive insufficient oxygen during the apnea to meet its increased metabolic demands—caused by the surge in sympathetic activity—and the increase in afterload—caused by peripheral vasoconstriction. Moreover, if the asphyxia is severe enough, cardiac arrhythmias can occur, possibly leading to a heart attack. These factors may account for the increased rates of death at night, typically attributed to heart attacks, reported in patients with OSA.

Aside from these acute but repeated effects of OSA, there are insidious chronic effects. Over time, the acute and repeated episodes of increases in sympathetic activity become permanent (chronic), persisting even when the individuals are awake. The

resulting effects on the heart and vasculature (the walls of the blood vessels become stiffer) include hypertension, a major factor causing heart attacks and strokes. (That obstructive sleep apnea *causes*, and is not just associated with, hypertension was first demonstrated using ingenious experiments in dogs by a Toronto group headed by E.A. Phillipson: D. Brooks et al. [1997]. *Journal of Clinical Investigation*, 99: 106–109.) Moreover, recent evidence shows that OSA increases the coagulability of the blood. Both hypertension and hypercoagulability, along with a host of others factors (including diabetes—often caused by obesity) contribute to, if not cause, the high rates of myocardial infarctions and strokes in patients with OSA. Not surprisingly, the cost to the Canadian healthcare system is high—about double that of age-matched controls (approximately \$4000 versus \$2000) over the 10 years before a diagnosis of OSA—because of the associated comorbidities (Ronald, J., et al. [1998]. *Sleep Research Online*, 1: 71–74). This is true even if one compares obese individuals with OSA to weight-matched controls without OSA (Banno, K., et al. [2009]. *Sleep*, 32: 247–52).

Treatment of OSA

Treatment of OSA is relatively straightforward. The patient wears a mask that blows air into the airway at a pressure slightly above atmospheric pressure; this is called *continuous positive airway pressure* (CPAP). The pressure splints the airway open, preventing the recurrent episodes of airway collapse and, therefore, apnea. Unfortunately, many people have difficulty tolerating the device, and so adherence can be low. Treating OSA will become increasingly important as the incidence of obesity continues to increase as the population ages.

Urinary system

Homeostasis

The urinary system contributes to homeostasis by helping regulate the volume, electrolyte composition, and pH of the internal environment and by eliminating metabolic waste products.

Homeostasis is essential for survival of cells

Cells make up body systems

Kidney glomeruli

The survival and proper functioning of cells depend on the maintenance of stable concentrations of salt, acids, and other electrolytes in the internal fluid environment.

Cell survival also depends on continual removal of toxic metabolic wastes that cells produce as they perform life-sustaining chemical reactions. The kidneys play a major role in maintaining homeostasis by regulating the concentration of many plasma constituents, especially electrolytes and water, and by eliminating all

metabolic wastes (except carbon dioxide, which is removed by the lungs). As plasma repeatedly filters through the kidneys, they retain constituents of value for the body and eliminate undesirable or excess materials in the urine. Of special importance is the kidneys' ability to regulate the volume and osmolarity (solute concentration) of the internal fluid environment by controlling salt and water balance. Also crucial is their ability to help regulate pH by controlling elimination of acid and base in the urine.

Clinical Connections

Jacob is 45 years old and an avid cyclist. On a daily basis, he cycles to and from work, a trip of 25 km each way. For the past two weeks, the average daytime high has exceeded 27°C. While mowing his lawn on yet another hot and sunny Saturday, he suddenly had an intense pain in his lower left side that radiated around his lower back. Upon arriving at the emergency room, the intensity of the pain was making him feel nauseous, and he was having problems sitting comfortably. Blood and urine samples were taken. His urine sample had a pinkish hue to it and upon analysis was found to have an osmolality of 1200 mOsm/l and contained small calcium oxalate crystals. Suspecting kidney stones as the source of the pain, an abdominal CT was ordered. The diagnosis of kidney stones was confirmed as the CT scan showed a few stones of varying size in his left kidney. He was given medication to help with the pain and instructed to drink lots of water to help pass the stones.

13.1 Introduction

Exchanges between the cells and the ECF could notably alter the composition of the ECF if there were no mechanisms to keep it stable.

The kidneys

The kidneys are involved in homeostatic function, assisting in electrolyte regulation (concentrations), acid–base balance, blood volume control, and blood pressure control. This is achieved both independently and through coordination with other organs; especially those of the endocrine system (Chapter 6).

The kidneys, controlled by hormonal and neural input, are the organs primarily responsible for maintaining the stability of ECF volume, electrolyte composition, and osmolarity (solute concentration). The kidneys maintain water and electrolyte balance within a narrow range, despite a wide range of intake and losses of electrolytes through other avenues. Kidneys not only adjust for wide variations in the ingestion of water (H_2O), salt, and other electrolytes, but also adjust urinary output of these ECF constituents to compensate for abnormal losses through heavy sweating, vomiting, diarrhoea, or haemorrhage.

When the ECF has a surplus of water or a particular electrolyte, such as salt (NaCl), it can eliminate the excess in the urine. In a deficit state, the kidneys cannot make up for a depleted constituent, but it can limit further urinary loss of the constituent and conserve it until the person can take in more. Consequently, the kidneys can compensate more efficiently for excesses than for deficits. The kidneys cannot completely halt the loss of a valuable substance in the urine, even though the substance may be in short supply. A prime example is the case of an H_2O deficit. Even if a person is not consuming any H_2O , the kidneys must put out a minimum about 500 mL of H_2O in the urine each day to fill another major role as the body's cleaners. Because H_2O eliminated in the urine is derived from the blood plasma, a person stranded without H_2O eventually urinates to death.

Additionally, the kidneys are the main route for eliminating potentially toxic metabolic wastes and foreign compounds from the body. These wastes cannot be eliminated as solids, and thus must be excreted in solution as waste-filled urine.

OVERVIEW OF KIDNEY FUNCTIONS

The kidneys perform the following functions, most of which help preserve the constancy of the internal fluid environment:

1. *Maintaining H_2O balance in the body* (Chapter 14)
2. *Maintaining the proper osmolarity of body fluids*, primarily through regulating H_2O balance. This is important to prevent osmotic fluxes into or out of the cells, which could lead to detrimental swelling or shrinking of the cells, respectively (Chapter 14).
3. *Regulating the quantity and concentration of most ECF ions*, including sodium (Na^+), chloride (Cl^-), potassium (K^+), calcium (Ca^{2+}), hydrogen ion (H^+), bicarbonate (HCO_3^-), phosphate (PO_4^{3-}), sulphate (SO_4^{2-}), and magnesium (Mg^{2+}). Even minor fluctuations in the ECF concentrations of some of these electrolytes can have profound influences. For example, changes in the ECF concentration of K^+ can potentially lead to fatal cardiac dysfunction (p. 356).
4. *Maintaining proper plasma volume*, which is important in long-term regulation of arterial blood pressure. This is

accomplished through the kidneys' regulatory role in salt (Na^+ and Cl^- ; NaCl) and H_2O balance (Chapter 14).

5. *Helping maintain the proper acid–base balance of the body* by adjusting urinary output of H^+ and HCO_3^- (Chapter 14)
6. *Excreting (eliminating) the end products (wastes) of bodily metabolism*, such as urea, uric acid, and creatinine. These wastes are toxic, especially to the brain.
7. *Excreting many foreign compounds*, such as drugs, food additives, pesticides, and other exogenous non-nutritive materials that have entered the body
8. *Producing erythropoietin*, a hormone that stimulates red blood cell production (Chapter 10)
9. *Producing renin*, an enzymatic hormone that triggers a chain reaction important in salt conservation by the kidneys
10. *Converting vitamin D into its active form* (Chapter 6)

The kidneys and urine

The kidneys are bean-shaped organs, with a concave side that faces medially (see > Figure 13-1a). They are located in the posterior aspect of the abdomen on each side of the spine and surrounded by two layers of fat. The top is approximately at the level of the twelfth thoracic vertebrae. An adult kidney is about 10 cm long, 5 cm wide, 3 cm thick, and weighs about 150 g. The right kidney sits below the liver and the left below the diaphragm.

Above each kidney is an adrenal gland. The size and location of the liver in the abdominal cavity causes the right kidney to be placed slightly lower than the left kidney, and the left kidney to be placed more medial compared with the right. The kidneys lie behind the peritoneum lining of the abdominal cavity. The renal artery, vein, nerves, and ureter are located on the medial side of each kidney. *The outer surface of the kidney is called the renal cortex, and deep to the cortex is the renal medulla.* Urine empties into the renal pelvis, which is the medial inner core of each kidney (> Figure 13-1b). The urine is then channelled into the ureter, a smooth muscle-walled duct that exits at the medial border. The blood supply for each kidney comes from the renal arteries, which branch out from the abdominal aorta.

The **urinary bladder**, which temporarily stores urine, is a hollow, distensible, smooth muscle-walled sac. Periodically, as a result of bladder contraction, urine is emptied from the bladder via the **urethra** to the outside. The urethra in females is straight and short, passing directly from the neck of the bladder to the outside (> Figure 13-2a; see also Figure 17-2). In males, the urethra is much longer and follows a curving course from the bladder to the outside, passing through both the prostate gland and the penis (Figure 13-1a and 13-2b; see also Figure 17-1). The male urethra serves the dual function of providing both a route for eliminating urine from the bladder and a passageway for semen from the reproductive organs. The prostate gland lies below the neck of the bladder and completely encircles the urethra.

Prostatic enlargement, which often occurs during middle to older age, can partially or completely occlude the urethra, impeding the flow of urine.

FIGURE 13-1 The urinary system. (a) The pair of kidneys forms the urine, which the ureters carry to the urinary bladder. Urine is stored in the bladder and periodically emptied to the exterior through the urethra. (b) The kidney consists of an outer, granular-appearing renal cortex and an inner, striated-appearing renal medulla. The renal pelvis at the medial inner core of the kidney collects urine after it is formed. (c) Each kidney has a million nephrons. The two types of these microscopic functional units are shown here, greatly exaggerated, in a medullary renal pyramid capped by a section of renal cortex.

The parts of the urinary system beyond the kidneys merely serve as ductwork to transport urine to the outside. Once formed by the kidneys, urine is not altered in composition or volume as it moves downstream through the rest of the tract.

The nephron

The basic functional unit of the kidney is the nephron. A functional unit is the smallest unit within an organ that is capable of performing all of that organ's functions; for the kidney, that

means the formation of urine. There are more than 1 million nephrons within the cortex and medulla of each healthy human adult kidney. Nephrons regulate water and solute (especially electrolytes) by filtering the blood under pressure and then reabsorbing necessary fluid and molecules back into the blood, and by secreting other unneeded molecules. The main function of the kidneys is to produce urine and by doing so maintain consistency in the ECF composition.

The arrangement of nephrons within the kidneys gives rise to two distinct regions: an outer region called the **renal cortex**,

► **FIGURE 13-2** Comparison of the urethra in females and males. (a) In females, the urethra is straight and short. (b) In males, the urethra, which is much longer, passes through the prostate gland and penis.

► **FIGURE 13-3** A nephron. A schematic representation of a cortical nephron, the most abundant type of nephron in humans

which looks granular, and an inner region, the **renal medulla**, which is made up of striated triangles, the **renal pyramids** (Figure 13-1b and 13-1c).

Knowledge of the structural arrangement of an individual nephron is essential for understanding the distinction between the cortical and medullary regions of the kidney and, more important, for understanding renal function. Each nephron consists of a *vascular component* and a *tubular component*, both of which are intimately related structurally and functionally (► Figure 13-3).

VASCULAR COMPONENT OF THE NEPHRON

The dominant parts of the nephron's vascular component are the **glomeruli** (singular, *glomerulus*). These ball-like tufts of capillaries filter some of the water and solutes from the blood passing through them. This filtered fluid, which is almost identical in composition to plasma, then passes through the nephron's tubular component, where various transport processes convert it into urine.

On entering the kidney, the renal artery subdivides to ultimately form many small vessels known as **afferent arterioles**, one of which supplies each

Overview of Functions of Parts of a Nephron

Vascular component

- **Afferent arteriole**—carries blood to the glomerulus
- **Glomerulus**—a tuft of capillaries that filters a protein-free plasma into the tubular component
- **Efferent arteriole**—carries blood from the glomerulus
- **Peritubular capillaries**—supply the renal tissue; involved in exchanges with the fluid in the tubular lumen

Tubular component

- **Bowman's capsule**—collects the glomerular filtrate
- **Proximal tubule**—uncontrolled reabsorption and secretion of selected substances occur here
- **Loop of Henle of long-looped nephrons**—establishes an osmotic gradient in the renal medulla that is important in the kidney's ability to produce urine of varying concentration
- **Distal tubule and collecting duct**—variable, controlled reabsorption of Na^+ and H_2O and secretion of K^+ and H^+ occur here; fluid leaving the collecting duct is urine, which enters the renal pelvis

Combined vascular/tubular component

- **Juxtaglomerular apparatus**—produces substances involved in the control of kidney function

► **FIGURE 13-4** Glomerulus vasculature

nephron. The afferent arteriole delivers blood to the glomerulus. The glomerular capillaries rejoin to form another arteriole, the **efferent arteriole**, through which blood that was not filtered into the tubular component leaves the glomerulus (Figure 13-3 and ► Figure 13-4). The efferent arterioles are the only arterioles in the body that drain from capillaries. Typically, arterioles break up into capillaries that rejoin to form venules. At the glomerular capillaries, no oxygen or nutrients are extracted from the blood for use by the kidney tissues nor are waste products picked up from the surrounding tissue. Thus, arterial blood enters the glomerular capillaries through the afferent arteriole, and arterial blood leaves the glomerulus through the efferent arteriole.

The efferent arteriole quickly subdivides into a second set of capillaries, the **peritubular capillaries**, which supply the renal tissue with blood and are important in exchanges between the tubular system and blood during conversion of the filtered fluid into urine. These peritubular capillaries, as their name implies, are intertwined around the tubular system (*peri* means “around”). The peritubular capillaries rejoin to form venules that ultimately drain into the renal vein, by which blood leaves the kidney.

TUBULAR COMPONENT OF THE NEPHRON

The nephron’s tubular component is a hollow, fluid-filled tube formed by a

single layer of epithelial cells. Even though the tubule is continuous from its beginning near the glomerulus to its ending at the renal pelvis, it is arbitrarily divided into various segments based on differences in structure and function along its length (Figure 13-3 and ► Figure 13-5). The tubular component begins with **Bowman’s capsule**, an expanded, double-walled invagination that cups around the glomerulus to collect the fluid filtered from the glomerular capillaries.

From the Bowman’s capsule, the filtered fluid passes into the **proximal tubule**, which lies entirely within the cortex and is highly coiled or convoluted throughout much of its course. The next segment, the **loop of Henle**, forms a sharp U-shaped or hairpin loop that dips into the renal medulla. The *descending limb* of the loop of Henle plunges from the cortex into the medulla; the *ascending limb* traverses back up into the cortex. The ascending limb returns to the glomerular region of its own nephron, where it passes through the fork formed by the afferent and efferent arterioles. Both the tubular and vascular cells at this point are specialized to form the **juxtaglomerular apparatus**, a structure that lies next to the glomerulus (*juxta* means “next to”). This specialized region plays an important role in regulating kidney function. Beyond the juxtaglomerular

For better visualization, the nephrons are grossly exaggerated in size, and the peritubular capillaries have been omitted, except for the vasa recta.

► **FIGURE 13-5** Comparison of juxtamedullary and cortical nephrons. The glomeruli of cortical nephrons lie in the outer cortex, whereas the glomeruli of juxtamedullary nephrons lie in the inner part of the cortex next to the medulla. The loops of Henle of cortical nephrons dip only slightly into the medulla, but the juxtamedullary nephrons have long loops of Henle that plunge deep into the medulla. The juxtamedullary nephrons’ peritubular capillaries form hairpin loops known as *vasa recta*.

Why It Matters The Nephron

The nephron is very important to the body's fluid regulation, and thus it is a target for drugs used to treat hypertension (high blood pressure). These drugs, called *diuretics*, inhibit the ability of the nephron to reabsorb water, which then increases the volume of urine produced and excreted each day. Recall that maintaining proper plasma volume is important in long-term regulation of blood pressure, accomplished through the kidneys' regulation of salt and water balance.

apparatus, the tubule once again coils tightly to form the **distal tubule**, which also lies entirely within the cortex. The distal tubule empties into a **collecting duct (tubule)**, with each collecting duct draining fluid from up to eight separate nephrons. Each collecting duct plunges down through the medulla to empty its fluid contents (now converted into urine) into the renal pelvis.

CORTICAL AND JUXTAMEDULLARY NEPHRONS

The two types of nephrons—*cortical nephrons* and *juxtamedullary nephrons*—are distinguished by the location and length of some of their structures (Figure 13-5). All nephrons originate in the cortex, but the glomeruli of **cortical nephrons** lie in the outer layer of the cortex, whereas the glomeruli of **juxtamedullary nephrons** lie in the inner layer of the cortex, next to the medulla. (Note the distinction between *juxtamedullary* nephrons and *juxtaglomerular* apparatus.) The concentration of urine in the kidney is mostly performed by the juxtamedullary nephron. Approximately 80 percent of all nephrons are cortical nephrons; these mostly perform excretory and regulatory functions. The remaining 20 percent are juxtamedullary nephrons, which concentrate and dilute urine. The presence of all glomeruli and associated Bowman's capsules in the cortex is responsible for this region's granular appearance. These two nephron types differ most markedly in their loops of Henle. The hairpin loop of cortical nephrons dips only slightly into the medulla. In contrast, the loop of juxtamedullary nephrons plunges through the entire depth of the medulla. Furthermore, the peritubular capillaries of juxtamedullary nephrons form hairpin vascular loops known as **vasa recta** (straight vessels), which run in close association with the long loops of Henle. In cortical nephrons, the peritubular capillaries do not form vasa recta, but instead entwine around these nephrons' short loops of Henle. As they course through the medulla, the collecting ducts of both cortical and juxtamedullary nephrons run parallel to the ascending and descending limbs of the juxtamedullary nephrons' long loops of Henle and vasa recta. The parallel arrangement of tubules and vessels in the medulla creates this region's striated appearance. More important, as you will see in Section

13.6, this arrangement—coupled with the permeability and transport characteristics of the long loops of Henle and vasa recta—plays a key role in the kidneys' ability to produce urine of varying concentrations, depending on the needs of the body.

The three basic renal processes

Three basic processes are involved in forming urine: *glomerular filtration*, *tubular reabsorption*, and *tubular secretion*. To aid in visualizing the relationships among these renal processes, it is useful to unwind the nephron schematically, as shown in > Figure 13-6.

GLOMERULAR FILTRATION

As blood flows through the glomerulus, protein-free plasma filters through the glomerular capillaries into Bowman's capsule. Normally, about 20 percent of the plasma that enters the glomerulus is filtered. This process, known as **glomerular**

- GF** = **Glomerular filtration**—nondiscriminant filtration of a protein-free plasma from the glomerulus into Bowman's capsule
- TR** = **Tubular reabsorption**—selective movement of filtered substances from the tubular lumen into the peritubular capillaries
- TS** = **Tubular secretion**—selective movement of nonfiltered substances from the peritubular capillaries into the tubular lumen

> **FIGURE 13-6 Basic renal processes.** Anything filtered or secreted but not reabsorbed is excreted in the urine and lost from the body. Anything filtered and subsequently reabsorbed, or not filtered at all, enters the venous blood and is saved for the body.

© 2016 Cengage

filtration, is the first step in urine formation. On average, 125 mL of glomerular filtrate (filtered fluid) are formed collectively through all the glomeruli each minute. This amounts to 180 L (about 47.5 gallons) each day. Considering that the average plasma volume in an adult is 2.75 L, this means that the kidneys filter the entire plasma volume about 65 times per day. If everything filtered passed out in the urine, the total plasma volume would be urinated in less than half an hour! This does not happen, however, because the kidney tubules and peritubular capillaries are intimately related throughout their lengths, so that materials can be transferred between the fluid inside the tubules and the blood within the peritubular capillaries.

TUBULAR REABSORPTION

As the filtrate flows through the tubules, substances of value to the body are returned to the peritubular capillary plasma. This selective movement of substances from inside the tubule (the tubular lumen) into the blood is called **tubular reabsorption**. Reabsorbed substances are not lost from the body in the urine, but instead are carried by the peritubular capillaries to the venous system and then to the heart to be recirculated. Of the 180 L of plasma filtered per day, 178.5 L, on average, are reabsorbed. The remaining 1.5 L left in the tubules pass into the renal pelvis to be eliminated as urine. In general, substances the body needs to conserve are selectively reabsorbed, whereas unwanted substances that must be eliminated stay in the urine.

TUBULAR SECRETION

The third renal process, **tubular secretion**, is the selective transfer of substances from the peritubular capillary blood into the tubular lumen. It provides a second route for substances to enter the renal tubules from the blood, the first being by glomerular filtration. Only about 20 percent of the plasma flowing through the glomerular capillaries is filtered into Bowman's capsule; the remaining 80 percent flows on through the efferent arteriole into the peritubular capillaries. In contrast, tubular secretion provides a mechanism for more rapid elimination of selected substances from the plasma. This is accomplished by extracting an additional quantity of a particular substance from the 80 percent of unfiltered plasma in the peritubular capillaries and adding it to the quantity of the substance already present in the tubule as a result of filtration.

URINE EXCRETION

Urine excretion is the elimination of substances from the body in the urine. It is not really a separate process but the result of the first three processes. All plasma constituents filtered or secreted but not reabsorbed remain in the tubules and pass into the renal pelvis to be excreted as urine and eliminated from the body (Figure 13-6). Note that anything filtered and subsequently reabsorbed, or not filtered at all, enters the venous blood from the peritubular capillaries and is therefore conserved for the body instead of being excreted in urine, despite passing through the kidneys.

THE BIG PICTURE OF THE BASIC RENAL PROCESSES

Glomerular filtration is largely an indiscriminate process. With the exception of blood cells and plasma proteins, all constituents within the blood—water, nutrients, electrolytes, wastes, and so on—nonselectively enter the tubular lumen as a bulk unit during filtration. That is, of the 20 percent of the plasma filtered at the glomerulus, everything in that part of the plasma enters Bowman's capsule, except for the plasma proteins. The highly discriminating tubular processes then work on the filtrate to return to the blood a fluid that has the composition and volume necessary to maintain the constancy of the internal fluid environment. The unwanted filtered material is left behind in the tubular fluid to be excreted as urine. Glomerular filtration can be thought of as pushing a part of the plasma—with all its essential components as well as those that need to be eliminated from the body—onto a tubular “conveyor belt” that terminates at the renal pelvis, which is the collecting point for urine within the kidney. All plasma constituents that enter this conveyor belt and are not subsequently returned to the plasma by the end of the line are spilled out of the kidney as urine. It is up to the tubular system to salvage by reabsorption the filtered materials that need to be preserved for the body, while leaving behind substances that must be excreted. In addition, some substances are not only filtered but also secreted onto the tubular conveyor belt, so the amounts of these substances excreted in the urine are greater than the amounts that were filtered. For many substances, these renal processes are subject to physiological control. Thus, the kidneys handle each constituent in the plasma in a characteristic manner by a particular combination of filtration, reabsorption, and secretion.

The kidneys act only on the plasma, yet the ECF consists of both plasma and interstitial fluid. The interstitial fluid is actually the true internal fluid environment of the body, because it is the only component of the ECF that comes into direct contact with the cells. However, because of the free exchange between plasma and interstitial fluid across the capillary walls (with the exception of plasma proteins), interstitial fluid composition reflects the composition of plasma. By performing their regulatory and excretory roles on the plasma, the kidneys maintain the proper interstitial fluid environment for optimal cell function. Most of the rest of this chapter is devoted to considering how the basic renal processes are accomplished and the mechanisms by which they are carefully regulated to help maintain homeostasis.

13.2 | Renal Blood Flow

The path of renal blood flow (RBF) is renal arteries → afferent arterioles → glomerular capillaries → efferent arterioles → proximal peritubular capillaries → vasa recta → distal peritubular capillaries → capillaries associated with the collecting duct → renal venules. The highest RBF occurs at rest, and is about 1200 mL/min, which is about 22 percent of cardiac output. The purpose of this relatively high blood flow is to supply the kidney with sufficient plasma for filtration, secretion,

and reabsorption. During exercise, RBF is reduced. Under extreme conditions—for example, shock—RBF can approach zero. Another purpose of the blood supply is to deliver oxygen for energy to perform active transport (e.g., of Na^+). However, resting RBF is more than adequate to satisfy the kidneys' O_2 requirements. Generally, blood flow could be reduced, and O_2 requirements would still be met.

Control of RBF is largely impacted by the ANS—specifically, the sympathetic division and the associated vasoconstriction. As well, the adrenal medulla reinforces the sympathetic vasoconstriction. Interestingly, although the nerves innervating the kidney aid in regulation of RBF, they are not essential for normal renal function. The kidney also has an intrinsic ability to control blood flow, which is termed autoregulation. It is thought that RBF autoregulation is based primarily on two mechanisms: the myogenic response and the tubuloglomerular feedback. The myogenic response is a function of smooth muscle to contract in response to external stretching force. In vascular smooth muscle this causes vasoconstriction on a rise in arterial pressure, thereby allowing for autoregulation. Tubuloglomerular feedback is a mechanism specific to the kidney that leads to constriction of the afferent arteriole in response to an increase in NaCl concentration in the distal tubule. These mechanisms allow the kidney to adjust resistance in order to maintain blood flow even when perfusion pressure changes.

Check Your Understanding 13.1

1. Schematically draw an “unwound” nephron, and use arrows to show the direction of movement between its vascular and tubular components during the three basic renal processes.
2. Distinguish between cortical and juxtamedullary nephrons.
3. Why is it advantageous that renal blood flow decreases during exercise?

13.3 | Glomerular Filtration

Fluid filtered from the glomerulus into Bowman's capsule must pass through the following three layers that make up the **glomerular membrane** (► Figure 13-7): (1) the glomerular capillary wall, (2) the basement membrane, and (3) the inner layer of Bowman's capsule. Collectively, these layers function as a fine molecular sieve that retains the blood cells and plasma proteins but permits water and solutes of small molecular dimension to filter through. Let's consider each layer in more detail.

The glomerular membrane

The *glomerular capillary wall* consists of a single layer of flattened endothelial cells. It is perforated by many large pores that

To be filtered, a substance must pass through

- 1 the pores between and the fenestrations within the endothelial cells of the glomerular capillary,
- 2 an acellular basement membrane, and
- 3 the filtration slits between the foot processes of the podocytes in the inner layer of Bowman's capsule.

► FIGURE 13-7 Layers of the glomerular membrane

► **FIGURE 13-8** Bowman's capsule podocytes with foot processes and filtration slits. Note the filtration slits between adjacent foot processes on this scanning electron micrograph. The podocytes and their foot processes encircle the glomerular capillaries.

make it more than 100 times as permeable to water and solutes as capillaries elsewhere in the body.

The *basement membrane* is an acellular (lacking cells) gelatinous layer composed of collagen and glycoproteins that is sandwiched between the glomerulus and Bowman's capsule. The collagen provides structural strength, and the glycoproteins discourage the filtration of small plasma proteins. The larger plasma proteins cannot be filtered, because they cannot fit through the capillary pores, but the pores are just barely large enough to permit passage of albumin, the smallest of plasma proteins. However, because the glycoproteins are negatively charged, they repel albumin and other plasma proteins, which are also negatively charged. Therefore, plasma proteins are almost completely excluded from the filtrate, with less than 1 percent of the albumin molecules escaping into Bowman's capsule.

Some renal diseases characterized by excessive albumin in the urine (*albuminuria*) are due to disruption of the negative charges within the basement membrane, which makes the glomerular membrane more permeable to albumin, even though the size of the capillary pores remains constant.

The final layer of the glomerular membrane is the inner layer of Bowman's capsule. It consists of **podocytes**, octopus-like cells that encircle the glomerular tuft. Each podocyte bears many elongated foot processes (*podo* means “foot”; a *process* is a projection or appendage) that interdigitate with foot processes of adjacent podocytes, much as you interlace your fingers between each other when you cup your hands around a ball (Figure 13-8). The narrow slits between adjacent foot processes, known as **filtration slits**, provide a pathway through which fluid leaving the glomerular capillaries can enter the lumen of Bowman's capsule.

Thus, the route that filtered substances take across the glomerular membrane is completely extracellular—first through

capillary pores, then through the acellular basement membrane, and finally through capsular filtration slits (Figure 13-7).

Glomerular capillary blood pressure

To accomplish glomerular filtration, a force must drive a part of the plasma in the glomerulus through the openings in the glomerular membrane. No active transport mechanisms or local energy expenditures are involved in moving fluid from the plasma across the glomerular membrane into Bowman's capsule. Passive physical forces similar to those acting across capillaries elsewhere accomplish glomerular filtration.

Because the glomerulus is a tuft of capillaries, the same principles of fluid dynamics that cause ultrafiltration across other capillaries (p. 409) apply here, except for two important differences: (1) the glomerular capillaries are much more permeable than capillaries elsewhere, so more fluid is filtered for a given filtration pressure; and (2) the balance of forces across the glomerular membrane is such that filtration occurs throughout the entire length of the capillaries. In contrast, the balance of forces in other capillaries shifts so that filtration occurs in the beginning part of the vessel but reabsorption occurs toward the vessel's end (see Figure 9-23).

FORCES INVOLVED IN GLOMERULAR FILTRATION

Three physical forces are involved in glomerular filtration (Table 13-1): (1) glomerular capillary blood pressure, (2) plasma-colloid osmotic pressure, and (3) Bowman's capsule hydrostatic pressure. Let's examine the role of each.

1. *Glomerular capillary blood pressure* is the fluid pressure exerted by the blood within the glomerular capillaries. It ultimately depends on the contraction of the heart (the source of energy that produces glomerular filtration) and the resistance to blood flow offered by the afferent and efferent arterioles. Glomerular capillary blood pressure, at an estimated average value of 55 mmHg, is higher than the capillary blood pressure (18 mmHg on average) found in other capillaries. The reason for the higher pressure in the glomerular capillaries is the larger diameter of the afferent arteriole compared with that of the efferent arteriole. Because blood can more readily enter the glomerulus through the wide afferent arteriole than it can leave through the narrower efferent arteriole, glomerular capillary blood pressure is maintained high as a result of blood damming up in the glomerular capillaries. Furthermore, because of the high resistance offered by the efferent arterioles, blood pressure does not have the same tendency to fall along the length of the glomerular capillaries as it does along other capillaries. This elevated, nondecremental glomerular blood pressure tends to push fluid out of the glomerulus into Bowman's capsule along the glomerular capillaries' entire length, and it is the major force producing glomerular filtration.

Whereas glomerular capillary blood pressure favours filtration, the two other forces acting across the glomerular membrane (plasma-colloid osmotic pressure and Bowman's capsule hydrostatic pressure) oppose filtration.

TABLE 13-1 Forces Involved in Glomerular Filtration

Force	Effect	Magnitude (MMHG)
Glomerular Capillary Blood Pressure	Favours filtration	55
Plasma-colloid Pressure	Opposes filtration	30
Bowman's Capsule Hydrostatic Pressure	Opposes filtration	15
Net Filtration Pressure (Difference between force favouring filtration and forces opposing filtration)	Favours filtration	10

$55 - (30 + 15) = 10$

2. *Plasma-colloid osmotic pressure* is caused by the unequal distribution of plasma proteins across the glomerular membrane. Because plasma proteins cannot be filtered, they are in the glomerular capillaries, but not in Bowman's capsule. Accordingly, the concentration of H_2O is higher in Bowman's capsule than in the glomerular capillaries. The resulting tendency for H_2O to move by osmosis down its own concentration gradient from Bowman's capsule into the glomerulus opposes glomerular filtration. This opposing osmotic force averages 30 mmHg, which is slightly higher than across other capillaries. It is higher because much more H_2O is filtered out of the glomerular blood, so the concentration of plasma proteins is higher than elsewhere.
3. *Bowman's capsule hydrostatic pressure*, the pressure exerted by the fluid in this initial part of the tubule, is estimated to be about 15 mmHg. This pressure, which tends to push fluid out of Bowman's capsule, opposes the filtration of fluid from the glomerulus into Bowman's capsule.

GLOMERULAR FILTRATION RATE

As you can see in Table 13-1, the forces acting across the glomerular membrane are not in balance. The total force favouring filtration is the glomerular capillary blood pressure at 55 mmHg. The total of the two forces opposing filtration is 45 mmHg.

The net difference favouring filtration (10 mmHg of pressure) is called the **net filtration pressure**. This modest pressure forces large volumes of fluid from the blood through the highly permeable glomerular membrane. The actual rate of filtration, the **glomerular filtration rate (GFR)**, depends not only on the net filtration pressure but also on how much glomerular surface area is available for penetration and how permeable the glomerular membrane is (i.e., how "holey" it is). These properties of the glomerular membrane are collectively referred to as the **filtration coefficient (K_f)**. Accordingly,

$$GFR = K_f \times \text{net filtration pressure}$$

Normally, about 20 percent of the plasma that enters the glomerulus is filtered at the net filtration pressure of 10 mmHg. This produces collectively through all glomeruli 180 L of glomerular filtrate each day for an average GFR of 125 mL/min in males and 160 L of filtrate per day for an average GFR of 115 mL/min in females.

An injection of inulin can be used to determine glomerular filtration rate. Inulin is a naturally occurring oligosaccharide produced by some plants and stored for energy. It is completely filtered by the nephron at the glomerulus but is then neither secreted nor reabsorbed by the tubules. This means it can be used as a clinical and highly accurate measure of the glomerular filtration rate.

Changes in GFR

Because the net filtration pressure that accomplishes glomerular filtration is simply due to an imbalance of opposing physical forces between the glomerular capillary plasma and Bowman's capsule fluid, alterations in any of these physical forces can affect the GFR. We now examine the effect that changes in each of these physical forces have on the GFR.

UNREGULATED INFLUENCES ON THE GFR

Plasma-colloid osmotic pressure and Bowman's capsule hydrostatic pressure are not subject to regulation and, under normal conditions, do not vary much.

However, they can change pathologically and thus inadvertently affect the GFR. Because plasma-colloid osmotic pressure opposes filtration, a decrease in plasma protein concentration, by reducing this pressure, leads to an increase in the GFR. An uncontrollable reduction in plasma protein concentration might occur, for example, in severely burned patients who lose a large quantity of protein-rich, plasma-derived fluid through the exposed burned lesions of their skin. Conversely, in situations in which the plasma-colloid osmotic pressure is elevated, such as in cases of dehydrating diarrhoea, the GFR is reduced.

Bowman's capsule hydrostatic pressure can become uncontrollably elevated, and filtration subsequently can decrease, given a urinary tract obstruction, such as a kidney stone or enlarged prostate. The damming up of fluid behind the obstruction elevates capsular hydrostatic pressure.

CONTROLLED ADJUSTMENTS IN THE GFR

Unlike plasma-colloid osmotic pressure and Bowman's capsule hydrostatic pressure—which may be uncontrollably altered

in various disease states and thereby inappropriately alter the GFR—glomerular capillary blood pressure can be controlled to adjust the GFR to suit the body's needs. Assuming that all other factors stay constant, as the glomerular capillary blood pressure goes up, the net filtration pressure increases and the GFR increases correspondingly. The magnitude of the glomerular capillary blood pressure depends on the rate of blood flow within each of the glomeruli. The amount of blood flowing into a glomerulus per minute is determined largely by the magnitude of the mean systemic arterial blood pressure and the resistance offered by the afferent arterioles. If resistance increases in the afferent arteriole, less blood flows into the glomerulus, decreasing the GFR. Conversely, if afferent arteriolar resistance is reduced, more blood flows into the glomerulus and the GFR increases. Two major control mechanisms regulate the GFR, both directed at adjusting glomerular blood flow by regulating the radius and thus the resistance of the afferent arteriole. These mechanisms are (1) autoregulation, which is aimed at preventing spontaneous changes in GFR; and (2) extrinsic sympathetic control, which is aimed at long-term regulation of arterial blood pressure.

MECHANISMS RESPONSIBLE FOR AUTOREGULATION OF THE GFR

Because arterial blood pressure is the force that drives blood into the glomerulus, the glomerular capillary blood pressure and, accordingly, the GFR would increase in direct proportion to an increase in arterial pressure if everything else remained constant (► Figure 13-9). Similarly, a fall in arterial blood pressure would be accompanied by a decline in GFR. Such spontaneous, inadvertent changes in GFR are largely prevented by intrinsic regulatory mechanisms initiated by the kidneys themselves, a process known as **autoregulation** (*auto* means “self”). The kidneys can, within limits, maintain a constant blood flow into the glomerular capillaries (and thus a constant glomerular capillary blood pressure and a stable GFR), despite changes in the driving arterial pressure. They do so primarily by altering afferent arteriolar calibre, thereby adjusting resistance to flow through these vessels. For example, if the GFR increases as a direct result of a rise in arterial pressure, the net filtration pressure and GFR can be reduced to normal by constriction of the afferent arteriole, which decreases the flow of blood into the glomerulus

► FIGURE 13-9 Direct effect of arterial blood pressure on the glomerular filtration rate (GFR)

(a)

(b)

► FIGURE 13-10 Adjustments of afferent arteriole calibre to alter the GFR.

(a) Arteriolar vasoconstriction reduces the GFR. (b) Arteriolar vasodilation increases the GFR

(► Figure 13-10a). This local adjustment lowers the glomerular blood pressure and the GFR to normal.

Conversely, when GFR falls in the presence of a decline in arterial pressure, glomerular pressure can be increased to normal by vasodilation of the afferent arteriole, which allows more blood to enter despite the reduction in driving pressure (► Figure 13-10b). The resultant buildup of glomerular blood volume increases glomerular blood pressure, which in turn brings the GFR back up to normal.

Two intrarenal mechanisms contribute to autoregulation: (1) a *myogenic* mechanism, which responds to changes in pressure within the nephron's vascular component; and (2) a *tubuloglomerular feedback* mechanism, which senses changes in the salt level in the fluid flowing through the nephron's tubular component.

1. The **myogenic** mechanism is a common property of vascular smooth muscle (*myogenic* means “muscle-produced”). Arteriolar vascular smooth muscle contracts inherently in response to the stretch accompanying

increased pressure within the vessel (p. 399). Accordingly, the afferent arteriole automatically constricts on its own when it is stretched because of an increased arterial driving pressure. This response helps limit blood flow into the glomerulus to normal, despite the elevated arterial pressure. Conversely, inherent relaxation of an unstretched afferent arteriole when pressure within the vessel is reduced increases blood flow into the glomerulus, despite the fall in arterial pressure.

2. The **tubuloglomerular feedback (TGF)** mechanism involves the *juxtaglomerular apparatus*, which is the specialized combination of tubular and vascular cells where the tubule, after having bent back on itself, passes through the angle formed by the afferent and efferent arterioles as they join the glomerulus (► Figure 13-11; see also Figure 13-3). Some of the pericytes within the wall of the afferent arteriole in this region are specialized to form **granular cells**, so called because they contain many secretory granules. Specialized tubular cells in this region are collectively known as the **macula densa**. The macula densa cells detect changes in the salt level of the fluid flowing past them through the tubule. Other mediators of TGF are ATP and adenosine.

If the GFR is increased due to an elevation in arterial pressure, more fluid than normal is filtered and flows through the distal tubule. In response to the resultant rise in salt delivery to the distal tubule, the macula densa cells release ATP. Extracellular

degradation of the ATP forms adenosine, which acts locally as a paracrine on the adjacent afferent arteriole; this causes vasoconstriction, which reduces glomerular blood flow and ultimately returns GFR to normal. In the opposite situation, when less salt is delivered to the distal tubule due to a spontaneous decline in GFR accompanying a fall in arterial pressure, less ATP is released by macula densa cells, and this results in less extracellular adenosine. The resultant afferent arteriolar vasodilation increases the glomerular flow rate, restoring the GFR to normal. By means of the TGF mechanism, the nephron is able to monitor the salt level in the fluid flowing through it and also use ATP and adenosine to regulate the rate of filtration through its glomerulus to keep the early distal tubular fluid and salt delivery constant.

IMPORTANCE OF AUTOREGULATION OF THE GFR

The myogenic and TGF mechanisms work in unison to autoregulate the GFR within the mean arterial blood pressure range of 80 to 180 mmHg. Within this wide range, intrinsic autoregulatory adjustments of afferent arteriolar resistance can compensate for changes in arterial pressure, thereby preventing inappropriate fluctuations in GFR, even though glomerular pressure tends to change in the same direction as arterial pressure. Normal mean arterial pressure is 93 mmHg, so the range of 80–180 mmHg encompasses the transient changes in blood pressure that accompany daily activities unrelated to the need for the kidneys to regulate water and salt excretion, such as the normal elevation in blood pressure during exercise. Autoregulation is important because unintentional shifts in GFR could

► **FIGURE 13-11 The juxtaglomerular apparatus.** The juxtaglomerular apparatus consists of specialized vascular cells (the granular cells) and specialized tubular cells (the macula densa) at a point where the distal tubule passes through the fork formed by the afferent and efferent arterioles of the same nephron.

lead to dangerous imbalances of fluid, electrolytes, and wastes. Because at least a certain portion of the filtered fluid is always excreted, the amount of fluid excreted in the urine is automatically increased as the GFR increases. If autoregulation did not occur, the GFR would increase and water and solutes would be lost needlessly as a result of the rise in arterial pressure during heavy exercise. If, by contrast, the GFR were too low, the kidneys could not eliminate enough wastes, excess electrolytes, and other materials that need to be excreted. Autoregulation thus greatly blunts the direct effect that changes in arterial pressure would otherwise have on GFR and subsequently on water, solute, and waste excretion.

When changes in mean arterial pressure fall outside the autoregulatory range, these mechanisms cannot compensate. Therefore, dramatic changes in mean arterial pressure (<80 mmHg or >180 mmHg) directly cause the glomerular capillary pressure and, accordingly, the GFR to decrease or increase in proportion to the change in arterial pressure.

IMPORTANCE OF EXTRINSIC SYMPATHETIC CONTROL OF THE GFR

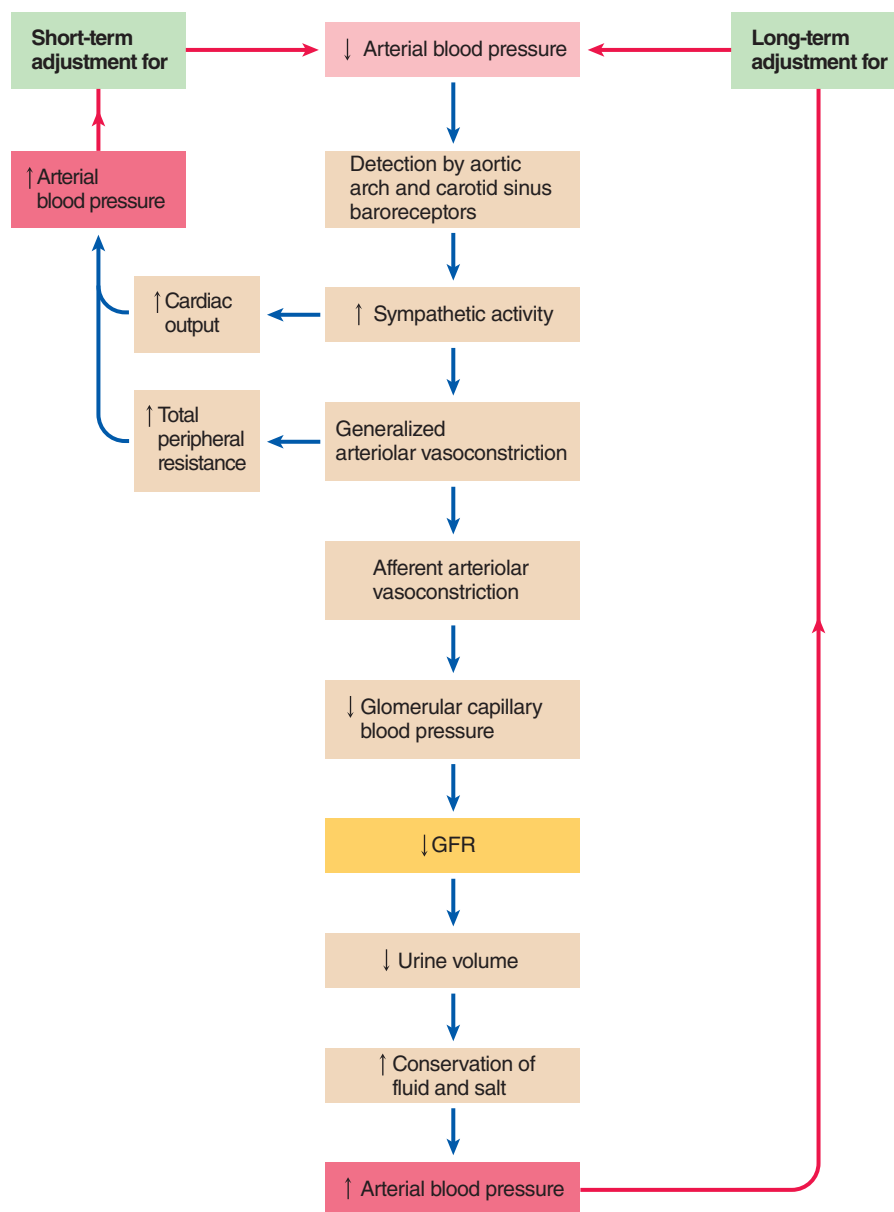

In addition to the intrinsic autoregulatory mechanisms designed to keep the GFR constant in the face of fluctuations in arterial blood pressure, the GFR can be *changed on purpose*—even when the mean arterial blood pressure is within the autoregulatory range—by extrinsic control mechanisms that override the autoregulatory responses. Extrinsic control of GFR, which is mediated by sympathetic nervous system input to the afferent arterioles, is aimed at regulating arterial blood pressure. The parasympathetic nervous system does not exert any influence on the kidneys.

If plasma volume is decreased—for example, by haemorrhage—the resulting fall in arterial blood pressure is detected by the arterial carotid sinus and aortic arch baroreceptors, which initiate neural reflexes to raise blood pressure toward normal (p. 420). These reflex responses are coordinated by the cardiovascular control centre in the brain stem and are mediated primarily through increased sympathetic activity to the heart and blood vessels. Although the resulting increase in both cardiac output and total peripheral resistance helps raise blood pressure toward normal, plasma volume is still reduced. In the long term, plasma volume must be restored to normal. One compensation for a depleted plasma volume is reduced urine output so that more fluid than normal is conserved for the body. Urine output is reduced in part

by reducing the GFR; if less fluid is filtered less is available to excrete.

ROLE OF THE BARORECEPTOR REFLEX IN EXTRINSIC CONTROL OF THE GFR

No new mechanism is needed to decrease the GFR. It is reduced by the baroreceptor reflex response to a fall in blood pressure (→ Figure 13-12). During this reflex, sympathetically induced vasoconstriction occurs in most arterioles throughout the body (including the afferent arterioles) as a compensatory mechanism to increase total peripheral resistance. The afferent arterioles are innervated with sympathetic vasoconstrictor fibres to a far greater extent than are the efferent arterioles. When the afferent arterioles carrying blood to the glomeruli constrict from increased sympathetic activity, less blood flows into the

→ **FIGURE 13-12** Baroreceptor reflex influence on the GFR in long-term regulation of arterial blood pressure

glomeruli than normal, lowering glomerular capillary blood pressure (see ▶ Figure 13-10a). The resulting decrease in GFR, in turn, reduces urine volume. In this way, some of the water and salt that would otherwise have been lost in the urine are saved for the body, helping in the long term to restore plasma volume to normal so that short-term cardiovascular adjustments that have been made are no longer necessary. Other mechanisms, such as increased tubular reabsorption of water and salt as well as increased thirst, also contribute to long-term maintenance of blood pressure, despite a loss of plasma volume, by helping to restore plasma volume.

Conversely, if blood pressure is elevated (e.g., because of an expansion of plasma volume following ingestion of excessive fluid), the opposite responses occur. When the baroreceptors detect a rise in blood pressure, sympathetic vasoconstrictor activity to the arterioles, including the renal afferent arterioles, is reflexly reduced, allowing afferent arteriolar vasodilation to occur. As more blood enters the glomeruli through the dilated afferent arterioles, glomerular capillary blood pressure rises, increasing the GFR (see Figure 13-10b). As more fluid is filtered, more fluid is available to be eliminated in the urine. Contributing to the increase in urine volume is a hormonally adjusted reduction in the tubular reabsorption of water and salt. These two renal mechanisms—increased glomerular filtration and decreased tubular reabsorption of water and salt—increase urine volume and eliminate the excess fluid from the body. Reduced thirst and fluid intake also help restore an elevated blood pressure to normal.

The GFR and the filtration coefficient

Up to now we have discussed changes in the GFR as a result of changes in net filtration pressure. The rate of glomerular filtration, however, depends on the filtration coefficient (K_f) as well as on the net filtration pressure. For years, K_f was considered a constant, except in disease situations in which the glomerular membrane becomes leakier than usual. Exciting new research to the contrary indicates that K_f is subject to change under physiological control. Both factors on which K_f depends—the surface area and the permeability of the glomerular membrane—can be modified by contractile activity within the membrane.

The surface area available for filtration within the glomerulus is represented by the inner surface of the glomerular capillaries that comes into contact with blood. Each tuft of glomerular capillaries is held together by **mesangial cells**. These cells contain contractile elements (i.e., actin-like filaments). Contraction of these mesangial cells closes off a portion of the filtering capillaries, reducing the surface area available for filtration within the glomerular tuft. When the net filtration pressure remains unchanged, this reduction in K_f decreases GFR. Sympathetic stimulation

causes the mesangial cells to contract—a second mechanism (besides promoting afferent arteriolar vasoconstriction) by which sympathetic activity can decrease the GFR.

Podocytes also possess actin-like contractile filaments. Their contraction or relaxation can, respectively, decrease or increase the number of open filtration slits in the inner membrane of Bowman's capsule by changing the shapes and proximities of the foot processes (▶ Figure 13-13). The number of slits is a determinant of permeability: the more open slits, the greater the permeability. Contractile activity of the podocytes, which in turn affects permeability and K_f , is under physiological control by mechanisms that are incompletely understood.

Before turning our attention to the process of tubular reabsorption, we are first going to examine the percentage of cardiac output that goes to the kidneys. This will reinforce the concept of how much blood flows through the kidneys and how much of that fluid is filtered and subsequently acted on by the tubules.

The kidneys and cardiac output

At the average net filtration pressure and K_f , 20 percent of the plasma that enters the kidneys is converted into glomerular filtrate. That means at an average GFR of 125 mL/min, the total renal plasma flow must average about 625 mL/min. Because 55 percent of whole blood consists of plasma (i.e., haematocrit = 45; p. 434), the total flow of blood through the

▶ **FIGURE 13-13** Change in the number of open filtration slits caused by podocyte relaxation and contraction. (a) Podocyte relaxation narrows the bases of the foot processes, increasing the number of fully open, intervening filtration slits that span a given area. (b) Podocyte contraction flattens the foot processes and thus decreases the number of intervening filtration slits.

kidneys averages 1140 mL/min. This quantity is about 22 percent of the total cardiac output of 5 L (5000 mL)/min, although the kidneys compose less than 1 percent of total body weight.

The kidneys need to receive such a seemingly disproportionate share of the cardiac output because they must continuously perform their regulatory and excretory functions on the huge volumes of plasma delivered to them to maintain stability in the internal fluid environment. Most of the blood goes to the kidneys not to supply the renal tissue but to be adjusted and purified by the kidneys. On average, 20–25 percent of the blood pumped out by the heart each minute “goes to the cleaners” instead of serving its normal purpose of exchanging materials with the tissues. Only by continuously processing such a large proportion of the blood can the kidneys precisely regulate the volume and electrolyte composition of the internal environment and adequately eliminate the large quantities of metabolic waste products that are constantly produced.

KIDNEY FUNCTION DURING EXERCISE

Exercise produces considerable changes in RBF and in electrolyte and protein excretion. RBF is reduced in proportion to exercise intensity; as exercise intensity increases, RBF decreases. Renal blood flow during maximal exercise may decrease by about 300 mL, receiving less than 5 percent of cardiac output.

This results from the redistribution of blood flow away from the renal, splanchnic, liver, and stomach vascular beds, which are nonessential during exercise, to the skeletal muscle, heart, and skin. During vigorous exercise, the body increases the reabsorption of water and salt in the proximal and distal tubules, and gradually returns them to the circulatory system. The elevated levels of vasopressin in the blood facilitate the reabsorption of water.

The conservation of body water and electrolytes during exercise is not substantial, as the maximum volume of water that can be reabsorbed during exercise is only 30–45 mL/h. When you compare the volume of water reabsorption by the kidneys with typical skin sweat rates (1000–2000 mL/h), it is clear the kidney cannot keep pace. The kidney water reabsorption is important in the first 48 hours post-exercise, when fluid restoration can gradually occur.

Check Your Understanding 13.2

1. Prepare a table showing the effect and magnitude of the physical forces involved in glomerular filtration.

2. Discuss how extrinsic control of the GFR is accomplished and the importance of this mechanism.

13.4 Tubular Reabsorption

All plasma constituents except the proteins are indiscriminately filtered together through the glomerular capillaries. In addition to waste products and excess materials that the body must eliminate, the filtered fluid contains nutrients, electrolytes, and

other substances that the body cannot afford to lose in the urine. The essential materials that are filtered are returned to the blood by *tubular reabsorption*. Tubular reabsorption is the method by which solutes and water are removed from the tubular fluid and transported into the blood. Reabsorption is a two-step process, beginning with the active or passive extraction of substances from the tubule fluid into the renal interstitium (connective tissue surrounding the nephrons) and then the transport (active and passive transport) of these substances from the interstitium into the bloodstream.

Highly selective and variable

Tubular reabsorption is a highly selective process. All constituents except plasma proteins are at the same concentration in the glomerular filtrate as in plasma. In most cases, the quantity reabsorbed of each substance is the amount required to maintain the proper composition and volume of the internal fluid environment. In general, the tubules have a high reabsorptive capacity for substances needed by the body and little or no reabsorptive capacity for substances of no value (■ Table 13-2). Accordingly, only a small percentage, if any, of filtered plasma constituents that are useful to the body are present in the urine, most having been reabsorbed and returned to the blood. Only excess amounts of essential materials, such as electrolytes, are excreted in the urine. For the essential plasma constituents regulated by the kidneys, absorptive capacity may vary depending on the body’s needs. In contrast, a large percentage of filtered waste products is present in the urine. These wastes, which are useless or even potentially harmful to the body if allowed to accumulate, are not reabsorbed to any extent. Instead, they stay in the tubules, to be eliminated in the urine. As water and other valuable constituents are reabsorbed, the waste products remaining in the tubular fluid become highly concentrated.

Of the 125 mL/min filtered, typically 124 mL/min are reabsorbed. Considering the magnitude of glomerular filtration, the extent of tubular reabsorption is tremendous: the tubules

■ TABLE 13-2 Fate of Various Substances Filtered by the Kidneys

Substance	Average Percentage of Filtered Substance Reabsorbed	Average Percentage of Filtered Substance Excreted
Water	99	1
Sodium	99.5	0.5
Glucose	100	0
Urea (a waste product)	50	50
Phenol (a waste product)	0	100

typically reabsorb 99 percent of the filtered water (210 L/day), 100 percent of the filtered sugar (1 kg/day), and 99.5 percent of the filtered salt (165 g/day).

Transepithelial transport

Transepithelial transport (*transepithelial* means “across the epithelium”) is also referred to as *transcellular transport*, and can be defined as solute movement across an epithelial cell layer through the cell. Throughout its entire length, the tubule wall is one cell thick and in close proximity to a surrounding peritubular capillary (► Figure 13-14). Adjacent tubular cells do not come into contact with each other, except where they are joined by tight junctions at their lateral edges near their *luminal membranes*, which face the tubular lumen. Interstitial fluid lies in the gaps between adjacent cells—the **lateral spaces**—as well as between the tubules and capillaries. The *basolateral membrane* faces the interstitial fluid at the base and lateral edges of the cell. The tight junctions largely prevent substances from moving *between* the cells, so generally materials must pass *through* the cells to leave the tubular lumen and gain entry to the blood.

STEPS OF TRANSEPITHELIAL TRANSPORT

To be reabsorbed, a substance must traverse five distinct barriers (Figure 13-14):

- Step 1: It must leave the tubular fluid by crossing the luminal membrane of the tubular cell.
- Step 2: It must pass through the cytosol from one side of the tubular cell to the other.
- Step 3: It must cross the basolateral membrane of the tubular cell to enter the interstitial fluid.

- Step 4: It must diffuse through the interstitial fluid.
- Step 5: It must penetrate the capillary wall to enter the blood plasma.

In contrast to transcellular (transepithelial) transport is the concept of paracellular transport. Paracellular transport refers to the movement of solvent across an epithelial cell layer through the tight junctions (between the epithelial cells). The primary role of the proximal tubule is fluid and electrolyte transport. As the proximal tubule epithelial cells have leaky tight junctions, fluid and solutes can cross this nephron segment not only transcellularly, but also paracellularly. However, the amount of transcellular transport (~95%) is much greater than paracellular transport, with paracellular transport suggested to be about 2–5 percent of total transport. Regulation of paracellular transport in the proximal tubule is yet to be fully identified, but some possible regulators of the tight junctions include influences of pressure, hormones, and cyclic nucleotides.

PASSIVE VERSUS ACTIVE REABSORPTION

The two types of tubular reabsorption—*passive reabsorption* and *active reabsorption*—depend on whether local energy expenditure is needed for reabsorbing a particular substance. In **passive reabsorption**, all steps in the transepithelial transport of a substance from the tubular lumen to the plasma are passive; that is, no energy is spent for the substance’s net movement, which occurs down electrochemical or osmotic gradients (p. 38). In contrast, **active reabsorption** takes place if any one of the steps in the transepithelial transport of a substance requires energy, even if the four other steps are passive. With active reabsorption, net movement of the substance from the tubular lumen to the plasma occurs *against* an electrochemical gradient. Substances

To be reabsorbed (to move from the filtrate to the plasma), a substance must cross five distinct barriers:

- | | | |
|-----------------------------|---------------------------------|----------------------|
| 1 the luminal cell membrane | 3 the basolateral cell membrane | 5 the capillary wall |
| 2 the cytosol | 4 the interstitial fluid | |

► FIGURE 13-14 Steps of transepithelial transport

© 2016 Cengage

that are actively reabsorbed are of particular importance to the body, such as glucose, amino acids, and other organic nutrients, as well as Na^+ and other electrolytes, such as PO_4^{3-} . Rather than specifically describe the reabsorptive process for each of the many filtered substances returned to the plasma, we will provide illustrative examples of the general mechanisms involved. But first we highlight the unique and important case of Na^+ reabsorption.

The $\text{Na}^+ - \text{K}^+$ ATPase pump

Sodium reabsorption is unique and complex. Of the total energy spent by the kidneys, 80 percent is used for Na^+ transport, indicating the importance of this process. Unlike most filtered solutes, Na^+ is reabsorbed throughout most of the tubule, but to varying extents in different regions. Of the Na^+ filtered, 99.5 percent is normally reabsorbed. Of the Na^+ reabsorbed, on average 67 percent is reabsorbed in the proximal tubule, 25 percent in the loop of Henle, and 8 percent in the distal and collecting tubules. Sodium reabsorption plays different important roles in each of these segments, as will become apparent as our discussion continues. Here is a preview of these roles.

- Sodium reabsorption in the *proximal tubule* plays a pivotal role in reabsorbing glucose, amino acids, H_2O , Cl^- , and urea.
- Sodium reabsorption in the ascending limb of the *loop of Henle*, along with Cl^- reabsorption, plays a critical role in the kidneys' ability to produce urine of varying concentrations and volumes, depending on the body's need to conserve or eliminate H_2O .
- Sodium reabsorption in the *distal and collecting tubules* is variable and subject to hormonal control. It plays a key role in regulating ECF volume, which is important in long-term control of arterial blood pressure and is also linked in part to K^+ secretion and H^+ secretion.

Sodium is reabsorbed throughout the tubule with the exception of the descending limb of the loop of Henle. You will learn about the significance of this exception later. Throughout all Na^+ reabsorbing segments of the tubule, the active step in Na^+ reabsorption involves the energy-dependent $\text{Na}^+ - \text{K}^+$ ATPase carrier located in the tubular cell's basolateral membrane (▶ Figure 13-15). This carrier is the same $\text{Na}^+ - \text{K}^+$ pump present in all cells that actively extrudes Na^+ from the cell (p. 45). As this basolateral pump transports Na^+ out of the tubular cell into the lateral space, it keeps the intracellular Na^+ concentration low while simultaneously building up the concentration of Na^+ in the lateral space; that is, it moves Na^+ against a concentration gradient. Because the intracellular Na^+ concentration is kept low by basolateral pump activity, a concentration gradient is established that favours the passive movement

of Na^+ from its higher concentration in the tubular lumen across the luminal border into the tubular cell. The nature of the luminal Na^+ channels and/or transport carriers that permit movement of Na^+ from the lumen into the cell varies for different parts of the tubule, but in each case, movement of Na^+ across the luminal membrane is always a passive step. For example, in the proximal tubule, Na^+ crosses the luminal border by a cotransport carrier that simultaneously moves Na^+ and an organic nutrient, such as glucose, from the lumen into the cell. You will learn more about this cotransport process shortly. By contrast, in the collecting duct, Na^+ crosses the luminal border through a Na^+ channel. Once Na^+ enters the cell across the luminal border by whatever means, it is actively extruded to the lateral space by the basolateral $\text{Na}^+ - \text{K}^+$ pump. This step is the same throughout the tubule. Sodium continues to diffuse down a concentration gradient from its high concentration in the lateral space into the surrounding interstitial fluid and finally into the peritubular capillary blood. Thus, net transport of Na^+ from the tubular lumen into the blood occurs at the expense of energy.

First let's consider the importance of regulating Na^+ reabsorption in the distal portion of the nephron and examine how this control is accomplished. Later, in Section 13.6, we will explore in further detail the roles of Na^+ reabsorption in the proximal tubule and in the loop of Henle.

Aldosterone and Na^+ reabsorption

In the proximal tubule and loop of Henle, a constant percentage of the filtered Na^+ is reabsorbed regardless of the Na^+ load

▶ **FIGURE 13-15 Sodium reabsorption.** The basolateral $\text{Na}^+ - \text{K}^+$ ATPase carrier actively transports Na^+ from the tubular cell into the interstitial fluid within the lateral space. This process establishes a concentration gradient for passive movement of Na^+ from the lumen into the tubular cell and from the lateral space into the peritubular capillary, accomplishing net transport of Na^+ from the tubular lumen into the blood at the expense of energy.

(total amount of Na^+ in the body fluids, not the concentration of Na^+ in the body fluids). In the distal part of the tubule, the reabsorption of a small percentage of the filtered Na^+ is subject to hormonal control. The extent of this controlled, discretionary reabsorption is inversely related to the magnitude of the Na^+ load in the body. If there is too much Na^+ , little of this controlled Na^+ is reabsorbed; instead, it is lost in the urine, thereby removing excess Na^+ from the body. If Na^+ is depleted, however, most or all of this controlled Na^+ is reabsorbed, conserving for the body Na^+ that otherwise would be lost in the urine.

The Na^+ load in the body is reflected by the ECF volume. Sodium and its accompanying anion Cl^- account for more than 90 percent of the ECF's osmotic activity. (NaCl is common table salt.) Recall that osmotic pressure can be thought of loosely as a force that attracts and holds H_2O (p. 38). When the Na^+ load is above normal and the ECF's osmotic activity is therefore increased, the extra Na^+ holds extra H_2O , expanding the ECF volume. Conversely, when the Na^+ load is below normal, thereby decreasing ECF osmotic activity, less H_2O than normal can be held in the ECF, so the ECF volume is reduced. Because plasma is part of the ECF, the most important result of a change in ECF volume is the matching change in blood pressure with expansion ($\uparrow$ blood pressure) or reduction ($\downarrow$ blood pressure) of the plasma volume. Thus, long-term control of arterial blood pressure ultimately depends on Na^+ -regulating mechanisms. We now turn our attention to these mechanisms.

ACTIVATION OF THE RENIN-ANGIOTENSIN SYSTEM

The most important and best-known hormonal system involved in regulating Na^+ is the **renin-angiotensin-aldosterone system (RAAS)**. The granular cells of the juxtaglomerular apparatus (see Figure 13-11) secrete an enzymatic hormone, **renin**, into the blood in response to a fall in NaCl /ECF volume/blood pressure. This function is in addition to the role the macula densa cells of the juxtaglomerular apparatus play in autoregulation. Specifically, the following three inputs to the granular cells increase renin secretion:

1. The granular cells themselves function as *intrarenal baroreceptors*. They are sensitive to pressure changes within the afferent arteriole. When the granular cells detect a fall in blood pressure, they secrete more renin.
2. The macula densa cells in the tubular portion of the juxtaglomerular apparatus are sensitive to the NaCl moving past them through the tubular lumen. In response to a fall in NaCl , the macula densa cells trigger the granular cells to secrete more renin.
3. The granular cells are innervated by the sympathetic nervous system. When blood pressure falls below normal, the baroreceptor reflex increases sympathetic activity. As part of this reflex response, increased sympathetic activity stimulates the granular cells to secrete more renin.

These interrelated signals for increased renin secretion all indicate the need to expand the plasma volume to increase the arterial pressure to normal on a long-term basis. Through a complex series of events involving the RAAS, increased renin

secretion brings about increased Na^+ reabsorption by the distal and collecting tubules. Chloride always passively follows Na^+ down the electrical gradient established by sodium's active movement. The ultimate benefit of this salt retention is that it osmotically promotes H_2O retention, which helps restore the plasma volume and, therefore, is important in the long-term control of blood pressure.

Let's examine in further detail the RAAS mechanism by which renin secretion ultimately leads to increased Na^+ reabsorption (Figure 13-16). Once secreted into the blood, renin acts as an enzyme to activate **angiotensinogen** into **angiotensin I**. Angiotensinogen, a plasma protein synthesized by the liver, is always present in the plasma in high concentration. On passing through the lungs via the pulmonary circulation, angiotensin I is converted into **angiotensin II** by **angiotensin-converting enzyme (ACE)**, which is abundant in the pulmonary capillaries. Angiotensin II is the main stimulus for secretion of the hormone *aldosterone* from the adrenal cortex. The *adrenal cortex* is an endocrine gland that produces several different hormones, each secreted in response to different stimuli.

FUNCTIONS OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

Among its actions, aldosterone increases Na^+ reabsorption by the distal and collecting tubules. It does so by promoting the insertion of additional Na^+ channels into the luminal membranes and additional Na^+-K^+ ATPase carriers into the basolateral membranes of the distal and collecting tubular cells. The net result is a greater passive inward flux of Na^+ into the tubular cells from the lumen and increased active pumping of Na^+ out of the cells into the plasma—that is, an increase in Na^+ reabsorption, with Cl^- following passively. RAAS thus promotes salt retention and a resulting H_2O retention and rise in arterial blood pressure. Acting in negative-feedback fashion, this system alleviates the factors that triggered the initial release of renin: namely, salt depletion, plasma volume reduction, and decreased arterial blood pressure (Figure 13-16).

In addition to stimulating aldosterone secretion, angiotensin II is a potent constrictor of the systemic arterioles, directly increasing blood pressure by increasing total peripheral resistance (p. 401). Furthermore, it stimulates thirst (increasing fluid intake) and stimulates vasopressin (a hormone that increases H_2O retention by the kidneys), both of which contribute to plasma volume expansion and elevation of arterial pressure.

The opposite situation exists when the Na^+ load, ECF and plasma volume, and arterial blood pressure are above normal. Under these circumstances, renin secretion is inhibited. Therefore, because angiotensinogen is not activated to angiotensin I and II, aldosterone secretion is not stimulated. Without aldosterone, the small aldosterone-dependent part of Na^+ reabsorption in the distal segments of the tubule does not occur. Instead, this nonreabsorbed Na^+ is lost in the urine. In the absence of aldosterone, the ongoing loss of this small percentage of filtered Na^+ can rapidly remove excess Na^+ from the body. Even though only about 8 percent of the filtered Na^+ depends on aldosterone for reabsorption, this small loss, multiplied many times as the entire

FIGURE 13-16 Renin–angiotensin–aldosterone system (RAAS). The kidneys secrete the hormone renin in response to reduced NaCl, ECF volume, and arterial blood pressure. Renin activates angiotensinogen, a plasma protein produced by the liver, into angiotensin I. Angiotensin I is converted into angiotensin II by angiotensin-converting enzyme (ACE) produced in the lungs. Angiotensin II stimulates the adrenal cortex to secrete the hormone aldosterone, which stimulates Na^+ reabsorption by the kidneys. The resulting retention of Na^+ exerts an osmotic effect that holds more H_2O in the ECF. Together, the conserved Na^+ and H_2O help correct the original stimuli that activated this hormonal system. Angiotensin II also exerts other effects that help rectify the original stimuli, such as by promoting arteriolar vasoconstriction.

plasma volume is filtered through the kidneys many times per day, can lead to a sizable loss of Na^+ .

In the complete absence of aldosterone, 20 g of salt may be excreted per day. With maximum aldosterone secretion, all the filtered Na^+ (and, accordingly, all the filtered Cl^-) is reabsorbed, so salt excretion in the urine is zero. The amount of aldosterone secreted, and consequently the relative amount of salt conserved versus salt excreted, usually varies between these extremes, depending on the body's needs. For example, an average salt consumer typically excretes about 10 g of salt per day in the urine, a heavy salt consumer excretes more, and someone who has lost considerable salt during heavy sweating excretes less urinary salt. By varying the amount of renin and aldosterone secreted in accordance with the salt-determined fluid load in

the body, the kidneys can finely adjust the amount of salt conserved or eliminated. In doing so, they maintain the salt load and ECF volume/arterial blood pressure at a relatively constant level, despite wide variations in salt consumption and abnormal losses of salt-laden fluid.

ROLE OF THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM IN VARIOUS DISEASES

Clinical Note Some cases of hypertension (high blood pressure) are due to abnormal increases in RAAS activity. This system is also responsible in part for the fluid retention and oedema accompanying congestive heart failure. Because of the failing heart, cardiac output is reduced and arterial blood pressure is low, despite a normal or even expanded plasma volume.

When a fall in blood pressure is due to a failing heart rather than a reduced salt/fluid load in the body, the salt- and fluid-retaining reflexes triggered by the low blood pressure are inappropriate. Sodium excretion may fall to virtually zero despite continued salt ingestion and accumulation in the body. The resulting expansion of the ECF produces oedema and exacerbates the congestive heart failure because the weakened heart cannot pump the additional plasma volume.

DRUGS THAT AFFECT SODIUM REABSORPTION

Because their salt-retaining mechanisms are being inappropriately triggered, patients with congestive heart failure are placed on low-salt diets. Often they are treated with **diuretics**, therapeutic agents that cause *diuresis* (increased urinary output) and thus promote loss of fluid from the body. Many of these drugs function by inhibiting tubular reabsorption of Na^+ . As more Na^+ is excreted, more H_2O is also lost from the body, helping remove the excess ECF.

ACE inhibitor drugs, which block the action of angiotensin-converting enzyme (ACE), and **aldosterone receptor blockers** are both also beneficial in treating hypertension and congestive heart failure. By blocking the generation of angiotensin II or by blocking the binding of aldosterone with its renal receptors, respectively, these two classes of drugs halt the ultimate salt- and fluid-conserving actions and arteriolar-constrictor effects of RAAS.

Atrial natriuretic peptide and reabsorption

Atrial natriuretic peptide (ANP) is a polypeptide hormone involved in the homeostatic control of body H_2O and Na^+ . ANP reduces H_2O and Na^+ loads on the circulatory system and thus lowers blood pressure, which is the opposite effect of aldosterone and the RAAS. ANP is released by atrial myocytes (muscle cells) from granules in the atria of the heart in response to high blood pressure, hypervolaemia, and exercise. When blood volume is increased or there is increased venous return (exercise), stretch receptors in the left atria, aortic arch, and carotid sinus stimulate the release of ANP (► Figure 13-17). Other potential stimulants for the release of ANP are sympathetic stimulation, elevated Na^+ concentration, angiotensin II, and endothelin (vasoconstrictor).

The main action of ANP is to directly inhibit Na^+ reabsorption in the distal nephron, thereby increasing Na^+ excretion in the urine. ANP further increases Na^+ excretion in the urine by inhibiting two steps of the Na^+ -conserving RAAS. ANP inhibits renin secretion by the kidneys and acts on the adrenal cortex to inhibit aldosterone secretion. ANP also promotes natriuresis and accompanying diuresis by increasing the GFR through dilation of the afferent arterioles, raising glomerular capillary blood pressure, and by relaxing the glomerular mesangial cells, leading to an increase in K_f . As more salt and water are filtered, more salt and water are excreted in the urine. Besides indirectly lowering blood pressure by reducing the Na^+ load and hence the fluid load in the body, ANP directly lowers blood pressure. It does so by decreasing the cardiac output and reducing peripheral vascular resistance by means of inhibiting sympathetic nervous activity to the heart and blood vessels. Of note, it was Canadian researcher Dr. A.J. De Bold who discovered ANP in the 1980s while at Queen's University in Kingston, Ontario.

► **FIGURE 13-17 Atrial natriuretic peptide.** The atria secrete the hormone atrial natriuretic peptide (ANP) in response to being stretched by Na^+ retention, expansion of the ECF volume, and increase in arterial blood pressure. ANP, in turn, promotes natriuretic, diuretic, and hypotensive effects to help correct the original stimuli that resulted in its release.

The relative contributions of ANP in maintaining salt and water balance and blood pressure regulation are presently being intensively investigated. Importantly, derangements of this system could logically contribute to hypertension. In fact, recent studies suggest that a deficiency of the counterbalancing natriuretic system may underlie some cases of long-term hypertension by leaving the powerful Na^+ -conserving system unopposed. The resulting Na^+ retention, especially in association with high salt intake, could expand ECF volume and elevate blood pressure.

We now shift our attention to the reabsorption of other filtered solutes. However, we will continue to discuss Na^+ reabsorption, because the reabsorption of many other solutes is linked in some way to Na^+ reabsorption.

Glucose and amino acids

Large quantities of nutritionally important organic molecules, such as glucose and amino acids, are filtered each day. Normally these substances are completely reabsorbed back into the blood by energy- and Na^+ -dependent mechanisms located in the proximal tubule, so none of these materials are usually excreted in the urine. This rapid and thorough reabsorption early in the tubules protects against the loss of these important organic nutrients.

Even though glucose and amino acids are moved uphill against their concentration gradients from the tubular lumen into the blood until their concentration in the tubular fluid is virtually zero, no energy is directly used to operate the glucose or amino acid carriers. Glucose and amino acids are transferred by secondary active transport. With this process, specialized *cotransport carriers* located only in the proximal tubule simultaneously transfer both Na^+ and the specific organic molecule from the lumen into the cell (p. 44). This luminal cotransport carrier is the means by which Na^+ passively crosses the luminal membrane in the proximal tubule. The lumen-to-cell Na^+ concentration gradient maintained by the energy-consuming basolateral Na^+-K^+ pump drives this cotransport system and pulls the organic molecule against its concentration gradient without the direct expenditure of energy. Because the overall process of glucose and amino acid reabsorption depends on the use of energy, these organic molecules are considered to be actively reabsorbed, even though energy is not used directly to transport them across the membrane. In essence, glucose and amino acids get a “free ride” at the expense of energy already used in the reabsorption of Na^+ . Secondary active transport requires the presence of Na^+ in the lumen; without Na^+ , the cotransport carrier is inoperable. Once transported into the tubular cells, glucose and amino acids passively diffuse down their concentration gradients across the basolateral membrane into the plasma, facilitated by a carrier that is not dependent on energy.

Actively reabsorbed substances

All actively reabsorbed substances bind with plasma membrane carriers that transfer them across the membrane against a concentration gradient. Each carrier is specific for the types of substances it can transport; for example, the glucose cotransport carrier cannot transport amino acids, or vice versa. Because a

limited number of each carrier type is present in the cells lining the tubules, there is an upper limit on how much of a particular substance can be actively transported from the tubular fluid in a given period of time. The maximum reabsorption rate is reached when all the specific carriers for a particular substance are fully occupied or saturated, so they cannot handle any additional passengers at that time. This transport maximum is designated as the **tubular maximum** (T_m). Any quantity of a substance filtered beyond its T_m is not reabsorbed and escapes instead into the urine. With the exception of Na^+ , all actively reabsorbed substances have a tubular maximum. (Even though individual Na^+ transport carriers can become saturated, the tubules as a whole do not display a tubular maximum for Na^+ , because aldosterone promotes the synthesis of more active Na^+-K^+ carriers in the distal and collecting tubular cells as needed.)

The plasma concentrations of some, but not all, substances that display carrier-limited reabsorption are regulated by the kidneys. How can the kidneys regulate some actively reabsorbed substances but not others, when the renal tubules limit the quantity of each of these substances that can be reabsorbed and returned to the plasma? We will compare glucose, a substance that has a T_m but is *not regulated* by the kidneys, with phosphate, a T_m -limited substance that is *regulated* by the kidneys.

Glucose and the kidneys

The normal plasma concentration of glucose is 100 mg of glucose/100 mL of plasma. Because glucose is freely filterable at the glomerulus, it passes into Bowman’s capsule at the same concentration it has in the plasma. Accordingly, 100 mg of glucose are present in every 100 mL of plasma filtered. With 125 mL of plasma normally being filtered each minute (average GFR = 125 mL/min), 125 mg of glucose pass into Bowman’s capsule with this filtrate every minute. The quantity of any substance filtered per minute, known as its **filtered load**, can be calculated as follows:

$$\begin{aligned}\text{Filtered load of a substance} &= \text{plasma concentration of the} \\ &\quad \text{substance} \times \text{GFR} \\ \text{Filtered load of glucose} &= 100 \text{ mg} / 100 \text{ mL} \times 125 \text{ mL} / \text{min} \\ &= 125 \text{ mg} / \text{min}\end{aligned}$$

At a constant GFR, the filtered load of glucose is directly proportional to the plasma glucose concentration. Doubling the plasma glucose concentration to 200 mg/100 mL doubles the filtered load of glucose to 250 mg/min, and so on (► Figure 13-18).

TUBULAR MAXIMUM FOR GLUCOSE

The T_m for glucose averages 375 mg/min; that is, the glucose carrier mechanism is capable of actively reabsorbing up to 375 mg of glucose per minute before it reaches its maximum transport capacity. At a normal plasma glucose concentration of 100 mg/100 mL, the 125 mg of glucose filtered per minute can readily be reabsorbed by the glucose carrier mechanism, because the filtered load is well below the T_m for glucose. Ordinarily, therefore, no glucose appears in the urine. Not until the filtered load of glucose exceeds 375 mg/min is the T_m reached. When more

FIGURE 13-18 Renal handling of glucose as a function of plasma glucose concentration. At a constant GFR, the quantity of glucose filtered per minute is directly proportional to the plasma concentration of glucose. All the filtered glucose can be reabsorbed up to the tubular maximum (T_m). If the amount of glucose filtered per minute exceeds the T_m , the maximum amount of glucose is reabsorbed (a T_m worth), and the rest stays in the filtrate to be excreted in urine. The renal threshold is the plasma concentration at which the T_m is reached and glucose first starts appearing in the urine.

glucose is filtered per minute than can be reabsorbed because the T_m is exceeded, the maximum amount is reabsorbed, while the rest stays in the filtrate to be excreted. Accordingly, the plasma glucose concentration must be greater than 300 mg/100 mL—more than three times the normal value—before the amount filtered exceeds 375 mg/min and glucose starts spilling into the urine.

RENAL THRESHOLD FOR GLUCOSE

The plasma concentration at which the T_m of a particular substance is reached and the substance first starts appearing in urine is called the **renal threshold**. At the average T_m of 375 mg/min and GFR of 125 mL/min, the renal threshold for glucose is 300 mg/100 mL.¹ Beyond the T_m , reabsorption stays constant at its maximum rate, and any further increase in the filtered load leads to a directly proportional increase in the amount of the substance excreted. For example, at a plasma glucose concentration of 400 mg/100 mL, the filtered load of glucose is 500 mg/min, 375 mg/min of which can be reabsorbed (a T_m

worth) and 125 mg/min of which are excreted in the urine. At a plasma glucose concentration of 500 mg/100 mL, the filtered load is 625 mg/min, but only 375 mg/min can be reabsorbed, and 250 mg/min spill into the urine (Figure 13-18).

The plasma glucose concentration can become extremely high in *diabetes mellitus*, an endocrine disorder involving inadequate insulin action. Insulin is a pancreatic hormone that facilitates transport of glucose into many body cells. When cellular glucose uptake is impaired, glucose that cannot gain entry into cells stays in the plasma, elevating the plasma glucose concentration. Consequently, although glucose does not normally appear in urine, it is found in the urine of people with diabetes when the plasma glucose concentration exceeds the renal threshold, even though renal function has not changed.

What happens when plasma glucose concentration falls below normal? The renal tubules, of course, reabsorb all the filtered glucose, because the glucose reabsorptive capacity is far from being exceeded. The kidneys cannot do anything to raise a low plasma glucose level to normal. They simply return all the filtered glucose to the plasma.

REASON THAT THE KIDNEYS DO NOT REGULATE GLUCOSE

The kidneys do not influence plasma glucose concentration over a wide range of values from abnormally low levels up to three times the normal level. Because the T_m for glucose is well above the normal filtered load, the kidneys usually conserve all the glucose, thereby protecting against loss of this important nutrient in the urine. The kidneys do not regulate glucose, because they do not maintain glucose at some specific plasma concentration. Instead, this concentration is normally regulated by endocrine and liver mechanisms, with the kidneys merely maintaining whatever plasma glucose concentration is set by these other mechanisms (except when excessively high levels overwhelm the kidneys' reabsorptive capacity). The same general principle holds true for other organic plasma nutrients, such as amino acids and water-soluble vitamins.

Phosphate and the kidneys

The kidneys do directly contribute to the regulation of many electrolytes, such as phosphate (PO_4^{3-}) and calcium (Ca^{2+}), because the renal thresholds of these inorganic ions equal their normal plasma concentrations. The transport carriers for these electrolytes are located in the proximal tubule. Here we use PO_4^{3-} as an example. Our diets are generally rich in PO_4^{3-} , but because the tubules can reabsorb up to the normal plasma concentration's worth of PO_4^{3-} and no more, the excess ingested PO_4^{3-} is quickly spilled into the urine, restoring the plasma concentration to normal. The greater the amount of PO_4^{3-} ingested beyond the body's needs, the greater is the amount excreted. In this way, the kidneys maintain the desired plasma PO_4^{3-} concentration while eliminating any excess PO_4^{3-} ingested.

Unlike the reabsorption of organic nutrients, the reabsorption of PO_4^{3-} and Ca^{2+} is also subject to hormonal control. Parathyroid hormone can alter the renal thresholds for PO_4^{3-} and

¹This is an idealized situation. In reality, glucose often starts spilling into the urine at glucose concentrations of 180 mg/100 mL and above. Glucose is often excreted before the average renal threshold of 300 mg/100 mL is reached for two reasons. First, not all nephrons have the same T_m , so some nephrons may have exceeded their T_m and be excreting glucose, while others have not yet reached their T_m . Second, the efficiency of the glucose cotransport carrier may not be working at its maximum capacity at elevated values less than the true T_m , so some of the filtered glucose may fail to be reabsorbed and spill into the urine even though the average renal threshold has not been reached.

Ca^{2+} , thus adjusting the quantity of these electrolytes conserved, depending on the body's momentary needs (Chapter 6).

Responsibility of Na^+ reabsorption for Cl^- , H_2O , and urea reabsorption

Not only is secondary active reabsorption of glucose and amino acids linked to the basolateral $\text{Na}^+ - \text{K}^+$ pump, but passive reabsorption of Cl^- , H_2O , and urea also depends on this active Na^+ reabsorption mechanism.

CHLORIDE REABSORPTION

The negatively charged chloride ions are passively reabsorbed down the electrical gradient created by the active reabsorption of the positively charged sodium ions. For the most part, chloride ions pass between, not through, the tubular cells. The amount of Cl^- reabsorbed is determined by the rate of active Na^+ reabsorption, instead of being directly controlled by the kidneys.

WATER REABSORPTION

Water is passively reabsorbed throughout the length of the tubule because it osmotically follows the Na^+ that is actively reabsorbed. Of the H_2O filtered, 65 percent—117 L per day—is passively reabsorbed by the end of the proximal tubule. Another 15 percent of the filtered H_2O is obligatorily reabsorbed from the loop of Henle. This 80 percent of the filtered H_2O is reabsorbed in the proximal tubule and Henle's loop, regardless of the H_2O load in the body, and is not subject to regulation. Variable amounts of the remaining 20 percent are reabsorbed in the distal portions of the tubule; the extent of reabsorption in the distal and collecting tubules is under direct hormonal control, depending on the body's state of hydration. No part of the tubule directly requires energy for this tremendous reabsorption of H_2O .

During reabsorption, H_2O passes through aquaporins (water channels), formed by specific plasma membrane proteins in the tubular cells. Different types of water channels are present in various parts of the nephron. The water channels in the proximal tubule are always open, which accounts for the high H_2O permeability of this region. The channels in the distal parts of the nephron, in contrast, are regulated by the hormone *vasopressin*, which accounts for the variable H_2O reabsorption in this region.

The main driving force for H_2O reabsorption in the proximal tubule is a compartment of hypertonicity in the lateral spaces between the tubular cells established by the basolateral pump's active extrusion of Na^+ (► Figure 13-19). As a result of this pump activity, the concentration of Na^+ rapidly diminishes in the tubular fluid and tubular cells, while it simultaneously increases in the localized region within the lateral spaces. This osmotic gradient induces the passive net flow of H_2O from the lumen into the lateral spaces, either through the cells or intercellularly through leaky

tight junctions. The accumulation of fluid in the lateral spaces results in a build-up of hydrostatic (fluid) pressure, which flushes H_2O out of the lateral spaces into the interstitial fluid and finally into the peritubular capillaries. Water also osmotically follows other preferentially reabsorbed solutes, such as glucose (which is also Na^+ dependent). However, the direct influence of Na^+ reabsorption on passive H_2O reabsorption is quantitatively more important.

This return of filtered H_2O to the plasma is enhanced by the fact that the plasma-colloid osmotic pressure is greater in the peritubular capillaries than elsewhere. The concentration of plasma proteins, which is responsible for the plasma osmotic pressure, is elevated in the blood entering the peritubular capillaries because of the extensive filtration of H_2O through the glomerular capillaries upstream. The plasma proteins left behind in the glomerulus are concentrated into a smaller volume of plasma H_2O , increasing the plasma-colloid osmotic pressure of the unfiltered blood that leaves the glomerulus and enters the peritubular capillaries. This force tends to “pull” H_2O into the peritubular capillaries simultaneously with the push of the hydrostatic pressure in the lateral spaces that drives H_2O toward the capillaries. By these means, 65 percent of the filtered H_2O —117 L per day—is passively reabsorbed by the end of the proximal tubule.

The mechanisms responsible for H_2O reabsorption beyond the proximal tubule are described later.

UREA REABSORPTION

Passive reabsorption of urea, in addition to Cl^- and H_2O , is also indirectly linked to active Na^+ reabsorption. **Urea** is a waste product from the breakdown of protein. The osmotically induced

► **FIGURE 13-19 Water reabsorption in the proximal tubule.** The force for H_2O reabsorption is the compartment of hypertonicity in the lateral spaces established by active extrusion of Na^+ by the basolateral pump. The resultant accumulation of H_2O in the lateral spaces creates a hydrostatic pressure that drives the H_2O into the peritubular capillaries.

reabsorption of H_2O in the proximal tubule secondary to active Na^+ reabsorption produces a concentration gradient for urea that favours passive reabsorption of this waste (► Figure 13-20). Extensive reabsorption of H_2O in the proximal tubule gradually reduces the original 125 mL/min of filtrate until only 44 mL/min of fluid remain in the lumen by the end of the proximal tubule (65% of the H_2O in the original filtrate, or 81 mL/min, has been reabsorbed). Substances that have been filtered but not reabsorbed become progressively more concentrated in the tubular fluid because H_2O is reabsorbed, and they are left behind. Urea is one such substance. Urea's concentration as it is filtered at the glomerulus is identical to its concentration in the plasma entering the peritubular capillaries. The quantity of urea present in the 125 mL of filtered fluid at the beginning of the proximal tubule, however, is concentrated almost threefold in the 44 mL left at the end of the proximal tubule. As a result, the urea concentration within the tubular fluid becomes much greater than

the urea concentration in the adjacent capillaries. Therefore, a concentration gradient is created for urea to passively diffuse from the tubular lumen into the peritubular capillary plasma. Because the walls of the proximal tubules are only somewhat permeable to urea, only about 50 percent of the filtered urea is passively reabsorbed by this means.

Even though only half of the filtered urea is eliminated from the plasma with each pass through the nephrons, this removal rate is adequate. The urea concentration in the plasma becomes elevated only in impaired kidney function, when much less than half of the urea is removed. An elevated urea level was one of the first chemical characteristics to be identified in the plasma of patients with severe renal failure. Accordingly, clinical measurement of **blood urea nitrogen (BUN)** came into use as a crude assessment of kidney function. It is now known that the most serious consequences of renal failure are not attributable to the retention of urea, which itself is not especially toxic, but rather to the accumulation of other substances that are not adequately excreted because of their failure to be properly secreted—most notably H^+ and K^+ . Health professionals still often refer to renal failure as **uraemia** (urea in the blood), indicating excess urea in the blood, even though urea retention is not this condition's major threat.

Unwanted waste products

The filtered waste products other than urea—such as *phenol* (mainly from ingested sources, but also produced within the body) and *creatinine*—are likewise concentrated in the tubular fluid as H_2O leaves the filtrate to enter the plasma. However, they are not passively reabsorbed, as urea is. Urea molecules, the smallest of the waste products, are the only wastes passively reabsorbed by this concentrating effect. Even though the other wastes are also concentrated in the tubular fluid, they cannot leave the lumen and move down their concentration gradients to be passively reabsorbed, because they cannot permeate the tubular wall. Therefore, the waste products, not being reabsorbed, generally remain in the tubules and are excreted in the urine in highly concentrated form. This excretion of metabolic wastes is not subject to physiological control. When renal function is normal, however, the excretory processes proceed at a satisfactory rate even though they are not controlled.

This completes our discussion of tubular reabsorption. We now turn our attention to the other basic renal process carried out by the tubules: tubular secretion.

► **FIGURE 13-20** Passive reabsorption of urea at the end of the proximal tubule. (a) In Bowman's capsule and at the beginning of the proximal tubule, urea is at the same concentration as in the plasma and surrounding interstitial fluid. (b) By the end of the proximal tubule, 65 percent of the original filtrate has been reabsorbed, concentrating the filtered urea in the remaining filtrate. This establishes a concentration gradient favouring passive reabsorption of urea.

Check Your Understanding 13.3

1. Show the steps of transepithelial transport on a sketch you make of a kidney tubule and associated peritubular capillary.
2. Describe the sequence of events that take place in the renin-angiotensin-aldosterone system in response to a fall in NaCl, ECF volume, and arterial blood pressure.
3. Explain how the kidneys regulate the plasma concentration of phosphate, but not of glucose, when the kidney tubules display a transport maximum (T_m) for both of these substances.

13.5 | Tubular Secretion

Like tubular reabsorption, tubular secretion involves transepithelial transport, but now the steps are reversed. *Tubular secretion* refers to the discrete transfer of substances from the peritubular capillaries into the tubular lumen. As a second route of entry into the tubules for selected substances, it hastens elimination of these compounds from the body. Anything that gains entry to the tubular fluid—whether by glomerular filtration or tubular secretion—and fails to be reabsorbed is eliminated in the urine.

The most important substances secreted by the tubules are hydrogen ion (H^+), potassium ion (K^+), and organic anions and cations, many of which are compounds foreign to the body.

Hydrogen ion secretion

Renal H^+ secretion is extremely important in regulating acid–base balance in the body. Hydrogen ions secreted into the tubular fluid are eliminated from the body in the urine. Hydrogen ions can be secreted by the proximal, distal, and collecting tubules, and the amount of this secretion depends on the acidity of the body fluids. When the body fluids are too acidic, H^+ secretion increases. Conversely, H^+ secretion is reduced when the H^+ concentration in the body fluids is too low. (See Chapter 14 for further detail.)

Potassium ion secretion

Potassium ions are selectively moved in opposite directions in different parts of the tubule; they are actively reabsorbed in the proximal tubule and actively secreted in the distal and collecting tubules. Early in the tubule, K^+ is reabsorbed in a constant, unregulated fashion, whereas later in the tubule, K^+ secretion is variable and subject to regulation. The filtered K^+ is almost completely reabsorbed in the proximal tubule, so most K^+ in the urine is derived from a controlled K^+ secretion in the distal parts of the nephron, rather than from filtration.

During K^+ depletion, K^+ secretion in the distal parts of the nephron is reduced to a minimum, so only the small percentage of filtered K^+ that escapes reabsorption in the proximal tubule is excreted in the urine. In this way, K^+ that normally would have been lost in urine is conserved for the body. Conversely, when plasma K^+ levels are elevated, K^+ secretion is adjusted so that just enough K^+ is added to the filtrate for elimination to reduce the plasma K^+ concentration to normal. Thus, K^+ secretion, not the filtration or reabsorption of K^+ , is varied in a controlled fashion to regulate the rate of K^+ excretion and maintain the desired plasma K^+ concentration.

MECHANISM OF K^+ SECRETION

Potassium ion secretion in the distal and collecting tubules is coupled to Na^+ reabsorption by the energy-dependent basolateral $\text{Na}^+ - \text{K}^+$ pump

(Figure 13-21). This pump not only moves Na^+ out of the cell into the lateral space but also transports K^+ from the lateral space into the tubular cells. The resulting high intracellular K^+ concentration favours net movement of K^+ from the cells into the tubular lumen. Movement across the luminal membrane occurs passively through the large number of K^+ channels in this barrier in the distal and collecting tubules. By keeping the interstitial fluid concentration of K^+ low as it transports K^+ into the tubular cells from the surrounding interstitial fluid, the basolateral pump encourages passive movement of K^+ out of the peritubular capillary plasma into the interstitial fluid. Potassium ion leaving the plasma in this manner is later pumped into the cells, from which it passively moves into the lumen. In this way, the basolateral pump actively induces the net secretion of K^+ from the peritubular capillary plasma into the tubular lumen in the distal parts of the nephron.

K^+ secretion is linked with Na^+ reabsorption by the $\text{Na}^+ - \text{K}^+$ pump, so why isn't K^+ secreted throughout the Na^+ -reabsorbing segments of the tubule, instead of taking place only in the distal parts of the nephron? The answer lies in the location of the passive K^+ channels. In the distal and collecting tubules, the K^+ channels are concentrated in the luminal membrane, providing a route for K^+ pumped into the cell to exit into the lumen, thus being secreted. In the other tubular segments, the K^+ channels are located primarily in the basolateral membrane. As a result, K^+ pumped into the cell from the lateral space by the $\text{Na}^+ - \text{K}^+$ pump simply moves back out into the lateral space through these channels. This K^+ recycling permits the ongoing operation of the $\text{Na}^+ - \text{K}^+$ pump to accomplish Na^+ reabsorption with no local net effect on K^+ .

▶ **FIGURE 13-21 Potassium ion secretion.** The basolateral pump simultaneously transports Na^+ into the lateral space and K^+ into the tubular cell. In the parts of the tubule that secrete K^+ , this ion leaves the cell through channels located in the luminal border, thus being secreted. (In the parts of the tubule that do not secrete K^+ , the K^+ pumped into the cell during Na^+ reabsorption leaves the cell through channels located in the basolateral border, thus being retained in the body.)

CONTROL OF K⁺ SECRETION

Several factors can alter the rate of K⁺ secretion, the most important being aldosterone. This hormone stimulates K⁺ secretion by the tubular cells late in the nephron, while simultaneously enhancing these cells' reabsorption of Na⁺. A rise in plasma K⁺ concentration directly stimulates the adrenal cortex to increase its output of aldosterone, which in turn promotes the secretion and ultimate urinary excretion and elimination of excess K⁺. Conversely, a decline in plasma K⁺ concentration causes a reduction in aldosterone secretion and a corresponding decrease in aldosterone-stimulated renal K⁺ secretion.

Note that a rise in plasma K⁺ concentration directly stimulates aldosterone secretion by the adrenal cortex, whereas a fall in plasma Na⁺ concentration stimulates aldosterone secretion by means of the complex RAAS pathway. Thus, aldosterone secretion can be stimulated by two separate pathways (► Figure 13-22). No matter what the stimulus, however, increased aldosterone secretion always promotes simultaneous Na⁺ reabsorption and K⁺ secretion. For this reason, K⁺ secretion can be inadvertently stimulated as a result of increased aldosterone activity brought about by Na⁺ depletion, ECF volume reduction, or a fall in arterial blood pressure totally unrelated to K⁺ balance. The resulting inappropriate loss of K⁺ can lead to K⁺ deficiency.

EFFECT OF H⁺ SECRETION ON K⁺ SECRETION

Another factor that can inadvertently alter the magnitude of K⁺ secretion is the acid–base status of the body. The basolateral pump in the distal portions of the nephron can secrete either

K⁺ or H⁺ in exchange for reabsorbed Na⁺. An increased rate of secretion of either K⁺ or H⁺ is accompanied by a decreased rate of secretion of the other ion. Normally, the kidneys secrete a preponderance of K⁺, but when the body fluids are too acidic and H⁺ secretion is increased as a compensatory measure, K⁺ secretion is correspondingly reduced. This reduced secretion leads to inappropriate K⁺ retention in the body fluids.

IMPORTANCE OF REGULATING PLASMA K⁺ CONCENTRATION

Except in the overriding circumstances of K⁺ imbalances inadvertently induced during renal compensations for Na⁺ or ECF volume deficits or acid–base imbalances, the kidneys usually exert a fine degree of control over plasma K⁺ concentration. This is extremely important, because even minor fluctuations in plasma K⁺ concentration can have detrimental consequences.

Clinical Note Potassium plays a key role in the membrane electrical activity of excitable tissues. Both increases and decreases in the plasma (ECF) K⁺ concentration can alter the intracellular-to-extracellular K⁺ concentration gradient, which in turn can change the resting membrane potential. A rise in ECF K⁺ concentration leads to a reduction in resting potential and a subsequent increase in excitability, especially of heart muscle. This cardiac overexcitability can lead to a rapid heart rate and even fatal cardiac arrhythmias. Conversely, a fall in ECF K⁺ concentration results in hyperpolarization of nerve and muscle cell membranes, which reduces their excitability. The manifestations of ECF K⁺ depletion are skeletal muscle weakness, diarrhoea, and abdominal distension caused by smooth muscle dysfunction, and abnormalities in cardiac rhythm and impulse conduction.

Organic anion and cation secretion

The proximal tubule contains two distinct types of secretory carriers: one for the secretion of organic anions and another for secretion of organic cations.

FUNCTIONS OF ORGANIC ION SECRETORY SYSTEMS

The organic ion secretory systems serve three important functions:

1. By adding more of a particular type of organic ion to the quantity that has already gained entry to the tubular fluid by glomerular filtration, these organic secretory pathways facilitate excretion of these substances. Included among these organic ions are certain blood-borne chemical messengers, such as prostaglandins, histamine, and norepinephrine, which having served their purpose, must be rapidly removed from the blood so that their biological activity is not unduly prolonged.
2. In some important instances, organic ions are poorly soluble in water. To be transported in blood, they are extensively but not irreversibly bound to plasma proteins. Because they are attached to plasma proteins, these substances cannot be filtered through the glomeruli. Tubular secretion facilitates elimination of these nonfilterable organic ions in urine. Even though a given organic ion is

► FIGURE 13-22 Dual control of aldosterone secretion by K⁺ and Na⁺

largely bound to plasma proteins, a small percentage of the ion always exists in free or unbound form in the plasma. Removal of this free organic ion by secretion permits the unloading of some of the bound ion, which is then free to be secreted. This, in turn, encourages the unloading of even more organic ion, and so on.

- Most importantly, the proximal tubule organic ion secretory systems play a key role in eliminating many foreign compounds from the body. These systems can secrete a large number of different organic ions, both those produced endogenously (within the body) and those foreign organic ions that have gained access to the body fluids. This nonselectivity permits these organic ion secretory systems to hasten removal of many foreign organic chemicals, including food additives, environmental pollutants (e.g., pesticides), drugs, and other non-nutritive organic substances that have entered the body. Even though this mechanism helps rid the body of potentially harmful foreign compounds, it is not subject to physiological adjustments. The carriers cannot increase their secretory pace when confronted with an elevated load of these organic ions.

The liver plays an important role in helping rid the body of foreign compounds. Many foreign organic chemicals are not ionic in their original form, so they cannot be secreted by the organic ion systems. The liver converts these foreign substances into an anionic form that facilitates their secretion by the organic anion system and, thus, accelerates their elimination.

 Many drugs, such as penicillin and nonsteroidal anti-inflammatory drugs (NSAIDs), are eliminated from the body by the organic ion secretory systems. To keep the plasma concentration of these drugs at effective levels, the dosage must be repeated on a regular, frequent basis to keep pace with the rapid removal of these compounds in the urine.

Summary of reabsorptive and secretory processes

This completes our discussion of the reabsorptive and secretory processes that occur across the proximal and distal portions of the nephron. These processes are summarized in ■ Table 13-3. To generalize, the proximal tubule does most of the reabsorbing. This mass reabsorber transfers much of the filtered water and needed solutes back into the blood in unregulated fashion. Similarly, the proximal tubule is the major site of secretion, with the exception of K^+ secretion. The distal and collecting tubules then determine the final amounts of H_2O , Na^+ , K^+ , and H^+ excreted in the urine and thus eliminated from the body. They do so by fine-tuning the amount of Na^+ and H_2O reabsorbed and the amount of K^+ and H^+ secreted. These processes in the distal part of the nephron are all subject to control, depending on the body's momentary needs. The unwanted filtered waste products are left behind to be eliminated in the urine, along with excess amounts of filtered or secreted nonwaste products that fail to be reabsorbed.

■ **TABLE 13-3** Summary of Transport across Proximal and Distal Portions of the Nephron

PROXIMAL TUBULE	
Reabsorption	Secretion
67 percent of filtered Na^+ actively reabsorbed; not subject to control; Cl^- follows passively	Variable H^+ secretion, depending on acid–base status of body
All filtered glucose and amino acids reabsorbed by secondary active transport; not subject to control	Organic ion secretion; not subject to control
Variable amounts of filtered PO_4^{3-} and other electrolytes reabsorbed; subject to control; 65 percent of filtered H_2O osmotically reabsorbed; not subject to control	
50 percent of filtered urea passively reabsorbed; not subject to control	
Almost all filtered K^+ reabsorbed; not subject to control	
DISTAL TUBULE AND COLLECTING DUCT	
Reabsorption	Secretion
Variable Na^+ reabsorption, controlled by aldosterone; Cl^- follows passively	Variable H^+ secretion, depending on acid–base status of body
Variable H_2O reabsorption, controlled by vasopressin	Variable K^+ secretion, controlled by aldosterone

Next we focus on the end result of the basic renal processes—what's left in the tubules to be excreted in urine, and, as a consequence, what has been cleared from plasma.

Check Your Understanding 13.4

- List the three secretory processes accomplished by the kidney tubules.
- Explain how most foreign organic compounds are eliminated from the body.

13.6 | Urine Excretion and Plasma Clearance

Of the 125 mL of plasma filtered per minute, typically 124 mL/min are reabsorbed, so the final quantity of urine formed averages 1 mL/min. Thus, of the 180 L filtered per day, 1.5 L of urine are excreted.

Urine contains high concentrations of various waste products plus variable amounts of the substances regulated by the kidneys—any excess having spilled into the urine. Useful substances are conserved by reabsorption, so they do not appear in the urine.

A relatively small change in the quantity of filtrate reabsorbed can bring about a large change in the volume of urine formed. For example, a reduction of less than 1 percent in the total reabsorption rate, from 124 to 123 mL/min, increases the urinary excretion rate by 100 percent, from 1 to 2 mL/min.

Plasma clearance: Volume

Compared with plasma entering the kidneys through the renal arteries, plasma leaving the kidneys through the renal veins lacks the materials that were left behind to be eliminated in the urine. By excreting substances in the urine, the kidneys clean, or clear, the plasma flowing through them of these substances. The **plasma clearance** of any substance is defined as the volume of plasma completely cleared of that substance by the kidneys per minute.² It refers not to the *amount of the substance* removed but to the *volume of plasma* from which that amount was removed. Plasma clearance is actually a more useful measure than urine excretion; it is more important to know what effect urine excretion has on removing materials from body fluids than to know the volume and composition of discarded urine. Plasma clearance expresses the kidneys' effectiveness in removing various substances from the internal fluid environment.

Plasma clearance can be calculated for any plasma constituent as follows:

$$\text{Clearance rate of a substance (mL/min)} = \frac{\text{urine concentration of the substance (quantity / mL urine)} \times \text{urine flow rate (mL / min)}}{\text{plasma concentration of the substance (quantity / mL plasma)}}$$

The plasma clearance rate varies for different substances, depending on how the kidneys handle each substance.

Plasma clearance rate if a substance is filtered but not reabsorbed

Assume that a plasma constituent, substance X, is freely filterable at the glomerulus, but is not reabsorbed or secreted. As 125 mL/min of plasma are filtered and subsequently reabsorbed, the quantity of

substance X originally contained within the 125 mL is left behind in the tubules to be excreted. Thus, 125 mL of plasma are cleared of substance X each minute (► Figure 13-23). (Of the 125 mL/min of plasma filtered, 124 mL/min of the filtered fluid are returned, through reabsorption, to the plasma minus substance X, thereby clearing this 124 mL/min of substance X. In addition, the 1 mL/min of fluid lost in urine is eventually replaced by an equivalent volume of ingested H₂O that is already clear of substance X. Therefore, 125 mL of plasma cleared of substance X are, in effect, returned to the plasma for every 125 mL of plasma filtered per minute.)

There is no endogenous chemical with the characteristics of substance X. All substances naturally present in the plasma, even wastes, are reabsorbed or secreted to some extent. However, **inulin** (do not confuse with insulin)—a harmless foreign carbohydrate produced by Jerusalem artichokes, onions, and garlic—is freely filtered and not reabsorbed or secreted: an ideal substance X. Inulin can be injected and its plasma clearance determined as a clinical means of ascertaining the GFR. All glomerular filtrate formed is cleared of inulin at the following rate:

$$\begin{aligned} \text{Clearance rate for inulin} &= \frac{30 \text{ mg / mL urine} \times 1.25 \text{ mL urine / min}}{0.30 \text{ mg / mL plasma}} \\ &= 125 \text{ mL plasma / min} \end{aligned}$$

So the volume of plasma cleared of inulin per minute equals the volume of plasma filtered per minute—that is, the GFR.

Although determination of inulin plasma clearance is accurate and straightforward, it is not very convenient, because inulin must be infused continuously throughout the determination to maintain a constant plasma concentration. Therefore, the plasma clearance of an endogenous substance, **creatinine**, is often used instead to find a rough estimate of the GFR. Creatinine, an end product of muscle metabolism, is produced at a relatively constant rate. It is freely filtered and not reabsorbed but is slightly secreted. Accordingly, creatinine clearance is not a completely accurate reflection of the GFR, but it does provide a close approximation and can be more readily determined than inulin clearance.

Plasma clearance rate if a substance is filtered and reabsorbed

Some or all of a reabsorbable substance that has been filtered is returned to the plasma. Because less than the filtered volume of plasma will have been cleared of the substance, the plasma clearance rate of a reabsorbable substance is always less than the GFR. For example, the plasma clearance for glucose is normally zero. All the filtered glucose is reabsorbed along with the rest of the returning filtrate, so none of the plasma is cleared of glucose (► Figure 13-23b).

For a substance that is partially reabsorbed, such as urea, only part of the filtered plasma is cleared of that substance. With about 50 percent of the filtered urea passively reabsorbed, only half of the filtered plasma, or 62.5 mL, is cleared of urea each minute (► Figure 13-23c).

²Actually, plasma clearance is an artificial concept, because when a particular substance is excreted in the urine, that substance's concentration in the plasma as a whole is uniformly decreased as a result of thorough mixing in the circulatory system. However, it is useful for comparative purposes to consider clearance in effect as the volume of plasma that would have contained the total quantity of the substance (at the substance's concentration prior to excretion) that the kidneys excreted in one minute; that is, the hypothetical volume of plasma completely cleared of that substance per minute.

(a) For a substance filtered and not reabsorbed or secreted, such as inulin, all of the filtered plasma is cleared of the substance.

(b) For a substance filtered, not secreted, and completely reabsorbed, such as glucose, none of the filtered plasma is cleared of the substance.

(c) For a substance filtered, not secreted, and partially reabsorbed, such as urea, only a portion of the filtered plasma is cleared of the substance.

(d) For a substance filtered and secreted but not reabsorbed, such as hydrogen ion, all of the filtered plasma is cleared of the substance, and the peritubular plasma from which the substance is secreted is also cleared.

© 2016 Cengage

FIGURE 13-23 Plasma clearance for substances handled in different ways by the kidneys

Plasma clearance rate if a substance is filtered and secreted but not reabsorbed

Tubular secretion allows the kidneys to clear certain materials from the plasma more efficiently. Only 20 percent of the plasma entering the kidneys is filtered. The remaining 80 percent passes unfiltered into the peritubular capillaries. The only means by which this unfiltered plasma can be cleared of any substance during this trip through the kidneys before being returned to the general circulation is by secretion. An example is hydrogen ion. Not only is filtered plasma cleared of nonreabsorbable H^+ , but the plasma from which H^+ is secreted is also cleared of H^+ . For example, if the quantity of H^+ secreted is equivalent to the quantity of H^+ present in 25 mL of plasma, the clearance rate for H^+ will be 150 mL/min at the normal GFR of 125 mL/min. Every minute 125 mL of plasma will lose its H^+ through filtration and failure of reabsorption, and 25 mL more of plasma will lose its H^+ through secretion. The plasma clearance for a secreted substance is always greater than the GFR (► Figure 13-23d).

Just as inulin can be used clinically to determine the GFR, plasma clearance of another foreign compound, the organic anion **para-aminohippuric acid (PAH)**, can be used to measure renal plasma flow. Like inulin, PAH is freely filterable and nonreabsorbable. It differs, however, in that all the PAH in the plasma that escapes filtration is secreted from the peritubular capillaries by the organic anion secretory pathway in the proximal tubule. In this way, PAH is removed from all the plasma that flows through the kidneys—both from plasma that is filtered and subsequently reabsorbed without its PAH, and from unfiltered plasma that continues on in the peritubular capillaries and loses its PAH by active secretion into the tubules. Because all the plasma that flows through the kidneys is cleared of PAH, the plasma clearance for PAH is a reasonable estimate of the rate of plasma flow through the kidneys. Typically, renal plasma flow averages 625 mL/min, for a RBF (plasma plus blood cells) of 1140 mL/min; this amounts to more than 20 percent of the cardiac output.

FILTRATION FRACTION

If you know PAH clearance (renal plasma flow) and inulin clearance (GFR), you can easily determine the **filtration fraction**, the fraction of plasma flowing through the glomeruli that is filtered into the tubules.

$$\begin{aligned}\text{Filtration fraction} &= \frac{\text{GFR (plasma inulin clearance)}}{\text{renal plasma flow (plasma PAH clearance)}} \\ &= \frac{125 \text{ mL/min}}{625 \text{ mL/min}} = 20 \text{ percent}\end{aligned}$$

Thus, 20 percent of the plasma that enters the glomeruli is typically filtered.

The kidneys and urine of varying concentrations

Having considered how the kidneys deal with a variety of solutes in the plasma, we now examine renal handling of plasma H_2O . The ECF osmolarity (solute concentration) depends on the

relative amount of H_2O compared with solute. At normal fluid balance and solute concentration, the body fluids are **isotonic** at an osmolarity of 300 mOsm/L (milliosmoles/litre). If too much H_2O is present relative to the solute load, the body fluids are **hypotonic**, which means they are too dilute at an osmolarity less than 300 mOsm/L. However, if a H_2O deficit exists relative to the solute load, the body fluids are too concentrated or are **hypertonic**, having an osmolarity greater than 300 mOsm/L.

Recall that the driving force for H_2O reabsorption throughout the entire length of the tubules is an osmotic gradient between the tubular lumen and the surrounding interstitial fluid. Therefore, given these osmotic considerations, you would expect that the kidneys could not excrete urine more or less concentrated than the body fluids. Indeed, this would be the case if the interstitial fluid surrounding the tubules in the kidneys were identical in osmolarity to the remaining body fluids. Water reabsorption would proceed only until the tubular fluid equilibrated osmotically with the interstitial fluid, and the body would have no way to eliminate excess H_2O when the body fluids were hypotonic or to conserve H_2O in the presence of hypertonicity.

Fortunately, a large **vertical osmotic gradient** is uniquely maintained in the interstitial fluid of the medulla of each kidney. The concentration of the interstitial fluid progressively increases from the cortical boundary down through the depth of the renal medulla until it reaches a maximum of 1200 mOsm/L in humans at the junction with the renal pelvis (► Figure 13-24).

The vertical osmotic gradient enables the kidneys to produce urine that ranges in concentration from 100 to 1200 mOsm/L, depending on the body's state of hydration. When the body is in ideal fluid balance, 1 mL/min of isotonic urine is formed.

► **FIGURE 13-24** Vertical osmotic gradient in the renal medulla. Schematic representation of the kidney rotated 90 degrees from its normal position in an upright person for better visualization of the vertical osmotic gradient in the renal medulla. The osmolarity of the interstitial fluid throughout the renal cortex is isotonic at 300 mOsm/L, but the osmolarity of the interstitial fluid in the renal medulla increases progressively from 300 mOsm/L at the boundary with the cortex to a maximum of 1200 mOsm/L at the junction with the renal pelvis.

When the body is overhydrated (too much H_2O), the kidneys can produce a large volume of dilute urine (up to 25 mL/min and hypotonic at 100 mOsm/L), eliminating the excess H_2O in the urine. Conversely, the kidneys can put out a small volume of concentrated urine (down to 0.3 mL/min and hypertonic at 1200 mOsm/L) when the body is dehydrated (too little H_2O), conserving H_2O for the body.

Unique anatomic arrangements and complex functional interactions between the various nephron components in the renal medulla establish and use the vertical osmotic gradient. Recall that the hairpin loop of Henle dips only slightly into the medulla in cortical nephrons, but in juxtamedullary nephrons the loop plunges through the entire depth of the medulla so that the tip of the loop lies near the renal pelvis (see Figure 13-5). Also, the vasa recta of juxtamedullary nephrons follow the same deep hairpin loop as the long loop of Henle. Flow in both the long loops of Henle and the vasa recta is considered countercurrent, because the flow in the two closely adjacent limbs of the loop moves in opposite directions. Also running through the medulla in the descending direction only, on their way to the renal pelvis, are the collecting ducts that serve both types of nephrons. This arrangement, coupled with the permeability and transport characteristics of these tubular segments, plays a key role in the kidneys' ability to produce urine of varying concentrations, depending on the body's needs for water conservation or elimination. Briefly, the juxtamedullary nephrons' long loops of Henle *establish* the vertical osmotic gradient; their vasa recta *preserve* this gradient while providing blood to the renal medulla; and the collecting ducts of all nephrons *use* the gradient, in conjunction with the hormone vasopressin, to produce urine of varying concentrations. Collectively, this entire functional organization is known as the **medullary countercurrent system**. We will examine each of its facets in detail.

The colour of human urine can vary with hydration level and other factors. A typical urine chart is set up on an eight-step scale, with the colour of urine ranging from a very light yellow (well hydrated) to a very dark yellow (severe dehydration). Hydration levels may vary based on fluid intake and sweat rate. The colours 1 through 3 show a balance in hydration. Colours 4 and 5 suggest mild dehydration. The colours 6 through 8 indicate severe dehydration. In general, colours 4 through 8 suggest that fluid intake needs to be increased.

Other factors, such as the removal of excess B vitamins from the bloodstream, may cause a yellowing of the urine. If blood is present in the urine (haematuria), there may be damage to the kidney, and immediate medical attention is required. A dark-orange to brown urine can be a sign of jaundice. Dark-coloured (melanuria) urine may be caused by a melanoma (a malignant tumour of melanocytes). Reddish urine is associated with porphyria, which is a disorder of certain enzymes associated with heme and its biochemical pathway. Milky white urine is a condition called *chyluria*, caused by the presence of chyle that consists of lymph fluid and fats.

The medullary vertical osmotic gradient

Here we follow the filtrate through a long-looped nephron to show how this structure establishes a vertical osmotic gradient in the medulla. Immediately after the filtrate is formed,

uncontrolled osmotic reabsorption of filtered H_2O occurs in the proximal tubule secondary to active Na^+ reabsorption. As a result, by the end of the proximal tubule about 65 percent of the filtrate has been reabsorbed, but the 35 percent remaining in the tubular lumen still has the same osmolarity as the body fluids. Therefore, the fluid entering the loop of Henle is still isotonic. The additional 15 percent of the filtered H_2O is obligatorily reabsorbed from the loop of Henle during the establishment and maintenance of the vertical osmotic gradient, thereby altering the osmolarity of the tubular fluid.

PROPERTIES OF THE DESCENDING AND ASCENDING LIMBS OF A LONG HENLE'S LOOP

The following functional distinctions between the descending limb of a long Henle's loop (which carries fluid from the proximal tubule down into the depths of the medulla) and the ascending limb (which carries fluid up and out of the medulla into the distal tubule) are crucial for establishing the incremental osmotic gradient in the medullary interstitial fluid.

The *descending limb* (1) is highly permeable to H_2O , and (2) does not actively extrude Na^+ —that is, does not reabsorb Na^+ . (It is the only segment of the entire tubule that does not do so.)

The *ascending limb* (1) actively transports $NaCl$ out of the tubular lumen into the surrounding interstitial fluid, and (2) is always impermeable to H_2O . Therefore, salt leaves the tubular fluid without H_2O osmotically following along.

MECHANISM OF COUNTERCURRENT MULTIPLICATION

The close proximity and countercurrent flow of the two limbs allow important interactions between them. Even though the flow of fluids is continuous through the loop of Henle, we will see what happens by going step by step, much like making an animated film run so slowly that each frame can be viewed. (See > Figure 13-25 to follow each of these steps.)

- Initial scene: Before the vertical osmotic gradient is established, the medullary interstitial fluid concentration is uniformly 300 mOsm/L, as are the rest of the body fluids.
- Step 1: The active $NaCl$ pump in the ascending limb can transport $NaCl$ out of the lumen until the surrounding interstitial fluid is 200 mOsm/L more concentrated than the tubular fluid in this limb. When the ascending limb pump starts actively extruding salt, the medullary interstitial fluid becomes hypertonic. Water cannot follow osmotically from the ascending limb, because this limb is impermeable to H_2O . However, net diffusion of H_2O does occur from the descending limb into the interstitial fluid. The tubular fluid entering the descending limb from the proximal tubule is isotonic. Because the descending limb is highly permeable to H_2O , net diffusion of H_2O occurs by osmosis out of the descending limb into the more concentrated interstitial fluid. The passive movement of H_2O out of the descending limb continues until the osmolarities of the fluid in the descending limb and interstitial fluid become equilibrated. Thus, the tubular fluid entering the loop of Henle immediately starts to become more concentrated as it loses H_2O .

3 The ascending limb pump and descending limb passive fluxes re-establish the 200 mOsm/L gradient at each horizontal level.

4 Let the fluid flow forward several "frames" once again.

FIGURE 13-25 Countercurrent multiplication in the renal medulla

At equilibrium, the osmolarity of the ascending limb fluid is 200 mOsm/L, and the osmolarities of the interstitial fluid and descending limb fluid are equal at 400 mOsm/L.

- Step 2: Advancing the entire column of fluid in the loop of Henle several frames, we see that a mass of 200 mOsm/L fluid exits from the top of the ascending limb into the distal tubule, and a new mass of isotonic fluid at 300 mOsm/L enters the top of the descending limb from the proximal tubule. At the bottom of the loop, a comparable mass of 400 mOsm/L fluid from the descending limb moves forward around the tip into the ascending limb, placing it opposite a

400 mOsm/L region in the descending limb. Note that the 200 mOsm/L concentration difference has been lost at both the top and the bottom of the loop.

- Step 3: The ascending limb pump again transports NaCl out, while H₂O passively leaves the descending limb until a 200 mOsm/L difference is reestablished between the ascending limb and both the interstitial fluid and descending limb at each horizontal level. Note, however, that the concentration of tubular fluid is progressively increasing in the descending limb and progressively decreasing in the ascending limb.

KEY

→ = Passive diffusion
 ←○ = Active transport
 All values in mOsm/litre

1 Let the pump begin. A 200 mOsm/litre gradient is established at each horizontal level.

2 Let the fluid flow forward several "frames."

5 The 200 mOsm/L gradient at each horizontal level is established once again.

6 The final vertical osmotic gradient is established and maintained by the ongoing countercurrent multiplication of the long loops of Henle.

- Step 4: As the tubular fluid is advanced still further, the 200 mOsm/L concentration gradient is disrupted once again at all horizontal levels.
- Step 5: Again, active extrusion of NaCl from the ascending limb, coupled with the net diffusion of H_2O out of the descending limb, reestablishes the 200 mOsm/L gradient at each horizontal level.
- Step 6 and on: As the fluid flows slightly forward again and this stepwise process continues, the fluid in the descending limb becomes progressively more hypertonic until it reaches a maximum concentration of 1200 mOsm/L at the bottom of the loop; this is four times the normal concentration of body

fluids. Because the interstitial fluid always achieves equilibrium with the descending limb, an incremental vertical concentration gradient, ranging from 300 to 1200 mOsm/L, is likewise established in the medullary interstitial fluid. In contrast, the concentration of the tubular fluid progressively decreases in the ascending limb because salt is pumped out, but H_2O is unable to follow. In fact, the tubular fluid even becomes hypotonic before it leaves the ascending limb to enter the distal tubule at a concentration of 100 mOsm/L—one-third the normal concentration of body fluids.

Note that although a gradient of only 200 mOsm/L exists between the ascending limb and the surrounding fluids at

each medullary horizontal level, a much larger vertical gradient exists from the top to the bottom of the medulla. Even though the ascending limb pump can generate a gradient of only 200 mOsm/L, this effect is multiplied into a large vertical gradient because of the countercurrent flow within the loop. This concentrating mechanism accomplished by the loop of Henle is known as **countercurrent multiplication**.

We have artificially described countercurrent multiplication in a stop-and-flow, stepwise fashion to facilitate understanding. It is important to realize that once the incremental medullary gradient is established, it stays constant. This is due to the continuous flow of fluid, the ongoing ascending limb active transport, and the accompanying descending limb passive fluxes.

BENEFITS OF COUNTERCURRENT MULTIPLICATION

If you consider only what happens to the tubular fluid as it flows through the loop of Henle, the whole process seems an exercise in futility. The isotonic fluid that enters the loop becomes progressively *more concentrated* as it flows down the descending limb, achieving a maximum concentration of 1200 mOsm/L, only to become progressively *more dilute* as it flows up the ascending limb, finally leaving the loop at a minimum concentration of 100 mOsm/L. What is the point of concentrating the fluid four-fold and then turning around and diluting it until it leaves at one-third the concentration at which it entered? Such a mechanism offers three benefits. First, it establishes a vertical osmotic gradient in the medullary interstitial fluid. This gradient, in turn, is used by the collecting ducts to concentrate the tubular fluid so that a urine *more concentrated* than normal body fluids can be excreted. Second, the fact that the fluid is hypotonic as it enters the distal parts of the tubule enables the kidneys to excrete a urine *more dilute* than normal body fluids. And third, it allows for the overall volume of urine to be significantly reduced, which also allows the body to conserve both salt and water. Let's see how.

Vasopressin-controlled H₂O reabsorption

Vasopressin is secreted from the posterior pituitary gland in response to a reduction in blood plasma volume or an increase in plasma osmolarity. Secretion in response to reduced plasma volume is activated by pressure receptors in the veins, atria, and carotids. Secretion in response to increases in plasma osmotic pressure is mediated by osmoreceptors in the hypothalamus.

Many factors can reduce the secretion of vasopressin from the posterior pituitary gland, including the consumption of caffeine. The resulting decrease in water reabsorption by the kidneys may lead to a higher urinary production. Thus, caffeine causes the body to lose more water and may lead to dehydration if it is consumed excessively. As well, angiotensin II, which causes vasoconstriction and the release of aldosterone from the adrenal cortex, also stimulates the release of vasopressin.

After the obligatory H₂O reabsorption from the proximal tubule (65% of the filtered H₂O) and loop of Henle (15% of the filtered H₂O), 20 percent of the filtered H₂O remains in the lumen to enter the distal and collecting tubules for variable reabsorption that is under hormonal control. This is still a large volume of filtered H₂O subject to regulated reabsorption; 20 percent $\times$ GFR (180 L/day) = 36 L/day to be reabsorbed to

varying extents, depending on the body's state of hydration. This is more than 13 times the amount of plasma H₂O in the entire circulatory system.

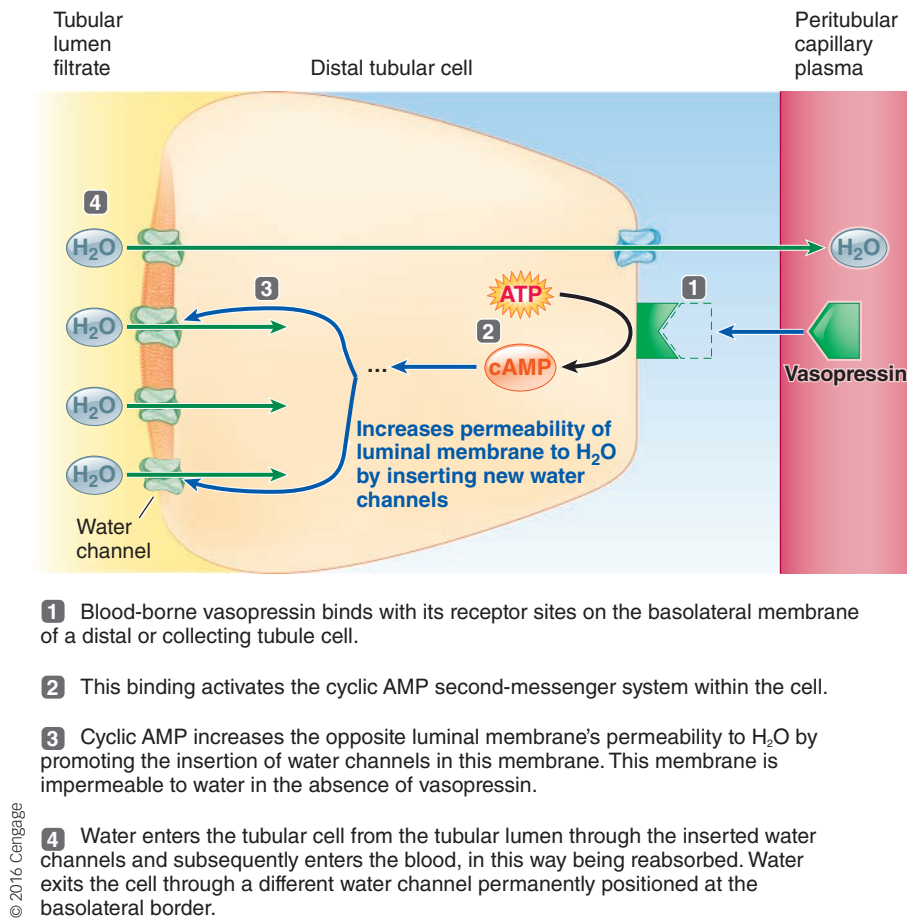

The fluid leaving the loop of Henle enters the distal tubule at 100 mOsm/L, so it is hypotonic to the surrounding isotonic (300 mOsm/L) interstitial fluid of the renal cortex, through which the distal tubule passes. The distal tubule then empties into the collecting duct, which is bathed by progressively increasing concentrations (300–1200 mOsm/L) of surrounding interstitial fluid as it descends through the medulla.

ROLE OF VASOPRESSIN

For H₂O absorption to occur across a segment of the tubule, two criteria must be met: (1) an osmotic gradient must exist across the tubule, and (2) the tubular segment must be permeable to H₂O. Unlike the proximal tubule, where the aquaporins are present and open, the distal and collecting tubules are *impermeable* to H₂O except in the presence of **vasopressin**—also known as **antidiuretic hormone** (*anti* means “against”; *diuretic* means “increased urine output”)³—which increases their permeability to H₂O. Vasopressin is produced by several specific neuronal cell bodies in the hypothalamus part of the brain, then stored in the posterior pituitary gland, which is attached to the hypothalamus by a thin stalk. The hypothalamus controls release of vasopressin from the posterior pituitary into the blood. In negative-feedback fashion, vasopressin secretion is stimulated by a H₂O deficit when the ECF is too concentrated (i.e., hypertonic) and H₂O must be conserved for the body; it is inhibited by a H₂O excess when the ECF is too dilute (i.e., hypotonic) and surplus H₂O must be eliminated in urine.

Vasopressin reaches the basolateral membrane of the tubular cells lining the distal and collecting tubules through the circulatory system. Here it binds with receptors specific for it (► Figure 13-26). This binding activates the cyclic AMP (cAMP) second-messenger system within the tubular cells, which ultimately increases permeability of the opposite luminal membrane to H₂O by promoting the translocation of aquaporins to the membrane surface; vasopressin's action is similar to that of insulin's on the GLUT4 receptor involved in glucose uptake by the skeletal muscle cell. Without these aquaporins, the luminal membrane is impermeable to H₂O. Once H₂O enters the tubular cells from the filtrate through these vasopressin-regulated luminal water channels, it passively leaves the cells down the osmotic gradient across the cells' basolateral membrane to enter the interstitial fluid. The H₂O channels in the basolateral membrane are always present, so this membrane is always permeable to H₂O. By permitting more H₂O to permeate from the lumen into the tubular cells, the additional vasopressin-regulated luminal channels increase H₂O reabsorption from the filtrate into the interstitial fluid. The tubular response to vasopressin is graded: the more vasopressin present, the more luminal water channels are inserted, and the greater the permeability of the distal and collecting tubules to H₂O. The increase in luminal membrane water channels is not permanent, however. The channels are retrieved when vasopressin secretion decreases and

³Even though textbooks traditionally have tended to use the name *antidiuretic hormone* for this hormone, especially when discussing its actions on the kidney, investigators in the field now prefer *vasopressin*.

► **FIGURE 13-26** Mechanism of action of vasopressin

cAMP activity is similarly decreased. Accordingly, H₂O permeability is reduced when vasopressin secretion decreases.

Vasopressin influences H₂O permeability only in the distal part of the nephron, especially the collecting ducts. It has no influence over the 80 percent of the filtered H₂O that is obligatorily reabsorbed without control in the proximal tubule and loop of Henle. The ascending limb of Henle's loop is always impermeable to H₂O, even in the presence of vasopressin.

REGULATION OF H₂O REABSORPTION IN RESPONSE TO A H₂O DEFICIT

When vasopressin secretion increases in response to a H₂O deficit and the permeability of the distal and collecting tubules to H₂O accordingly increases, the hypotonic tubular fluid entering the distal part of the nephron can lose progressively more H₂O by osmosis into the interstitial fluid. This occurs as the tubular fluid first flows through the isotonic cortex and then is exposed to the ever-increasing osmolarity of the medullary interstitial fluid when it plunges toward the renal pelvis (► Figure 13-27a). As the 100 mOsm/L tubular fluid enters the distal tubule and is exposed to a surrounding interstitial fluid of 300 mOsm/L, H₂O leaves the tubular fluid by osmosis across the now permeable tubular cells until the tubular fluid reaches a maximum concentration of 300 mOsm/L by the end of the distal tubule. As this 300 mOsm/L tubular fluid progresses farther into the collecting duct, it is exposed to even higher osmolarity in the surrounding

medullary interstitial fluid. Consequently, the tubular fluid loses more H₂O by osmosis and becomes further concentrated, only to move farther forward and be exposed to an even higher interstitial fluid osmolarity and lose even more H₂O, and so on.

Under the influence of maximum levels of vasopressin, it is possible to concentrate the tubular fluid up to 1200 mOsm/L by the end of the collecting ducts. No further modification of the tubular fluid occurs beyond the collecting duct, so what remains in the tubules at this point is urine. As a result of this extensive vasopressin-promoted reabsorption of H₂O in the late segments of the tubule, a small volume of urine concentrated up to 1200 mOsm/L can be excreted. As little as 0.3 mL of urine may be formed each minute, less than one-third the normal urine flow rate of 1 mL/min. The reabsorbed H₂O entering the medullary interstitial fluid is picked up by the peritubular capillaries and returned to the general circulation, thus being conserved for the body.

Although vasopressin promotes H₂O conservation by the body, it cannot completely halt urine production, even when a person is not taking in any H₂O, because a minimum volume of H₂O must be excreted with the solute wastes. Collectively, the waste products and other constituents eliminated in the urine average 600 mOsm each day. Because the maximum

urine concentration is 1200 mOsm/L, the minimum volume of urine required to excrete these wastes is 500 mL/day (600 mOsm of waste / day ÷ 1200 mOsm / L of urine = 0.5L, or 500mL / day, or 0.3mL / min of urine = 0.5 L, or 500 mL/day, or 0.3 mL/min). So under maximal vasopressin influence, 99.7 percent of the 180 L of plasma H₂O filtered per day is returned to the blood, with an obligatory H₂O loss of 0.5 L.

The kidneys' ability to tremendously concentrate urine to minimize H₂O loss when necessary is possible only because of the presence of the vertical osmotic gradient in the medulla. If this gradient did not exist, the kidneys could not produce a urine more concentrated than the body fluids, no matter how much vasopressin was secreted, because the only driving force for H₂O reabsorption is a concentration differential between the tubular fluid and the interstitial fluid.

Clinical Connections

Jacob had a prolonged period of continuous exercise in very hot conditions and did not stay adequately hydrated. Excessive sweating increases the osmolality in all of the body's fluid compartments. Ultimately, this leads to the secretion of vasopressin (antidiuretic hormone) to enhance water reabsorption in the distal tubules. Given his urine osmolality

Clinical Connections *Continued*

of 1200 mOsm/L, his urine was as concentrated as possible. Under these conditions, salt crystals can precipitate and form stones. Staying hydrated by drinking lots of water decreases vasopressin secretion and allows the urine to dilute so that precipitation does not occur. It also helps to flush out any stones that have already formed.

The pain associated with kidney stones is not caused by the presence of stones within the kidneys themselves. As stones enter the urinary tract, the smooth muscle of the ureter contracts in attempt to move the stones forward. The stones cause a distension of the ureter, which is the source of the pain. The ureter lining can also tear, resulting in bleeding, which gives a pink hue to the urine.

REGULATION OF H₂O REABSORPTION IN RESPONSE TO A H₂O EXCESS

Conversely, when a person consumes large quantities of H₂O, the excess H₂O must be removed from the body without simultaneously losing solutes that are critical for maintaining homeostasis. Under these circumstances, no vasopressin is secreted, so the distal and collecting tubules remain impermeable to H₂O. The tubular fluid entering the distal tubule is hypotonic (100 mOsm/L), having lost salt without an accompanying loss of H₂O in the ascending limb of Henle's loop. As this hypotonic fluid passes through the distal and collecting tubules (► Figure 13-27b), the medullary osmotic gradient cannot exert any influence because of the late tubular segments' impermeability to H₂O. In other words, none of the H₂O remaining in the tubules can leave the lumen to be reabsorbed, even though the tubular fluid is less concentrated than the surrounding interstitial fluid. Therefore, in the absence of vasopressin, the 20 percent of the filtered fluid that reaches the distal tubule is not reabsorbed. Meanwhile, excretion of wastes and other urinary solutes remains constant. The net result is a large volume of dilute urine, which helps rid the body of excess H₂O. Urine osmolarity may be as low as 100 mOsm/L, the same as in the fluid entering the distal tubule. Urine flow may be increased up to 25 mL/min in the absence of vasopressin, compared with the normal urine production of 1 mL/min.

The ability to produce urine less concentrated than the body fluids depends on the fact that the tubular fluid is hypotonic as it enters the distal part of the nephron. This dilution is accomplished in the ascending limb when NaCl is actively extruded, but H₂O cannot follow. Therefore, the loop of Henle, by simultaneously establishing the medullary osmotic gradient and diluting the tubular fluid before it enters the distal segments, plays a key role in allowing the kidneys to excrete urine that ranges in concentration from 100 to 1200 mOsm/L.

Countercurrent exchange within the vasa recta

The vasa recta supply the renal medulla with blood to nourish its tissues and also to transport the water reabsorbed by the loops of Henle and collecting ducts back to the general circulation.

Another key contribution of the vasa recta is to support the countercurrent multiplier mechanism, which produces a high concentration of solutes in the interstitial fluid. It accomplishes this due to the following important characteristics: (1) the hairpin (U-shape) construction of the vasa recta loops back through the concentration gradient; (2) the blood flow in the vasa recta is opposite that of the fluid movement through the loop of Henle; (3) the vasa recta lie in close proximity to the loop of Henle; (4) the two arms of the vasa recta lie in close proximity to each other; and (5) the vasa recta are highly permeable (NaCl and H_2O). These characteristics allow the rapid exchange of fluid and solutes (H_2O and NaCl) in the two parallel streams and thereby maintain a large concentration difference between the two ends of the vasa recta. This enables the blood in the vasa recta to leave the medulla and enter the renal vein essentially isotonic ($\sim 300\text{--}320\text{ mOsm/L}$) to incoming arterial blood (► Figure 13-28).

As blood passes down the descending limb of the vasa recta, it equilibrates with the progressively increasing concentration of the surrounding interstitial fluid. It picks up Na^+ and Cl^- (NaCl) and some urea, and loses H_2O until it is very hypertonic (1200 mOsm/L) by the bottom of the loop. Then, as blood flows up the ascending limb, NaCl diffuses back out into the interstitium, and H_2O reenters the vasa recta because the surrounding interstitial fluid has progressively decreasing concentrations; the passive exchange allows the blood leaving the vasa recta to be isotonic ($\sim 300\text{--}320\text{ mOsm/L}$). This passive exchange of solutes and H_2O between the two limbs of the vasa recta and the interstitial fluid is known as **countercurrent exchange**. Unlike countercurrent multiplication, it does not establish the concentration gradient. Rather, it preserves (*prevents the dissolution of*) the gradient. Because blood enters and leaves the medulla at the same osmolarity as a result of countercurrent exchange, the medullary tissue is nourished with blood, yet the incremental gradient of hypertonicity in the medulla is preserved.

Water reabsorption

It is important to distinguish between the reabsorption of H_2O that must follow solute reabsorption and the reabsorption of “free” H_2O that is not linked to solute reabsorption (i.e., *free water clearance*). Here are the significant differences.

- In the tubular segments permeable to H_2O , solute reabsorption is always accompanied by comparable H_2O reabsorption because of osmotic considerations. Therefore, the total volume of H_2O reabsorbed is determined in large part by the total mass of solute reabsorbed; this is especially true of NaCl , because it is the most abundant solute in the ECF.
- Solute excretion is always accompanied by comparable H_2O excretion because of osmotic considerations. This fact is responsible for the obligatory excretion of at least a minimal volume of H_2O , even when a person is severely dehydrated.

► **FIGURE 13-28** Countercurrent exchange in the renal medulla. Hypothetical pattern of blood flow. If the blood supply to the renal medulla flowed straight through from the cortex to the inner medulla, the blood would be isotonic on entering but very hypertonic on exiting, having picked up salt and lost water as it equilibrated with the surrounding interstitial fluid at each incremental horizontal level. It would be impossible to maintain the vertical osmotic gradient, because the salt pumped out by the ascending limb of Henle's loop would be continuously flushed away by blood flowing through the medulla. However, the actual shape of the vasa recta mimics the loop of Henle, but the blood flow is reversed. Blood equilibrates with the interstitial fluid at each incremental horizontal level in both the descending limb and the ascending limb of the vasa recta, so blood is isotonic as it enters and leaves the medulla. This countercurrent exchange prevents dissolution of the medullary osmotic gradient, while providing blood to the renal medulla.

For the same reason, when excess unreabsorbed solute is present in the tubular fluid, its presence exerts an osmotic effect to hold excessive H_2O in the lumen. This phenomenon is known as *osmotic diuresis*. Diuresis is increased urinary excretion, of which there are two types: osmotic diuresis and water diuresis.

Osmotic diuresis involves the increased excretion of both H_2O and solute due to an excess of unreabsorbed solute in the tubular fluid, such as occurs in diabetes mellitus. The large quantity of unreabsorbed glucose that remains in the tubular fluid in people with diabetes osmotically drags H_2O with it into the urine. Some diuretic drugs act by blocking specific solute reabsorption so that extra H_2O spills into the urine along with the unreabsorbed solute.

Water diuresis, in contrast, involves the increased urinary output of H₂O with little or no increase in excretion of solutes. Excess water that is excreted is termed **free water**. The total plasma volume that is cleared of excess water each minute is termed **free water clearance**. The concept of free water clearance is important because it indicates how rapidly the kidneys are changing the body fluid osmolarity. It can be calculated as follows:

$$\text{Clearance of H}_2\text{O} = \frac{\text{Urine volume per minute} - \text{Osmolar substances}}{\text{Osmolar substances}}$$

Importantly, a loss or gain of free water that is not accompanied by a comparable solute deficit or excess in the body leads to changes in ECF osmolarity. Such an imbalance between H₂O and solute is corrected by partially dissociating H₂O reabsorption from solute reabsorption in the distal portions of the nephron through the combined effects of vasopressin secretion and the medullary osmotic gradient. Through this mechanism, free H₂O can be reabsorbed without a comparable solute reabsorption to correct for hypertonicity of the body fluids. Conversely, a large quantity of free H₂O can be excreted unaccompanied by a comparable solute excretion (i.e., water diuresis) to rid the body of excess pure H₂O, thus correcting for hypotonicity of the body fluids. Water diuresis is normally a compensation for ingesting too much H₂O.

Excessive water diuresis follows alcohol ingestion. Because alcohol inhibits vasopressin secretion, the kidneys inappropriately lose too much H₂O. Typically, more fluid is lost in the urine than is consumed in the alcoholic beverage, so the body becomes dehydrated despite substantial fluid ingestion.

■ Table 13-4 summarizes how various tubular segments of the nephron handle Na⁺ and H₂O and the significance of these processes.

Renal failure

- 1. Urine excretion and the resulting clearance of wastes and excess electrolytes from the plasma are crucial for maintaining homeostasis. When the functions of both kidneys are so disrupted that they cannot perform their regulatory and excretory functions sufficiently to maintain homeostasis, renal failure has set in. **Renal failure** can be described physiologically as a decrease in the glomerular filtration rate, with a biochemical symptom of elevated serum creatinine. One of the most widely used blood chemistry tests of renal function is the serum creatinine test. Serum creatinine levels can be influenced by the amount of skeletal muscle mass, however, and thus age, sex, and race need to be considered when using this test

Tubular Segment	Na ⁺ REABSORPTION		H ₂ O REABSORPTION	
	Percentage of Reabsorption in This Segment	Distinguishing Features	Percentage of Reabsorption in This Segment	Distinguishing Features
Proximal Tubule	67	Active; uncontrolled; plays a pivotal role in the reabsorption of glucose, amino acids, Cl ⁻ , H ₂ O, and urea	65	Passive; obligatory osmotic reabsorption following active Na ⁺ reabsorption
Loop of Henle	25	Active, uncontrolled; Na ⁺ along with Cl ⁻ reabsorption from the ascending limb helps establish the medullary interstitial vertical osmotic gradient, which is important in the kidneys' ability to produce urine of varying concentrations and volumes, depending on the body's needs	15	Passive; obligatory osmotic reabsorption from the descending limb as the ascending limb extrudes NaCl into the interstitial fluid (i.e., reabsorbs NaCl)
Distal and Collecting Tubules	8	Active; variable and subject to aldosterone control; important in the regulation of ECF volume and long-term control of blood pressure; linked to K ⁺ secretion and H ⁺ secretion	20	Passive; not linked to solute reabsorption; variable quantities of "free" H ₂ O reabsorption subject to vasopressin control; driving force is the vertical osmotic gradient in the medullary interstitial fluid established by the long loops of Henle; important in regulating ECF osmolarity

as a marker of renal function. More accurate methods of assessing renal function tend to be more expensive. Renal failure has a variety of causes, some of which begin elsewhere in the body and affect renal function secondarily. Among the causes are the following: *Infectious organisms*, either blood-borne or gaining entrance to the urinary tract through the urethra

2. *Toxic agents*, such as lead, arsenic, pesticides, or even long-term exposure to high doses of aspirin
3. *Inappropriate immune responses*, such as *glomerulonephritis*, which occasionally follow streptococcal throat infections, as antigen–antibody complexes leading to localized inflammatory damage are deposited in the glomeruli (p. 478)
4. *Obstruction of urine flow* by kidney stones, tumours, or an enlarged prostate gland, with back pressure reducing glomerular filtration as well as damaging renal tissue
5. *An insufficient renal blood supply* that leads to inadequate filtration pressure, which can occur secondary to circulatory disorders, such as heart failure, haemorrhage, shock, or narrowing and hardening of the renal arteries by atherosclerosis

Although these conditions may have different origins, almost all can cause some degree of nephron damage. The glomeruli and tubules may be independently affected, or both may be dysfunctional. Regardless of cause, renal failure can manifest itself either as (1) *acute renal failure*, characterized by a sudden onset with rapidly reduced urine formation until less than the essential minimum of around 500 mL of urine is produced per day; or (2) *chronic renal failure*, characterized by slow, progressive, insidious loss of renal function. A person may die from acute renal failure, or the condition may be reversible and lead to full recovery. Chronic renal failure, in contrast, is not reversible. Gradual, permanent destruction of renal tissue eventually proves fatal. Chronic renal failure is insidious, because up to 75 percent of the kidney tissue can be destroyed before the loss of kidney function is even noticeable. Because of the abundant reserve of kidney function, only 25 percent of the kidney tissue is needed to adequately maintain all the essential renal excretory and regulatory functions. With less than 25 percent of functional kidney tissue remaining, however, renal insufficiency becomes apparent. *End-stage renal failure* ensues when 90 percent of kidney function has been lost.

We will not be describing the different stages and symptoms associated with various renal disorders, but ■ Table 13-5 summarizes the potential consequences of renal failure to give you an idea of the broad effects of kidney impairment. The extent of these effects should not be surprising, considering the central role the kidneys play in maintaining homeostasis. When the kidneys cannot maintain a normal internal environment, widespread disruption of cell activities can bring about abnormal function in other organ systems as well. By the time end-stage renal failure occurs, literally every body system has become impaired to some extent.

Because chronic renal failure is irreversible and eventually fatal, treatment is aimed at maintaining renal function by

alternative methods, such as dialysis and kidney transplantation. (For further explanation of these procedures, see Concepts, Challenges, and Controversies.)

This completes our discussion of kidney function. In the remainder of the chapter, we focus on the plumbing that stores and carries the urine formed by the kidneys to the outside.

Check Your Understanding 13.5

1. State how the plasma clearance rate for each of the following substances compares with the GFR: (a) a substance that is filtered but not reabsorbed or secreted, (b) a substance that is filtered and reabsorbed but not secreted, and (c) a substance that is filtered and secreted but not reabsorbed.
2. Identify and explain which nephron component establishes, which component preserves, and which component uses the vertical osmotic gradient in the renal medulla.
3. Explain how vasopressin increases the permeability of the distal and collecting tubules to H₂O.

Urine storage

Once urine has been formed by the kidneys, it is transmitted through the ureters to the urinary bladder. Urine does not flow through the ureters by gravitational pull alone. Peristaltic (forward-pushing) contractions of the smooth muscle within the ureteral wall propel the urine forward from the kidneys to the bladder. The ureters penetrate the wall of the bladder obliquely, coursing through the wall several centimetres before they open into the bladder cavity. This anatomic arrangement prevents back-flow of urine from the bladder to the kidneys when pressure builds up in the bladder. As the bladder fills, the ureteral ends within its wall are compressed closed. Urine can still enter, however, because ureteral contractions generate enough pressure to overcome the resistance and push urine through the occluded ends.

ROLE OF THE BLADDER

The bladder can accommodate large fluctuations in urine volume. The bladder wall consists of smooth muscle lined by a special type of epithelium. It was once assumed that the bladder was an inert sac. However, both the epithelium and the smooth muscle actively participate in the bladder's ability to accommodate large changes in urine volume. The epithelial lining can increase and decrease in surface area by the orderly process of membrane recycling as the bladder alternately fills and empties. Membrane-enclosed cytoplasmic vesicles are inserted by exocytosis into the surface area during bladder filling; then the vesicles are withdrawn by endocytosis to shrink the surface area following emptying (p. 46). As is characteristic of smooth muscle, bladder muscle can stretch tremendously without building up bladder wall tension (p. 333). In addition, the highly folded bladder wall flattens out during filling to increase bladder storage capacity. Because the kidneys continuously form urine, the bladder must have enough storage capacity to preclude the need to continually get rid of the urine.

TABLE 13-5 Potential Ramifications of Renal Failure

Uremic toxicity caused by retention of waste products

Nausea, vomiting, diarrhoea, and ulcers caused by a toxic effect on the digestive system

Bleeding tendency arising from a toxic effect on platelet function

Mental changes—such as reduced alertness, insomnia, and shortened attention span, progressing to convulsions and coma—caused by toxic effects on the central nervous system

Abnormal sensory and motor activity caused by a toxic effect on the peripheral nerves

Metabolic acidosis* caused by the inability of the kidneys to adequately secrete H^+ that is continually being added to the body fluids as a result of metabolic activity

Altered enzyme activity caused by the action of too much acid on enzymes

Depression of the central nervous system caused by the action of too much acid interfering with neuronal excitability

Potassium retention* resulting from inadequate tubular secretion of K^+

Altered cardiac and neural excitability as a result of changing the resting membrane potentials of excitable cells

Sodium imbalances caused by the inability of the kidneys to adjust Na^+ excretion to balance changes in Na^+ consumption

Elevated blood pressure, generalized oedema, and congestive heart failure if too much Na^+ is consumed

Hypotension and, if severe enough, circulatory shock if too little Na^+ is consumed

Phosphate and calcium imbalances arising from impaired reabsorption of these electrolytes

Disturbances in skeletal structures caused by abnormalities in deposition of calcium phosphate crystals, which harden bone

Loss of plasma proteins as a result of increased “leakiness” of the glomerular membrane

Oedema caused by a reduction in plasma-colloid osmotic pressure

Inability to vary urine concentration as a result of impairment of the countercurrent system

Hypotonicity of body fluids if too much H_2O is ingested

Hypertonicity of body fluids if too little H_2O is ingested

Hypertension arising from the combined effects of salt and fluid retention and vasoconstrictor action of excess angiotensin II

Anaemia caused by inadequate erythropoietin production

Depression of the immune system, most likely caused by toxic levels of wastes and acids

Increased susceptibility to infections

* Among the most life-threatening consequences of renal failure.

© 2016 Cengage

The bladder smooth muscle is richly supplied by parasympathetic fibres, stimulation of which causes bladder contraction. If the passageway through the urethra to the outside is open, bladder contraction empties urine from the bladder. The exit from the bladder, however, is guarded by two sphincters: the *internal urethral sphincter* and the *external urethral sphincter*.

ROLE OF THE URETHRAL SPHINCTERS

A **sphincter** is a ring of muscle that, when contracted, closes off passage through an opening. The **internal urethral sphincter**—which is smooth muscle and, accordingly, is under involuntary control—is not really a separate muscle, but instead consists of the last part of the bladder. Although it is not a true sphincter, it performs the same function as a sphincter. When the bladder is relaxed, the anatomic arrangement of the internal urethral sphincter region closes the outlet of the bladder.

Farther down the passageway, the urethra is encircled by a layer of skeletal muscle, the **external urethral sphincter**. This

sphincter is reinforced by the entire **pelvic diaphragm**, a skeletal muscle sheet that forms the floor of the pelvis and helps support the pelvic organs (see ▶ Figure 13-2). The motor neurons that supply the external sphincter and pelvic diaphragm fire continuously at a moderate rate, unless they are inhibited, keeping these muscles tonically contracted so they prevent urine from escaping through the urethra. Normally, when the bladder is relaxed and filling, both the internal and external urethral sphincters are closed to keep urine from dribbling out. Furthermore, because the external sphincter and pelvic diaphragm are skeletal muscle and thus under voluntary control, the person can deliberately tighten them to prevent urination from occurring even when the bladder is contracting and the internal sphincter is open.

MICTURITION REFLEX

Micturition (urination), the process of bladder emptying, is governed by two mechanisms: the micturition reflex and voluntary control. The **micturition reflex** is initiated when stretch

Dialysis: Cellophane Tubing or Abdominal Lining as an Artificial Kidney

BECAUSE CHRONIC RENAL FAILURE IS IRREVERSIBLE and eventually fatal, treatment is aimed at maintaining renal function by alternative methods, such as dialysis and kidney transplantation. The process of dialysis bypasses the kidneys to maintain normal fluid and electrolyte balance and remove wastes artificially. In the original method of dialysis, **haemodialysis**, a patient's blood is pumped through cellophane tubing that is surrounded by a large volume of fluid similar in composition to normal plasma. After dialysis, the blood is returned to the patient's circulatory system. Like capillaries, cellophane is highly permeable to most plasma constituents but is impermeable to plasma proteins. As blood flows through the tubing, solutes move across the cellophane down their individual concentration gradients; plasma proteins, however, stay in the blood. Urea and other wastes, which are absent in the dialysis fluid, diffuse out of the plasma into the surrounding fluid, cleaning the blood of these wastes. Plasma constituents that are not regulated by the kidneys and are at normal concentration, such as glucose, do not move across the cellophane into the dialysis fluid, because there is no driving force to produce their movement. (The dialysis fluid's glucose concentration is the same as normal plasma glucose concentration.) Electrolytes, such as K^+ and PO_4^{3-} , are higher than their normal plasma concentrations because the diseased kidneys cannot eliminate excess quantities of these substances. So they move out of the plasma until equilibrium is achieved between the plasma and the dialysis fluid. Because the dialysis fluid's solute concentrations are maintained at normal plasma values, the solute concentration of the blood returned to the patient after dialysis is essentially normal. Haemodialysis is repeated as often as necessary to maintain the plasma composition within an acceptable level. Typically, it is done three times per week for several hours at each session.

In a more recent method of dialysis, **continuous ambulatory peritoneal dialysis (CAPD)**, the peritoneal membrane (the lining of the abdominal cavity) is used as the dialysis membrane. With this method, two litres of dialysis fluid are inserted into the patient's abdominal cavity through a permanently implanted catheter. Urea, K^+ , and other wastes and excess electrolytes diffuse from the plasma across the peritoneal membrane into the dialysis fluid, which is drained off and replaced several times a day. The CAPD method offers several

advantages: The patient can self-administer, the patient's blood is continuously purified and adjusted, and the patient can engage in normal activities while dialysis is being accomplished. One drawback is the increased risk of peritoneal infections.

Although dialysis can remove metabolic wastes and foreign compounds and help maintain fluid and electrolyte balance within acceptable limits, this plasma-cleansing technique cannot make up for the failing kidneys' reduced ability to produce hormones (erythropoietin and renin) and to activate vitamin D. One new experimental technique incorporates living kidney cells derived from pigs within a dialysis-like machine. Standard ultrafiltration technology like that used in haemodialysis purifies and adjusts the plasma as usual. Importantly, the living cells not only help maintain even better control of plasma constituents, especially K^+ , but also add the deficient renal hormones to the plasma passing through the machine and activate vitamin D. This promising new technology has not yet been tested in large-scale clinical trials.

For now, transplanting a healthy kidney from a donor is another option for treating chronic renal failure. A kidney is one of the few transplants that can be provided by a living donor. Because 25 percent of the total kidney tissue can maintain the body, both the donor and the recipient have ample renal function with only one kidney each. The biggest problem with transplants is the possibility that the patient's immune system will reject the organ. Risk of rejection can be minimized by matching the tissue types of the donor and the recipient as closely as possible (the best donor choice is usually a close relative), coupled with immunosuppressive drugs.

Another new technique on the horizon for treating end-stage renal failure is a continuously functioning artificial kidney that mimics natural renal function. Using nanotechnology (very small-scale devices), researchers are working on a device that contains two membranes, the first for filtering blood as the glomerulus does and the second for mimicking the renal tubules by selectively altering the filtrate. The device, which will directly process the blood on an ongoing basis without using dialysis fluid, will return important substances to the body while discharging unneeded substances to a discardable bag that will serve as an external bladder. Scientists have developed computer models for such a device and thus far have created the filtering membrane.

receptors within the bladder wall are stimulated (▶ Figure 13-29). The bladder in an adult can accommodate approximately 250–400 millilitres of urine before the tension within its walls begins to rise sufficiently to activate the stretch receptors (▶ Figure 13-30). The greater the distension beyond this, the greater is the extent of receptor activation. Afferent fibres from the stretch receptors carry impulses into the spinal cord

and eventually, via interneurons, stimulate the parasympathetic supply to the bladder and inhibit the motor-neuron supply to the external sphincter. Parasympathetic stimulation of the bladder causes it to contract. No special mechanism is required to open the internal sphincter; changes in the shape of the bladder during contraction mechanically pull the internal sphincter open. Simultaneously, the external sphincter relaxes as its motor

FIGURE 13-29 Reflex and voluntary control of micturition

neuron supply is inhibited. Now both sphincters are open, and urine is expelled through the urethra by the force of bladder contraction. This micturition reflex, which is entirely a spinal reflex, governs bladder emptying in infants. As soon as the bladder fills enough to trigger the reflex, the baby automatically wets.

VOLUNTARY CONTROL OF MICTURITION

In addition to triggering the micturition reflex, bladder filling also gives rise to the conscious urge to urinate. The perception of bladder fullness appears before the external sphincter reflexly

FIGURE 13-30 Pressure changes within the urinary bladder as the bladder fills with urine

relaxes, warning that micturition is imminent. As a result, voluntary control of micturition, learned during toilet training in early childhood, can override the micturition reflex so that bladder emptying can take place at the person's convenience rather than when bladder filling first activates the stretch receptors. If the time when the micturition reflex is initiated is inopportune for urination, the person can voluntarily prevent bladder emptying by deliberately tightening the external sphincter and pelvic diaphragm. Voluntary excitatory impulses from the cerebral cortex override the reflex inhibitory input from the stretch receptors to the involved motor neurons (the relative balance of EPSPs and IPSPs), keeping these muscles contracted so that no urine is expelled.

Urination cannot be delayed indefinitely. As the bladder continues to fill, reflex input from the stretch receptors increases with time. Finally, reflex inhibitory input to the external sphincter motor neuron becomes so powerful that it can no longer be overridden by voluntary excitatory input, so the sphincter relaxes and the bladder uncontrollably empties.

Micturition can also be deliberately initiated, even though the bladder is not distended, by voluntarily relaxing the external sphincter and pelvic diaphragm. Lowering of the pelvic floor allows the bladder to drop downward, which simultaneously pulls open the internal urethral sphincter and stretches the

Why It Matters Urinary Incontinence

Urinary incontinence, or inability to prevent discharge of urine, occurs when descending pathways in the spinal cord that mediate voluntary control of the external sphincter and pelvic diaphragm are disrupted, as in spinal cord injury. Because the components of the micturition reflex arc are still intact in the lower spinal cord, bladder emptying is governed by an uncontrollable spinal reflex, as

in infants. A lesser degree of incontinence characterized by urine escaping when bladder pressure suddenly increases transiently, such as during coughing or sneezing, can result from impaired sphincter function. This is common in women who have borne children or in men whose sphincters have been injured during prostate surgery.

bladder wall. The subsequent activation of the stretch receptors brings about bladder contraction by the micturition reflex. Voluntary bladder emptying may be further assisted by contracting the abdominal wall and respiratory diaphragm. The resulting increase in intra-abdominal pressure squeezes down on the bladder to facilitate its emptying.

Chapter in Perspective: Focus on Homeostasis

The kidneys contribute to homeostasis more extensively than any other single organ. They regulate the electrolyte composition, volume, osmolarity, and pH of the internal environment and eliminate all the waste products of bodily metabolism, except for respiration-removed carbon dioxide. They accomplish these regulatory functions by eliminating in the urine substances the body doesn't need, such as metabolic wastes and excess quantities of ingested salt or water, while conserving useful substances. The kidneys can maintain the plasma constituents they regulate within the narrow range compatible with life, despite wide variations in intake and losses of these substances through other avenues. Illustrating the magnitude of the kidneys' task, about 25 percent of the blood pumped into the systemic circulation goes to the kidneys to be adjusted and purified, and 75 percent of the blood is used to supply all the other tissues.

The kidneys contribute to homeostasis in the following specific ways:

REGULATORY FUNCTIONS

- The kidneys regulate the quantity and concentration of most ECF electrolytes, including those important in maintaining proper neuromuscular excitability.
- They help maintain proper pH by eliminating excess H^+ (acid) or HCO_3^- (base) in the urine.
- They help maintain proper plasma volume, which is important in long-term regulation of arterial blood pressure, by controlling

salt balance in the body. The ECF volume, including plasma volume, reflects total salt load in the ECF, because Na^+ and its attendant anion, Cl^- , are responsible for more than 90 percent of the ECF's osmotic (water-holding) activity.

- The kidneys maintain water balance in the body, which is important in maintaining proper ECF osmolarity (concentration of solutes). This role is important in maintaining stability of cell volume by keeping water from osmotically moving into or out of the cells, thereby preventing them from swelling or shrinking, respectively.

EXCRETORY FUNCTIONS

- The kidneys excrete the end products of metabolism in urine. If allowed to accumulate, these wastes are toxic to cells.
- The kidneys also excrete many foreign compounds that enter the body.

HORMONAL FUNCTIONS

- The kidneys produce erythropoietin, the hormone that stimulates the bone marrow to produce red blood cells. This action contributes to homeostasis by helping maintain the optimal O_2 content of blood. More than 98 percent of O_2 in the blood is bound to haemoglobin within red blood cells.
- They also produce renin, the hormone that initiates the renin-angiotensin-aldosterone pathway for controlling renal tubular Na^+ reabsorption, which is important in long-term maintenance of plasma volume and arterial blood pressure.

METABOLIC FUNCTIONS

- The kidneys help convert vitamin D into its active form. Vitamin D is essential for Ca^{2+} absorption from the digestive tract. Calcium, in turn, exerts a wide variety of homeostatic functions.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-49)

- Part of the kidneys' energy supply is used to accomplish glomerular filtration. (*True or false?*)
 - Sodium reabsorption is under hormonal control throughout the length of the tubule. (*True or false?*)
 - Glucose and amino acids are reabsorbed by secondary active transport. (*True or false?*)
 - Solute excretion is always accompanied by comparable H_2O excretion. (*True or false?*)
 - Water excretion can occur without comparable solute excretion. (*True or false?*)
 - The functional unit of the kidneys is the _____
 - _____ is the only ion actively reabsorbed in the proximal tubule and actively secreted in the distal and collecting tubules.
 - The daily minimum volume of obligatory H_2O loss that must accompany excretion of wastes is _____ mL.
 - Indicate whether each of the factors would (a) increase or (b) decrease the GFR, if everything else remained constant.
 - a rise in Bowman's capsule pressure resulting from ureteral obstruction by a kidney stone
 - a fall in plasma protein concentration resulting from loss of these proteins from a large burned surface of skin
 - a dramatic fall in arterial blood pressure following severe haemorrhage (80 mmHg)
 - afferent arteriolar vasoconstriction
 - tubuloglomerular feedback response to decreased salt delivery to the distal tubule
 - myogenic response of an afferent arteriole stretched as a result of an increased driving blood pressure
 - increased sympathetic activity to the afferent arterioles
 - contraction of mesangial cells
 - contraction of podocytes
 - Which filtered substance is normally NOT present in the urine at all?
 - Na^+
 - PO_4^{3-}
 - urea
 - H^+
 - glucose
 - Reabsorption of which substance is NOT linked in some way to active Na^+ reabsorption?
 - glucose
 - PO_4^{3-}
 - H_2O
 - urea
 - Cl^-
- In questions 12–14, indicate, by writing the identifying letters in the proper order in the blanks, the proper sequence through which fluid flows as it traverses the structures in question.
- ureter
 - kidney
 - urethra
 - bladder
 - renal pelvis

13. a. efferent arteriole — — — — —
 b. peritubular capillaries
 c. renal artery
 d. glomerulus
 e. afferent arteriole
 f. renal vein

14. a. loop of Henle — — — — —
 b. collecting duct
 c. Bowman's capsule
 d. proximal tubule
 e. renal pelvis
 f. distal tubule
 g. glomerulus

15. Using the answer code on the right, indicate what the osmolarity of the tubular fluid is at each of the designated points in a nephron:

- | | |
|--|--|
| — 1. Bowman's capsule | (a) isotonic (300 mOsm/L) |
| — 2. end of proximal tubule | (b) hypotonic (100 mOsm/L) |
| — 3. tip of Henle's loop of juxtamedullary nephron (at the bottom of the U-turn) | (c) hypertonic (1200 mOsm/L) |
| — 4. end of Henle's loop of juxtamedullary nephron (before entry into distal tubule) | (d) ranging from hypotonic to hypertonic (100 mOsm/L to 1200 mOsm/L) |
| — 5. end of collecting duct | |

Written Questions

- List the functions of the kidneys.
- Describe the anatomy of the urinary system. Describe the components of a nephron.
- Describe the three basic renal processes, and indicate how they relate to urine excretion.
- Distinguish between *secretion* and *excretion*.
- Discuss the forces involved in glomerular filtration. What is the average GFR?
- How is GFR regulated as part of the baroreceptor reflex?
- Why do the kidneys receive a seemingly disproportionate share of the cardiac output? What percentage of RBF is normally filtered?
- List the steps in transepithelial transport.
- Distinguish between active and passive reabsorption.
- Describe all the tubular transport processes that are linked to the basolateral $\text{Na}^+ - \text{K}^+$ ATPase carrier.
- Describe the renin-angiotensin-aldosterone system. Discuss the source and function of atrial natriuretic peptide.
- To what do the terms *tubular maximum* (T_m) and *renal threshold* refer? Compare two substances that display a T_m : one substance that *is* and one that *is not* regulated by the kidneys.

- What is the importance of tubular secretion? What are the most important secretory processes?
- What is the average rate of urine formation?
- Define *plasma clearance*.
- What establishes a vertical osmotic gradient in the medullary interstitial fluid? Of what importance is this gradient?
- Discuss the function and mechanism of action of vasopressin.
- Describe the transfer of urine to, the storage of urine in, and the emptying of urine from the bladder.

Quantitative Exercises (Solutions in Appendix E, p. A-50)

- Two patients are voiding protein in their urine. To determine whether or not this proteinuria indicates a serious problem, a physician injects small amounts of inulin and PAH into each patient. Recall that inulin is freely filtered and neither secreted nor reabsorbed in the nephron and that PAH at this concentration is completely removed from the blood by tubular secretion. The data collected are given in the following table, where $[X]_u$ is the concentration of substance X (either inulin or PAH) in the urine (in mM); $[X]_p$ is the concentration of X in the plasma, and v_u is the flow rate of urine (in mL/min).

Patient	$[I]_u$	$[I]_p$	$[PAH]_u$	$[PAH]_p$	$[V]_u$
1	25	2	186	3	10
2	31	1.5	300	4.5	6

- Calculate each patient's GFR and renal plasma flow.
 - Calculate the RBF for each patient, assuming both have a haematocrit of 0.45.
 - Calculate the filtration fraction for each patient.
 - Which of the values calculated for each patient are within the normal range? Which values are abnormal? What could be causing these deviations from normal?
- What is the filtered load of sodium if inulin clearance is 125 mL/min and the sodium concentration in plasma is 145 mM?
 - Calculate a patient's rate of urine production, given that his inulin clearance is 125 mL/min and his urine and plasma concentrations of inulin are 300 mg/L and 3 mg/L, respectively.
 - If the urine concentration of a substance is 7.5 mg/mL of urine, its plasma concentration is 0.2 mg/mL of plasma, and the urine flow rate is 2 mL/min, what is the clearance rate of the substance? Is the substance being reabsorbed or secreted by the kidneys?

POINTS TO PONDER

(Explanations in Appendix E, p. A-50)

1. The juxtamedullary nephrons of animals adapted to survive with minimal water consumption, such as desert rats, have relatively much longer loops of Henle than humans have. Of what benefit would these longer loops be?
2. a. If the plasma concentration of substance X is 200 mg/100 mL and the GFR is 125 mL/min, how much is the filtered load of this substance?
b. If the T_m for substance X is 200 mg/min, how much of the substance will be reabsorbed at a plasma concentration of 200 mg/100 mL and a GFR of 125 mL/min?
c. How much of substance X will be excreted?
3. *Conn's syndrome* is an endocrine disorder brought about by a tumour of the adrenal cortex that secretes excessive aldosterone in uncontrolled fashion. Given what you know about the functions of aldosterone, describe the most prominent features of this condition.
4. Because of a mutation, a child was born with an ascending limb of Henle that was water permeable. What would be the minimum/maximum urine osmolarities (in units of mOsm/L) the child could produce?
a. 100/300
b. 300/1200
c. 100/100
d. 1200/1200
e. 300/300
5. An accident victim suffers permanent damage of the lower spinal cord and is paralyzed from the waist down. Describe what governs bladder emptying in this individual.

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-50)

1. Marcus T. has noted a gradual decrease in his urine flow rate and is now experiencing difficulty in initiating micturition. He needs to urinate frequently, and often he feels as if his bladder is not empty even though he has just urinated. Analysis of Marcus's urine reveals no abnormalities. Are his urinary tract symptoms most likely caused by kidney disease, a bladder infection, or prostate enlargement?

Fluid and Acid–Base Balance

Body systems maintain homeostasis

Skeleton X-ray

Cells make up body systems

Homeostasis

The kidneys, in conjunction with hormones involved in salt and water balance, are responsible for maintaining the volume and osmolarity of the extracellular fluid (internal environment). Along with the respiratory system and chemical buffer systems in the body fluids, the kidneys also contribute to homeostasis by maintaining the proper pH in the internal environment.

Homeostasis is essential for survival of cells

Mark Giles/Science Source

Osmosis

Homeostasis depends on maintaining a balance between the input and the output of all constituents in the internal fluid environment. Regulation of fluid balance involves two separate components:

1. *control of ECF volume*, which includes circulating plasma volume; and
2. *control of ECF osmolarity*, which includes the solute concentration.

The kidneys control ECF volume by regulating salt balance and ECF osmolarity by regulating water balance. They maintain this balance by adjusting the output of salt and water in the urine, as

needed to compensate for variations in the input and output of these constituents.

Similarly, the kidneys help maintain acid–base balance by adjusting the urinary output of hydrogen ions (acid) and bicarbonate ions (base) as needed. Also contributing to acid–base balance in the body fluids are the chemical buffer systems (e.g., bicarbonate buffer system) and the respiratory system (i.e., the lungs). For example, the lungs can adjust the rate at which hydrogen ion–generating carbon dioxide is eliminated by increasing or decreasing the rate and depth of breathing.

Fluid and Acid–Base Balance

CONTENTS AT A GLANCE

- 14.1 Balance concept
- 14.2 Fluid balance
- 14.3 Acid–base balance

Clinical Connections

Diane, a 22-year-old female university student, has been healthy until recently. Despite having an increased appetite and no change in her level of activity, she had a weight loss of 5 kg (11 lb) over the past 15 days. She has also felt intensely thirsty and has been producing frequent, large volumes of urine. When Diane experienced generalized abdominal pain, vomiting, and increasing lethargy, her friend brought her immediately to the emergency room for an assessment.

Diane was found to have an elevated heart rate (tachycardia) and decreased blood pressure (hypotensive). Her plasma glucose level was extremely elevated at 25 mmol/L (Normal: ≤ 11.1 mmol/L), and ketoacids were present in her blood. Further bloodwork revealed the following:

Serum pH: 7.25 (LOW)	(Normal: 7.35–7.45)
Arterial pCO ₂ : 30 mmHg (LOW)	(Normal: 35–40 mmHg)
Plasma HCO ₃ ⁻ : 13 mEq/L (LOW)	(Normal: 23–29 mEq/L)
Anion Gap: 22 mEq/L (HIGH)	(Normal: 8–16 mEq/L)

Diane was diagnosed as having diabetic ketoacidosis (DKA), and treatment was initiated.

14.1 | Balance Concept

The cells of complex multicellular organisms are able to survive and function only within a very narrow range of composition of the extracellular fluid (ECF)—that is, the internal fluid environment that bathes them.

The internal pool of a substance

The quantity of any particular substance in the ECF is considered a readily available internal **pool**. The amount of the substance in the pool may be increased either by transferring more in from the external environment (most commonly by ingestion) or by metabolically producing it within the body (► Figure 14-1). Substances may be removed from the body by being excreted to the outside or by being used up in a metabolic reaction. If the quantity of a substance is to remain stable within the body, its **input** through ingestion or metabolic production must be balanced by an equal **output** through excretion or metabolic consumption. This relationship, known as the **balance concept**, is extremely important in maintaining homeostasis. Not all input and output pathways are applicable for each body-fluid constituent. For example, salt is not synthesized or consumed by the body, so the stability of salt concentration in the body fluids depends entirely on a balance between salt ingestion and salt excretion.

EXCHANGES BETWEEN THE POOL AND OTHER INTERNAL SITES

The ECF pool can be altered by transferring a particular ECF constituent into storage within the body. If the body as a whole has a surplus or deficit of a particular stored substance, the storage site can be expanded or partially depleted to maintain the ECF concentration of the substance within homeostatically prescribed limits. For example, after absorption of a meal, when

more glucose is entering the plasma than is being consumed by the cells, the extra glucose can be temporarily stored, in the form of glycogen, in muscle and liver cells. This storage depot can then be tapped between meals as needed to maintain the plasma glucose level when no new nutrients are being added to the blood by eating. This internal storage capacity is limited, however. Although an internal exchange between the ECF and a storage depot can temporarily restore the plasma concentration of a particular substance to normal, in the long run any excess or deficit of that constituent must be compensated for by appropriate adjustments in total body input or output.

Another possible internal exchange between the pool and the rest of the body is the reversible incorporation of certain plasma constituents into more complex molecular structures. For example, iron is incorporated into haemoglobin within the red blood cells during their synthesis, but it is released intact back into the body fluids when the red cells degenerate. This process differs from the metabolic consumption of a substance, in which the substance is irretrievably converted into another form—for example, glucose converted into carbon dioxide plus water plus energy. It also differs from storage in that the latter serves no purpose other than storage. By contrast, reversible incorporation into a more complex structure serves a specific purpose.

Maintenance of a balanced ECF constituent

When total body input of a particular substance equals its total body output, a **stable balance** exists. When the gains via input for a substance exceed its losses via output, a **positive balance** exists. The result is an increase in the total amount of the substance in the body. In contrast, when losses for a substance exceed its gains, a **negative balance** exists, and the total amount of the substance in the body decreases.

► FIGURE 14-1 Inputs to and outputs from the internal pool of a body constituent

Changing the magnitude of any of the input or output pathways for a given substance can alter its plasma concentration. To maintain homeostasis, any change in input must be balanced by a corresponding change in output (e.g., increased salt intake must be matched by a corresponding increase in salt output in the urine), and, conversely, increased losses must be compensated for by increased intake. Thus, maintaining a stable balance requires control. However, not all input and output pathways are regulated to maintain balance. Generally, input of various plasma constituents is poorly controlled or not controlled at all. We frequently ingest salt and water, for example, not because we need them but because we want them, so the intake of salt and water is highly variable. Likewise, hydrogen ion (H^+) is uncontrollably generated internally and added to the body fluids. Salt, water, and H^+ can also be lost to the external environment to varying degrees through the digestive tract (vomiting), skin (sweating), and elsewhere without regard for the salt, water, or H^+ balance in the body. Compensatory adjustments in the urinary excretion of these substances maintain the body fluids' volume and salt and acid composition within the extremely narrow homeostatic range compatible with life, despite the wide variations in input and unregulated losses of these plasma constituents. It is important to note that although excretion of solutes by the kidney is extremely efficient, it does have a maximum concentrating ability. Ingesting solutes in concentrations above this maximum results in an inability to fully eliminate them. In these situations, it is possible for solute concentrations to rise to a level that, without treatment, can be fatal.

The rest of this chapter is devoted to discussing the regulation of fluid balance (maintaining salt and water balance) and acid–base balance (maintaining H^+ balance).

Check Your Understanding 14.1

1. List the possible inputs to and outputs from the internal pool of a given body constituent. Define *stable balance*, *positive balance*, and *negative balance*.

14.2 | Fluid Balance

Water is by far the most abundant component of the human body, constituting 60 percent of body weight, on average, but ranging from 40 to 80 percent. The H_2O content of an individual remains fairly constant, largely because the kidneys efficiently regulate **water balance**, but the percentage of body H_2O varies from person to person. The reason for the wide range in body H_2O among individuals is the variability in the amount of their adipose tissue (fat). Adipose tissue has a low H_2O percentage compared with other tissues. Plasma, as you might suspect, is more than 90 percent H_2O . Even the soft tissues, such as skin, muscles, and internal organs, consist of 70 to 80 percent H_2O . The relatively drier skeleton is only 22 percent H_2O . Fat, however, is the driest tissue of all, having only 10 percent H_2O content. Accordingly, a high body H_2O percentage is associated with

leanness, and a low body H_2O percentage with obesity, because a larger proportion of the overweight body consists of relatively dry fat.

The percentage of body H_2O is also influenced by the sex and age of the individual. Women have a lower body H_2O percentage than men, primarily because the female sex hormone, estrogen, promotes fat deposition in the breasts, buttocks, and elsewhere. This not only gives rise to the typical female figure but also endows women with a higher proportion of adipose tissue and, therefore, a lower body H_2O proportion. The percentage of body H_2O also decreases progressively with age.

Body water distribution

Body water is distributed between two major fluid compartments: fluid within the cells, **intracellular fluid (ICF)**, and fluid surrounding the cells, **extracellular fluid (ECF)** (■ Table 14-1). (The terms H_2O and *fluid* are commonly used interchangeably. Although this usage is not entirely accurate, because it ignores the solutes in body fluids, it is acceptable when discussing total volume of fluids, because the major proportion of these fluids consists of H_2O .)

PROPORTION OF H_2O IN THE MAJOR FLUID COMPARTMENTS

The ICF compartment composes about two-thirds of the total body H_2O . Even though each cell contains its own unique mixture of constituents, these trillions of minute fluid compartments are similar enough to be considered collectively as one large fluid compartment.

The remaining third of the body H_2O found in the ECF compartment is further subdivided into plasma and interstitial fluid. The **plasma**, which makes up about 25 percent of the ECF volume, is the fluid portion of blood. The **interstitial fluid**,

■ TABLE 14-1 Classification of Body Fluid

Compartment	Volume of Fluid (in Litres)	Percentage of Body Fluid	Percentage of Body Weight
Total Body Fluid	42	100	60
Intracellular Fluid (ICF)	28	67	40
Extracellular Fluid (ECF)	14	33	20
<i>Plasma</i>	3.5	8.3 (25% of ECF)	5
<i>Interstitial fluid</i>	10.5	25 (75% of ECF)	15
<i>Lymph</i>	Negligible	Negligible	Negligible
<i>Transcellular fluid</i>	Negligible	Negligible	Negligible

which represents the other 75 percent of the ECF compartment, is the fluid in the spaces between cells. It bathes and makes exchanges with tissue cells.

MINOR ECF COMPARTMENTS

Two other minor categories are included in the ECF compartment: lymph and transcellular fluid. **Lymph** is the fluid being returned from the interstitial fluid to the plasma by means of the lymphatic system, where it is filtered through lymph nodes for immune defence purposes (pp. 411 and 464). **Transcellular fluid** consists of a number of small, specialized fluid volumes, all of which are secreted by specific cells into a particular body cavity to perform some specialized function. Transcellular fluid includes *cerebrospinal fluid* (the brain and spine); *intraocular fluid* (the eye); *synovial fluid* (the joints); *pericardial, intrapleural, and peritoneal fluids* (the heart, lungs, and intestines, respectively); and the *digestive juices* (the stomach).

Although these fluids are extremely important functionally, they represent an insignificant fraction of total body H₂O. Furthermore, the transcellular compartment as a whole usually does not reflect changes in the body's fluid balance. For example, cerebrospinal fluid does not decrease in volume when the body as a whole is experiencing a negative H₂O balance. This is not to say that these fluid volumes never change. Localized changes in a particular transcellular fluid compartment can occur pathologically (such as too much intraocular fluid accumulating in the eyes of people with glaucoma; p. 153), but such a localized fluid disturbance does not affect the fluid balance of the body. Therefore, the transcellular compartment can usually be ignored when dealing with problems of fluid balance. The main exception to this generalization occurs when digestive juices are abnormally lost from the body during heavy vomiting or diarrhoea, which can bring about a fluid imbalance.

Clinical Note Bioelectrical impedance can be a useful technique for body composition analysis in healthy individuals and in those with a number of chronic conditions, such as mild to moderate obesity, diabetes mellitus, and other medical conditions in which major disturbances of water distribution are not prominent.

Plasma and interstitial fluid

Several barriers separate the body-fluid compartments, and they limit the movement of H₂O and solutes between the various compartments to differing degrees.

THE BARRIER BETWEEN PLASMA AND INTERSTITIAL FLUID: BLOOD VESSEL WALLS

The two components of the ECF—plasma and interstitial fluid—are separated by the walls of the blood vessels. However,

H₂O and all plasma constituents except for plasma proteins are continuously and freely exchanged between plasma and interstitial fluid by passive means across the thin, pore-lined capillary walls. Accordingly, plasma and interstitial fluid are nearly identical in composition, except that interstitial fluid lacks plasma proteins. Any change in one of these ECF compartments is quickly reflected in the other compartment, because they are constantly mixing.

THE BARRIER BETWEEN THE ECF AND ICF: CELLULAR PLASMA MEMBRANES

In contrast to the very similar solute concentrations of the plasma and interstitial fluid compartments, the ECF differs significantly from that of the ICF (► Figure 14-2). The physical barrier that separates the ECF and ICF is the cell membrane. Unlike the constant mixing between the plasma and interstitial fluid compartments, the cell membrane is highly selective and only permits the passage of certain materials. Due to this high specificity for movement there is a pronounced difference in the composition of the ECF and ICF compartments.

There are several differences among the ECF and ICF. First, the ICF has proteins that cannot permeate the enveloping membranes to leave the cells. Like most proteins, they are negatively charged and therefore can attract positively charged ions. Second there is an unequal distribution of Na⁺ and K⁺ and their attendant anions. This is the result of the membrane-bound Na⁺–K⁺ ATPase pump that is present in all cells. It actively transports three Na⁺ out of and two K⁺ into cells. As a result, Na⁺ is the primary ECF cation, and K⁺ is the primary ICF cation.

► FIGURE 14-2 Ionic composition of the major body-fluid compartments

All of these substances can result in the movement of H_2O into the cell, which will cause the cell to swell and lyse if not checked. The Na^+-K^+ ATPase pump is also a mechanism to prevent this. Additionally, this unequal distribution of Na^+ and K^+ , coupled with differences in membrane permeability to these ions, is crucial for the electrical properties of cells. These include both the initiation and the propagation of action potentials in excitable tissues (see Chapters 2 and 3). The concept of having an unequal distribution of solutes in different fluid compartments is known as **chemical disequilibrium**.

Except for the extremely small, electrically unbalanced portion of the total intracellular and extracellular ions involved in membrane potential, most ECF and ICF ions are electrically balanced. In the ECF, for example, Na^+ is accompanied primarily by the chloride anion (Cl^-) and to a lesser extent by bicarbonate (HCO_3^-). In the ICF, K^+ is accompanied by phosphate (PO_4^{3-}) and the negatively charged proteins trapped within the cell.

Most cells are freely permeable to water. Recall (p. 409) that the movement of water between the ECF compartments (plasma and the interstitial fluid) across capillary walls is governed by Starling forces. These forces, resulting from the imbalances between capillary hydrostatic pressure and colloid osmotic pressure, dictate whether water is absorbed into a capillary from the interstitial space or filtered out of a capillary into the interstitial space. In contrast, the movement of water across the cell membrane (between the interstitial fluid and the ICF) occurs as a result of osmotic effects alone. The hydrostatic pressures of the interstitial fluid and ICF are both extremely low and fairly constant, and therefore do not significantly contribute to the movement of water.

ECF volume and osmolarity

Extracellular fluid serves as an intermediary between the cells and the external environment. All exchanges of water and other constituents between the ICF and external world must occur through the ECF. Water added to the body fluids always enters the ECF compartment first, and fluid always leaves the body via the ECF.

Plasma is the only fluid that can be acted on directly to control its volume and composition. Plasma circulates through all of the reconditioning organs that perform homeostatic adjustments (p. 386). Any adjustments made to the plasma equally effect the interstitial fluid, as a result of the free exchange between these compartments across the capillary walls. As a general rule of thumb, any control mechanism that changes plasma, will similarly change the interstitial fluid compartment. In contrast to this, the degree to which the ICF is influenced by the ECF is dictated by the permeability of cell membrane.

Two factors are regulated to maintain **fluid balance** in the body: ECF volume and ECF osmolarity. Although regulation of these two factors is interrelated, both being dependent on the relative NaCl and H_2O load in the body, the reasons that they are closely controlled are different:

1. *ECF volume* must be closely regulated to help *maintain blood pressure*. Maintaining *salt balance* is of primary importance in the long-term regulation of ECF volume.

2. *ECF osmolarity* must be closely regulated to *prevent swelling or shrinking of cells*. Maintaining *water balance* is of primary importance in regulating ECF osmolarity.

Control of ECF volume

ECF volume acts directly on blood pressure by changing plasma volume. For example, expanding ECF volume raises arterial blood pressure by increasing plasma volume. Two compensatory measures come into play to transiently adjust blood pressure until the ECF volume can be restored to normal. Let's review them.

REVIEW OF SHORT-TERM CONTROL MEASURES TO MAINTAIN BLOOD PRESSURE

1. *The baroreceptor reflex alters both cardiac output and total peripheral resistance* to adjust blood pressure in the proper direction through autonomic nervous system effects on the heart and blood vessels (p. 420). Cardiac output and total peripheral resistance both increase to raise blood pressure when it falls too low, and conversely, both decrease to reduce blood pressure when it rises too high.
2. *Fluid shifts occur temporarily and automatically between plasma and interstitial fluid* as a result of changes in the balance of hydrostatic and osmotic forces (Starling forces) acting across the capillary walls when plasma volume deviates from normal (p. 409). For example, a reduction in plasma volume is partially compensated for by a shift of fluid out of the interstitial compartment and into the blood vessels. This helps to expand the circulating plasma volume at the expense of the interstitial compartment. Conversely, when plasma volume is too large, much of the excess fluid shifts into the interstitial compartment.

These two measures are short-term adjustment to help keep blood pressure fairly constant, but they are not long-term solutions. Furthermore, these short-term compensatory measures have a limited ability to minimize a change in blood pressure. For example, if plasma volume is too inadequate, blood pressure remains too low no matter how vigorous the pump action of the heart, how constricted the resistance vessels, or what proportion of interstitial fluid shifts into the blood vessels.

LONG-TERM CONTROL MEASURES TO MAINTAIN BLOOD PRESSURE

It is important that other compensatory measures come into play in the long run to restore the ECF volume to normal. Long-term regulation of blood pressure rests with the kidneys and the thirst mechanism, controlling urinary output and fluid intake, respectively. Although these two measures play an important long-term influence on arterial blood pressure, urinary output by the kidneys is most crucial for maintaining blood pressure. You will see why as we discuss these long-term mechanisms in more detail.

Control of salt

By way of review, sodium and its attendant anions account for more than 90 percent of the ECF’s osmotic activity. As the kidneys conserve salt, they automatically conserve water because water follows Na^+ osmotically. As a result, this retained salt solution is isotonic (p. 40). In other words, changing the amount of salt in the ECF does not change its concentration; it merely changes the volume of the ECF. An increase to salt in the ECF leads to an increase in water retention, so the ECF remains isotonic, but increased in volume. Similarly, a reduction in salt leads to decreased water retention, so the ECF remains isotonic, but reduced in volume. The total mass of Na^+ salts in the ECF is referred to as the **Na^+ load**, and determines the ECF’s volume. Appropriately, regulation of ECF volume therefore depends primarily on controlling salt balance.

To maintain **salt balance** at a set level, salt input must equal salt output in order to prevent salt accumulation or deficit in the body. Athletes often challenge the body’s ability to manage salt balance during ultra-endurance sporting events.

POOR CONTROL OF SALT INTAKE

The only avenue for salt input is ingestion, which typically is well in excess of the body’s need for replacing obligatory salt losses. In our example of a typical daily salt balance (Table 14-2), salt intake is 10.5 g per day. (The average Canadian salt intake is around 3.5 g per day.) Only 0.5 g of salt per day is adequate to replace the small amounts of salt usually lost in the feces and sweat, not considering salt lost during regular physical activity of moderate to high intensity.

The salt intake of humans is not well controlled and as a result, we typically consume salt in excess of our needs. Carnivores (meat eaters) and omnivores (eaters of meat and plants, like humans), naturally get enough salt in fresh meat (meat contains an abundance of salt-rich ECF). From a physiologic standpoint, humans normally do not display a regulatory appetite to seek additional salt. In fact, humans generally only have a hedonistic (pleasure-seeking) reason for consuming salt—we consume it because we like it. In contrast, herbivores (plant eaters) lack salt in their diet and develop salt hunger from a regulatory

standpoint. Herbivores will travel many kilometres to a salt lick to meet their physiologic need for salt.

PRECISE CONTROL OF SALT OUTPUT IN THE URINE

To maintain salt balance, excess ingested salt must be excreted in the urine. The three avenues for salt output are the obligatory loss of salt in *sweat and feces* and the controlled excretion of salt in *urine* (Table 14-2). The total amount of sweat produced is unrelated to salt balance and determined rather by factors that control body temperature. The small amount of salt normally lost in feces is also not subject to control. This uncontrollable loss of salt is referred to as **obligatory loss**. Except during heavy sweating or diarrhoea, this obligatory loss amounts to only about 0.5 g of salt per day. This represents the only salt that normally needs to be replaced by salt intake.

Since human salt consumption typically exceeds the amount that needs to be replaced from obligatory losses, the kidneys precisely excrete excess salt in the urine to maintain salt balance. In our example, 10 g of salt are eliminated in the urine per day so that total salt output exactly equals salt input. By regulating the rate of urinary salt excretion (i.e., by regulating the rate of Na^+ excretion), the kidneys normally keep the total Na^+ mass in the ECF constant, despite any notable changes in dietary intake or unusual losses through sweating or diarrhoea. In keeping the total Na^+ mass in the ECF constant, the ECF volume, in turn, is maintained within the narrowly prescribed limits essential for normal circulatory function.

Deviations in the ECF volume accompanying changes in the salt load trigger renal compensatory responses that quickly bring the Na^+ load and ECF volume back to normal. Sodium is freely filtered at the glomerulus and actively reabsorbed, but it is not secreted by the tubules. Therefore, the amount of Na^+ excreted in the urine represents the amount of Na^+ filtered minus the amount reabsorbed.

$$\text{Na}^+ \text{ excreted} = \text{Na}^+ \text{ filtered} - \text{Na}^+ \text{ reabsorbed}$$

The kidneys accordingly adjust the amount of salt excreted by controlling two processes: (1) the glomerular filtration rate (GFR), and (2) tubular reabsorption of Na^+ . The regulation of these two processes are discussed in Chapter 13, so here we examine how these processes relate to the long-term control of ECF volume and blood pressure.

- *The amount of Na^+ filtered is controlled by regulating the GFR.* The amount of Na^+ filtered is equal to the plasma Na^+ concentration multiplied by the GFR. At any given plasma Na^+ concentration, a change in the GFR will correspondingly change the amount of Na^+ and the accompanying fluid filtered. Thus, control of the GFR can adjust the amount of Na^+ filtered each minute. Recall that the GFR is deliberately changed to alter the amount of salt and fluid filtered as part of the general baroreceptor reflex response to change in blood pressure (see Figure 13-12). The amount of salt filtered is therefore adjusted as part of the general blood pressure-regulating reflexes. It is important to note that the Na^+ load in the body is not sensed as such. Rather, it is monitored indirectly through the effect that Na^+ ultimately has on blood

■ TABLE 14-2 Daily Salt Balance

SALT INPUT		SALT OUTPUT	
Avenue	Amount (g/day)	Avenue	Amount (g/day)
Ingestion	10.5	Obligatory loss in sweat and feces	0.5
		Controlled excretion in urine	10.0
Total Input	10.5	Total output	10.5

pressure via its role in determining the ECF volume. Fittingly, baroreceptors that monitor fluctuations in blood pressure bring about adjustments in the amounts of Na^+ filtered and eventually excreted.

- The amount of Na^+ reabsorbed is controlled through the renin–angiotensin–aldosterone system. The amount of Na^+ reabsorbed also depends on regulatory systems that play an important role in controlling blood pressure. Although Na^+ is reabsorbed throughout most of the length of the nephron, only its reabsorption in the distal aspects are subject to control. The main factor controlling the extent of Na^+ reabsorption in the distal tubule and collecting ducts is the important renin–angiotensin–aldosterone system (RAAS). Activation of the RAAS, specifically aldosterone, promotes Na^+ reabsorption and thereby Na^+ retention. Na^+ retention, in turn, promotes osmotic retention of H_2O and the subsequent expansion of plasma volume and elevation of arterial blood pressure. Appropriately, this Na^+ –conserving system can be activated by a number of means. Namely, by a reduction in salt, ECF volume, and/or arterial blood pressure (see Figure 13-16).

Thus, control of GFR and Na^+ reabsorption are interrelated and intimately tied to long-term regulation of ECF volume as reflected by blood pressure. For example, a fall in arterial blood pressure carries with it two very important effects. First, there is a reflex reduction in the GFR to decrease the amount of Na^+ filtered. Second, there is a hormonally adjusted increase in the amount of Na^+ reabsorbed by the action of aldosterone (► Figure 14-3). Together, these effects conserve the amount of Na^+ by reducing the amount of Na^+ excreted. This is accompanied by a reduction in water excretion, which helps compensate for the fall in arterial pressure.

Control of ECF osmolarity

Maintaining fluid balance depends on regulating both ECF volume and ECF osmolarity. Whereas regulating ECF volume is important in long-term control of blood pressure, regulating ECF osmolarity is important in preventing changes in cell volume. The **osmolarity** of a fluid is a measure of the concentration of the individual solute particles dissolved in it. The higher the osmolarity is, the higher the concentration of solutes. Recall that water moves by osmosis down its concentration gradient from an area of lower solute (higher water) concentration to an area of higher solute (lower water) concentration.

► FIGURE 14-3 Dual effect of a fall in arterial blood pressure on renal handling of Na^+

IONS RESPONSIBLE FOR ECF AND ICF OSMOLARITY

Osmosis occurs across the cellular plasma membranes only when a difference in concentration of nonpenetrating solutes exists between the ECF and ICF. Solute particles that can penetrate a barrier separating two fluid compartments quickly become equally distributed between the two compartments and thus do not contribute to osmotic differences.

Sodium and its attendant anions are by far the most abundant nonpenetrating solutes in the ECF. Since they are nonpenetrating, they account for the vast majority of the osmotic activity of the ECF. In contrast, K^+ and its accompanying anions are the most abundant nonpenetrating solutes of the ICF and are therefore responsible for its osmotic activity. Even though small amounts of Na^+ and K^+ passively diffuse across the plasma membrane all the time, these ions behave as if they were nonpenetrating because of Na^+ – K^+ pump activity. Any Na^+ that passively diffuses down its electrochemical gradient into the cell is promptly pumped back outside, so the result is the same as if Na^+ were barred from the cells. In reverse, K^+ , in effect, remains trapped within the cells. The resulting unequal distribution of Na^+ and K^+ and their accompanying anions between the ECF and ICF is responsible for the osmotic activity of these two fluid compartments.

Normally, the osmolarities of the ECF and ICF are the same, because the total concentration of K^+ and other effectively nonpenetrating solutes inside the cells is equal to the total

concentration of Na^+ and other effectively nonpenetrating solutes in the fluid surrounding the cells. Even though nonpenetrating solutes in the ECF and ICF differ, their concentrations are normally identical. Note that it is the number, not the nature of the unequally distributed particles per volume that determines the osmolarity of the fluid. The identical osmolarities of the ECF and ICF results in no net movement of water into or out of the cells, which leads to a constant cellular volume.

IMPORTANCE OF REGULATING ECF OSMOLARITY

Any circumstance that results in a loss or gain of *free* H_2O (i.e., loss or gain of H_2O that is not accompanied by comparable solute deficit or excess) leads to changes in ECF osmolarity. If there is a deficit of free H_2O in the ECF, the solutes become too concentrated and ECF osmolarity becomes abnormally high (i.e., it becomes *hypertonic*; p. 41). If there is excess free H_2O in the ECF, the solutes become too dilute and ECF osmolarity becomes abnormally low (i.e., it becomes *hypotonic*). When ECF osmolarity changes with respect to ICF osmolarity, osmosis takes place. Water either leaves or enters the cells, depending on whether the ECF is more or less concentrated, respectively, than the ICF.

The osmolarity of the ECF must therefore be regulated to prevent these undesirable shifts of H_2O out of or into the cells. It is crucial that the ECF osmolarity be maintained within a very narrow range to prevent cell shrinking (osmotic fluid shift from the ICF to the ECF) or swelling (osmotic fluid shift from the ECF to the ICF).

The following sections examine the fluid shifts that occur between the ECF and ICF when ECF osmolarity becomes either hypertonic or hypotonic relative to the ICF. Then we consider how water balance and, consequently, ECF osmolarity are normally maintained to minimize harmful changes in cell volume.

ECF hypertonicity and shrinking cells

Hypertonicity of the ECF, the excessive concentration of ECF solutes, is often associated with **dehydration**—that is, a negative free water balance.

CAUSES OF HYPERTONICITY

Hypertonicity can be brought about in four major ways:

1. *Insufficient* water intake, such as might occur during desert travel or might accompany difficulty in swallowing
2. *Excessive* water loss, such as might occur during heavy sweating, vomiting, or diarrhoea. Even though both water and solutes are lost during these conditions, relatively more water is lost, resulting in more concentrated solutes in the plasma.
3. **Diabetes insipidus**, a disease characterized by a deficiency of vasopressin (see Why It Matters, p. 615).
4. **Iatrogenic** hypertonicity, caused, for example, by intravenous fluid replacement with hypertonic saline. Iatrogenic means the condition results from medical intervention.

DIRECTION AND RESULTING SYMPTOMS OF H_2O MOVEMENT DURING HYPERTONICITY

Whenever the ECF compartment becomes hypertonic, water moves out of the cells by osmosis into the more concentrated ECF until the ICF osmolarity equilibrates with the ECF. As water leaves the cells, they shrink. Of particular concern is that considerable shrinking of brain neurons disturbs the myelin sheath and effects overall brain function. The manifestations of this include mental confusion and irrationality, delirium, convulsions, coma, or even death.

Rivalling the neural symptoms in seriousness are the circulatory disturbances. Since most cases of ECF hypertonicity are the result of dehydration, the extent to which the plasma volume is reduced determines the severity in physiologic changes. This ranges from a slight reduction in blood pressure to circulatory shock and death.

Other more common signs and symptoms are evident even in very mild cases of dehydration. These include dry skin, sunken eyeballs, a parched tongue, dry lips, more concentrated urine, and reduced urine volume.

ECF hypotonicity and swelling cells

Hypotonicity of the ECF is often associated with excess free H_2O , sometimes referred to as **overhydration**. When a positive free H_2O balance exists, the ECF is less concentrated (more dilute) than normal.

CAUSES OF HYPOTONICITY (OVERHYDRATION)

Under normal circumstances, hypotonicity of the ECF does not occur because any surplus free water is promptly excreted in the urine. Despite this, hypotonicity can still occur and the major causes are as follows:

1. Patients with *renal failure* who cannot excrete a dilute urine become hypotonic when they consume relatively more water than solutes.
2. Hypotonicity can occur transiently in healthy people if water is *rapidly ingested* to such an excess that the kidneys can't respond quickly enough to eliminate the extra water.
3. Hypotonicity can occur when excess water without solute is retained in the body as a result of *inappropriate secretion of vasopressin*.
4. Similar to hypertonicity, iatrogenic hypotonicity can occur by intravenous fluid replacement with hypotonic fluids (e.g., hypotonic saline).

Vasopressin is normally secreted in response to a water deficit, which is relieved by increasing water reabsorption in the distal part of the nephrons. However, vasopressin release occurs for other reasons, even when there is no water deficit. These include pain, acute infections, trauma, and other stressful situations. The increased vasopressin secretion and resulting water retention elicited by stress are appropriate in anticipation of potential blood loss in the stressful situation. The extra, retained water could minimize the effect a loss of blood volume would have on blood pressure. However, because modern-day stressful

Vasopressin (*a.k.a.* antidiuretic hormone) increases the permeability of the distal and collecting tubules to H_2O and thus enhances H_2O conservation by reducing urinary output of H_2O (p. 592). This is accomplished via the translocation of aquaporins (water channels) to the surface of the luminal side of various parts of the nephron—specifically, to the distal and collecting tubules. The aquaporins allow for H_2O to be reabsorbed in these parts of the nephron. In a condition called *diabetes insipidus*, this normal response of water conservation by vasopressin does not occur. This condition is not to be confused with diabetes mellitus, where the major problem is with insulin and glucose regulation. Patients with *diabetes insipidus* can produce up to 20 L of very dilute urine daily, compared with the normal average of 1.5 L/day.

In general, individuals with diabetes insipidus have their symptoms for one of two reasons. Some patients release a normal amount of vasopressin from the posterior pituitary gland, but the kidneys are

unable to respond to it. This variant of diabetes insipidus is referred to as *nephrogenic diabetes insipidus* because the problem originates from the level of the kidney. Nephrogenic diabetes insipidus can be caused by medications (e.g., lithium carbonate, a mood stabilizer).

Other patients do not release vasopressin from the posterior pituitary despite a normally functioning kidney. This variant is referred to as *central diabetes insipidus* because the problem originates from the level of the pituitary gland. Some infections, inflammatory conditions or even a tumour pressing on the pituitary gland can lead to central diabetes insipidus. Central diabetes insipidus is treated by replacing vasopressin, often in the form of a nasal spray. Those with diabetes insipidus must keep pace with the tremendous loss of H_2O in the urine to avoid quickly becoming dehydrated. Frequently, those with *diabetes insipidus* complain that they spend an extraordinary amount of time day and night going to the bathroom and getting drinks.

situations generally do not involve blood loss, the increased vasopressin secretion is inappropriate as far as the body's fluid balance is concerned. The reabsorption and retention of too much water dilute the body's solutes.

DIRECTION AND RESULTING SYMPTOMS OF WATER MOVEMENT DURING HYPOTONICITY

Excess free water retention first dilutes the ECF compartment, making it hypotonic. The resulting difference in osmotic potential between the ECF and ICF induces water to move from the more dilute ECF and into the ICF, resulting in cellular swelling. In contrast to the shrinking of cerebral neurons in hypertonic states, pronounced swelling of brain cells also leads to brain dysfunction in hypotonic states. Symptoms include confusion, irritability, lethargy, headache, dizziness, vomiting, drowsiness, convulsions, coma, and even death.

Non-neural symptoms of overhydration include muscle weakness (from muscle cell swelling), hypertension (from expansion of plasma volume), and oedema (from increased hydrostatic pressure).

The condition of overhydration, hypotonicity, and cellular swelling due to excess free water retention is sometimes referred to as **water intoxication**. This should not be confused with the fluid retention that occurs with excess salt retention. In the case of fluid retention, the ECF is still isotonic because the increase in salt is matched by a corresponding increase in water. Since the interstitial fluid is isotonic, no osmotic gradient exists to drive extra H_2O into the cells. The excess salt and H_2O burden is therefore confined to the ECF compartment, with circulatory consequences being the most important concern. When water intoxication occurs, there is excess free water in the ECF. Therefore, an osmotic gradient exists between the ECF and the ICF, and in addition to any circulatory disturbances, symptoms caused by cellular swelling also become a problem.

Let us now contrast the situations of hypertonicity and hypotonicity with what happens as a result of isotonic fluid gain or loss.

MAINTENANCE OF CELL WATER WHEN ECF IS ISOTONIC

An example of an isotonic fluid gain is therapeutic intravenous administration of an isotonic solution, such as isotonic saline (also known as *normal saline*). When an isotonic fluid is injected into the ECF compartment, ECF volume increases, but the concentration of ECF solutes remains unchanged; in other words, the ECF is still isotonic. Since the osmolarity of the ECF has not changed, there is no osmotic gradient between the ECF and the ICF. Therefore, no net fluid shift occurs between the two compartments. The ECF compartment has increased in volume without shifting water into the cells. Thus, for intravenous fluid therapy, unless a qualified health professional is trying to correct an osmotic imbalance, the fluid of choice is isotonic with the ECF. This prevents fluctuations in intracellular volume and possible neural symptoms.

Similarly, in an isotonic fluid loss, such as haemorrhage, the loss is confined to the ECF compartment, with no corresponding loss of fluid from the ICF. Fluid does not shift out of the cells because the ECF remaining within the body is still isotonic. Of course, many other mechanisms counteract loss of blood, but the ICF compartment is not directly affected by the loss.

Thus, when the ECF and ICF are in osmotic equilibrium, no net movement of H_2O into or out of the cells occurs. This is true regardless of whether the ECF volume increases or decreases. Shifts in water between the ECF and ICF take place only when the concentration of solutes in the ECF changes due to a loss or gain of free water.

Now let's look at how free water balance is normally maintained.

CONTROL OF WATER BALANCE

Control of free water balance is crucial for regulating ECF osmolarity. Increases in free water cause the ECF to become too dilute, and deficits of free water cause the ECF to become too concentrated. These types of changes must immediately be corrected in order to avoid harmful osmotic fluid shifts into or out of the cells.

To maintain a stable water balance, water input must equal water output.

SOURCES OF WATER INPUT

- In a person's typical daily water balance (■ Table 14-3), a little more than a litre of water is added to the body by *drinking liquids*.
- Surprisingly, an amount almost equal to that is obtained from *eating solid food*. Recall that muscles consist of about 75 percent water; meat (animal muscle) is therefore 75 percent water. Fruits and vegetables consist of 60–90 percent water. Therefore, people normally get almost as much water from solid foods as from the liquids they drink.
- The third source of water input is *metabolically produced* water. Chemical reactions within the cells convert food and O₂ into energy, producing CO₂ and H₂O in the process (e.g., the electron transport train). This **metabolic water** produced during cell metabolism averages about 350 mL/day.

The average water intake from these three sources totals 2600 mL/day. Medically, another source of water is intravenous infusion of fluid.

SOURCES OF WATER OUTPUT

- The body loses close to a litre of water daily without being aware of it. This is referred to as **insensible loss** (i.e., the person has no sensory awareness of it) and occurs from the

lungs and the *nonsweating skin*. During respiration, inspired air becomes saturated with water within the airways. This water is lost when the moistened air is subsequently expired. Normally we are not aware of this water loss, but on cold days when water vapour condenses, we can “see our breath.” The other insensible loss is continual loss of water from the skin even in the absence of sweating. Water molecules can diffuse through skin cells and evaporate without being noticed. Fortunately, the skin is fairly waterproofed by its keratinized exterior layer, which protects against a much greater loss of water by this avenue (p. 461). If this protective surface layer is lost, for example in the case of skin burns, there is a significantly increased fluid loss from the burned surface. Those with serious burns are at a much higher risk of severe dehydration. As a result, one critically important component of burn management is adequate fluid replacement therapy to counteract this increased water loss.

- Sensible loss (i.e., the person has sensory awareness) of water from the skin occurs through *sweating*. At an air temperature of 20°C, an average of 100 mL of water is lost daily through sweating. Loss of water through sweating can vary substantially depending on the environmental temperature, the humidity, and the degree of physical activity. It may range from zero millilitres to as much as several litres per hour in very hot weather.
- Another avenue for water loss is through the *feces*. Normally, only about 100 mL of water are lost through this route each day. During fecal formation in the large intestine, most water is absorbed out of the digestive tract lumen into the blood, thereby conserving fluid and solidifying the digestive tract's contents for elimination. Significantly increased water loss through the digestive tract can occur in the case of vomiting and/or diarrhoea.
- By far the most important output mechanism for water is *urine excretion*, with 1500 mL (1.5 L) of urine being produced daily on average.

The example in Table 14-3 shows that the total water input is the same as the total water output (2600 mL/day). This balance is not by chance. Water input must match water output in order for the body to maintain both water balance and a normal solute concentration of the ECF.

FACTORS REGULATED TO MAINTAIN WATER BALANCE
Of the many sources of water input and output, only two can be regulated to maintain water balance. Water input is regulated by thirst, and this influences the amount of fluid ingested. Also, water output regulated by the kidneys influences how much urine is formed. The most important mechanism controlling water balance is urine output.

Other factors that involve water input and output are also regulated, but not for the purpose of maintaining water balance. For example, the food we eat contains water, but the amount of food we ingest is regulated to maintain energy balance. Furthermore, we regulate the amount we sweat, but this is to help us maintain a constant body temperature. Metabolic water production and insensible losses are completely unregulated.

■ TABLE 14-3 Daily Water Balance

WATER INPUT		WATER OUTPUT	
Avenue	Quantity (mL/day)	Avenue	Quantity (mL/day)
Fluid Intake	1250	Insensible loss (from lungs and nonsweating skin)	900
Water in Food Intake	1000		
Metabolically Produced Water	350	Sweat	100
		Feces	100
		Urine	1500
Total Input	2600	Total output	2600

CONTROL OF WATER OUTPUT IN THE URINE BY VASOPRESSIN

Fluctuations in ECF osmolarity caused by imbalances between water input and output are quickly compensated for by changes in the amount of urinary excretion of water. This can happen without a change in the usual excretion of salt. This means that water balance can be regulated independently of solute regulation, so that the amount of free water retained or eliminated can be varied to quickly restore ECF osmolarity to normal. Free water reabsorption and excretion are adjusted through changes in vasopressin secretion (p. 592). Throughout most of the nephron, H₂O reabsorption is important in regulating ECF volume; this is because salt reabsorption (regulated by aldosterone) is accompanied by comparable H₂O reabsorption. In contrast, the distal and collecting tubules have variable free water reabsorption without comparable salt reabsorption. This is the result of the increasing vertical osmotic gradient in the renal medulla. Vasopressin increases the permeability of the distal and collecting tubules to water. Depending on the amount of vasopressin present, the amount of free water reabsorbed can be adjusted as necessary to restore ECF osmolarity to normal.

Vasopressin is produced by the hypothalamus and stored in the posterior pituitary gland. It is released from the posterior pituitary on command from the hypothalamus.

CONTROL OF H₂O INPUT BY THIRST

Clinical Note Thirst is the subjective sensation that drives you to ingest H₂O. A **thirst centre** is located in the hypothalamus in close proximity to the vasopressin-secreting cells. Excessive thirst is known as *polydipsia*; excessive urination is known as *polyuria*. Both of these signs are often present in individuals with untreated diabetes mellitus and are the result of high glucose concentration in the plasma and urine.

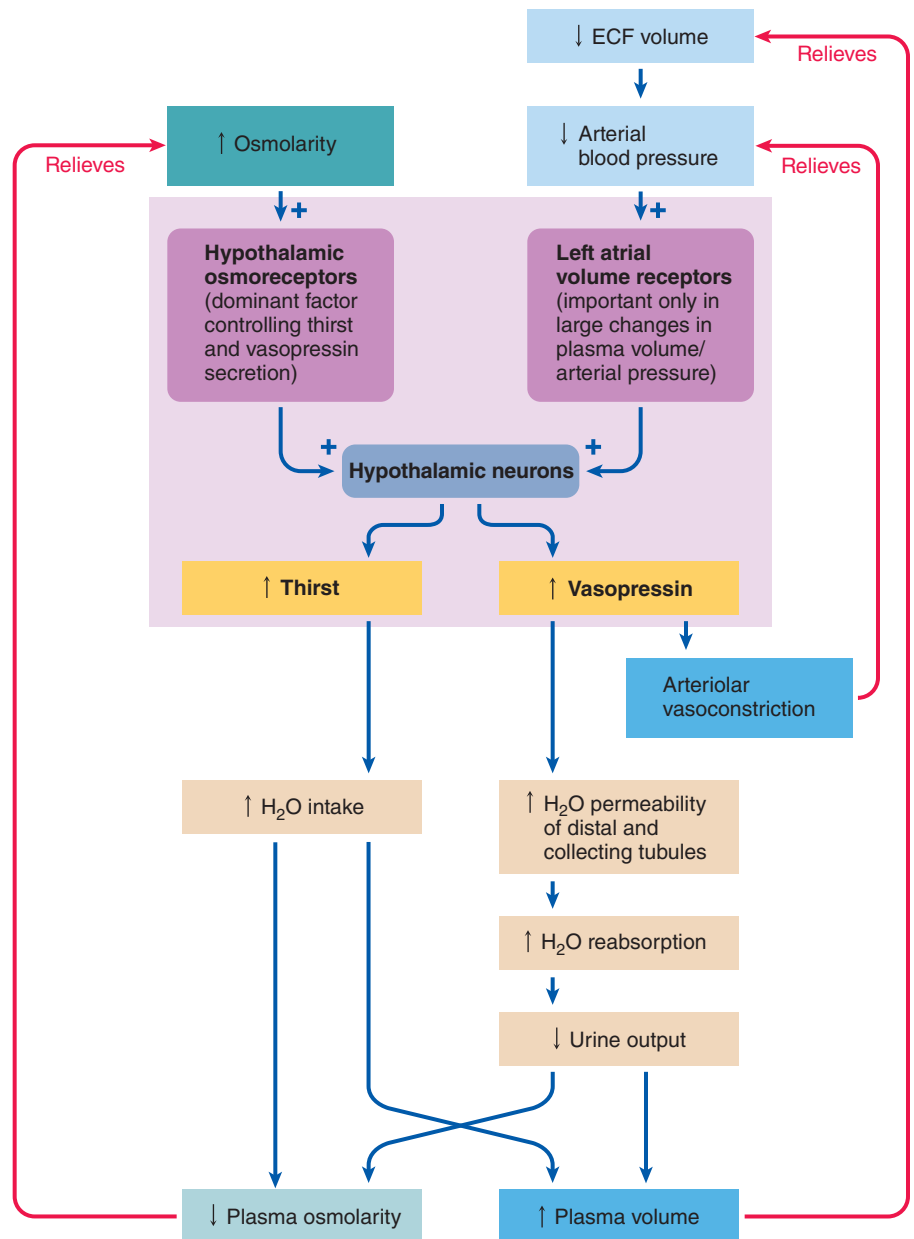

Vasopressin secretion and thirst: Largely triggered simultaneously

The hypothalamic control centres that regulate vasopressin secretion and thirst act simultaneously. Both centres are stimulated by a free water deficit and suppressed by a free water excess. Appropriately, the same circumstances that call for reducing urinary output to conserve body water also give rise to the sensation of thirst to replenish body water.

ROLE OF HYPOTHALAMIC OSMORECEPTORS

The predominant excitatory input for both vasopressin secretion and thirst comes from **hypothalamic osmoreceptors** located near

the vasopressin-secreting cells and thirst centre. These osmoreceptors monitor the osmolarity of fluid surrounding them. Because this fluid reflects the concentration of the entire internal fluid environment, as the osmolarity increases and the need for water conservation increases, vasopressin secretion and thirst are both stimulated (▶ Figure 14-4). As a result, reabsorption of water in the distal and collecting tubules is increased. This leads to a decreased urine output and increased water conservation. At the same time, the thirst centre is stimulated, and water intake is encouraged. These actions restore depleted water stores and relieve hypertonicity by diluting the solutes to their normal concentration. In contrast, water excess manifests as a reduced ECF osmolarity, and this prompts increased urine output (through decreased vasopressin release) and suppression of thirst. Together, these factors reduce free water in the body and restore normal ECF osmolarity.

▶ FIGURE 14-4 Control of increased vasopressin secretion and thirst during a water deficit

ROLE OF LEFT ATRIAL VOLUME RECEPTORS

Although the major stimulus for vasopressin secretion and thirst is an increase in ECF osmolarity, the vasopressin-secreting cells and thirst centre are both influenced to a moderate extent by an overall change to ECF volume. This is mediated by input from the **left atrial volume receptors**. Located in the left atrium, these volume receptors monitor the pressure of blood flowing through, which reflects the ECF volume. In response to a major reduction in ECF volume (>7% loss of volume) and therefore a concordant change to arterial pressure, the left atrial volume receptors reflexively stimulate both vasopressin secretion and thirst. This degree of volume loss is often seen in the case of severe haemorrhage. The outpouring of vasopressin and the increased thirst lead to decreased urine output and increased fluid intake, respectively. Furthermore, the concentration of vasopressin at the circulating levels, elicited by a large decline in ECF volume and arterial pressure, exerts a potent vasoconstrictor effect on arterioles (giving rise to its name; p. 402). By helping increase both the plasma volume and the total peripheral resistance, vasopressin helps relieve the low blood pressure that elicited vasopressin secretion. Conversely, vasopressin and thirst are both inhibited when ECF/plasma volume and arterial blood pressure are elevated. The resultant suppression of water intake, coupled with elimination of excess plasma volume in the urine, helps restore a normal blood pressure and plasma volume.

Recall that low ECF/plasma volume and low arterial blood pressure also reflexively increase aldosterone secretion. The resulting increase in Na⁺ reabsorption ultimately leads to osmotic retention of water, expansion of ECF volume, and an increase in arterial blood pressure. In fact, aldosterone-controlled Na⁺ reabsorption is the most important factor in regulating ECF volume, with the vasopressin and thirst mechanism playing a supportive role only.

ROLE OF ANGIOTENSIN II

Another stimulus for increasing both thirst and vasopressin is angiotensin II (■ Table 14-4). As all hormones need receptors, the

receptor for angiotensin is a G protein, which has two structures often termed A1 and A2. Angiotensin II is the primary ligand, or binding molecule, of both A1 and A2. When the renin–angiotensin–aldosterone mechanism is activated to conserve Na⁺, angiotensin II acts directly on the brain to give rise to the urge to drink. A molecule that increases the urge to drink is known as a **dipsogen**. Concurrently, angiotensin II stimulates vasopressin secretion, and this reduces urine output by increasing water reabsorption in the kidney (p. 576). The resultant increased water intake and decreased urine output help correct the reduction in ECF volume that triggered the renin–angiotensin–aldosterone system.

REGULATORY FACTORS THAT DO NOT LINK VASOPRESSIN AND THIRST

Several factors increase release of vasopressin secretion, but not thirst. Vasopressin can be stimulated by stress-related inputs—such as pain, fear, and trauma. These do not directly relate to water balance. In fact, water retention from the inappropriate secretion of vasopressin can bring about hypotonicity in the ECF fluid, and an overall water surplus. In contrast, alcohol acts to inhibit vasopressin secretion and can lead to ECF hypertonicity by promoting excessive free water excretion.

One stimulus that promotes thirst but not vasopressin secretion is the direct effect of dryness of the mouth. Nerve endings in the mouth are directly stimulated by dryness, which causes an intense sensation of thirst. This can often be relieved by moistening the mouth, even if no water is actually ingested. A dry mouth, known as **xerostomia**, can exist when salivation is suppressed by factors unrelated to the water content of the body, such as nervousness, excessive smoking, medications, or even certain medical conditions (e.g., Sjögren’s syndrome).

Factors that affect vasopressin secretion or thirst and are not related to the water balance in the body are usually short-lived. The dominant, long-standing control of vasopressin and thirst is directly correlated with the state of water in the body—namely, the status of ECF osmolarity and ECF volume.

■ TABLE 14-4 Factors Controlling Vasopressin Secretion and Thirst

Factor	Effect on Vasopressin Secretion	Effect on Thirst	Comment
↑ ECF Osmolarity	↑	↑	Major stimulus for vasopressin secretion and thirst
↓ ECF Volume	↑	↑	Important only in large changes in ECF volume/arterial blood pressure
Angiotensin II	↑	↑	Part of dominant pathway for promoting compensatory salt and H ₂ O retention when ECF volume/arterial blood pressure are reduced
Pain, Fear, Trauma, and Other Stress-Related Inputs	Inappropriate ↑ unrelated to body’s H ₂ O balance	No effect	Promotes excess H ₂ O retention and ECF hypotonicity (resultant H ₂ O retention of potential value in maintaining arterial blood pressure in case of blood loss in the stressful situation)
Alcohol	Inappropriate ↓ unrelated to body’s H ₂ O balance	No effect	Promotes excess H ₂ O loss and ECF hypertonicity

Clinical Connections

Diane developed diabetic ketoacidosis (DKA) as a result of undiagnosed Type I diabetes mellitus (DM). This disease usually affects individuals under the age of 30 and is the result of autoimmune destruction of pancreatic insulin-producing beta islet cells. Without insulin, glucose cannot be transported into the cells of the body from the blood. Therefore, it accumulates in the bloodstream and creates severe hyperglycaemia.

Hyperglycaemia causes an increased osmolarity of the blood, and this, in turn, activates central osmoreceptors and the thirst centre. Patients, therefore, often experience extreme thirst and excessive oral fluid intake, known as *polydipsia*.

Under normal circumstances, glucose is reabsorbed into the bloodstream in the kidney via protein-mediated transport. In untreated Type I DM, the level of hyperglycaemia often surpasses the ability of the kidney to reabsorb all the glucose. The glucose that remains in the renal tubules increases the osmolarity of the filtrate. Consequently, less water is reabsorbed from the nephron, and more frequent, larger volumes of urine are produced. This is known as *polyuria*.

The polyuria eventually reduces the volume of intravascular fluid and causes dehydration. To maintain a constant cardiac output and blood pressure, the heart rate increases (tachycardia). Without treatment, the level of dehydration can eventually become so profound that a normal cardiac output cannot be maintained. At this point, a decrease in blood pressure occurs (hypotension). One very important initial step in the management of new onset Type I DM and DKA is rehydration in the form of intravenous fluid replacement.

ORAL WATER METERING

“Oral water metering” appears to exist in most animals. For example, a thirsty animal will rapidly drink only enough water to satisfy its water deficit. It will generally stop drinking before the

ingested H_2O has even had time to be absorbed from the digestive tract and return the ECF compartment to normal. Exactly what factors are involved in signalling that enough water has been consumed is still uncertain. This mechanism seems to be less effective in humans because we frequently drink more than is necessary to meet the needs of our body or may not drink enough to make up a deficit.

NONPHYSIOLOGICAL INFLUENCES ON FLUID INTAKE

Even though the thirst mechanism exists to control water intake, fluid consumption by humans is often complex and also influenced by habit and sociological factors. Thus, even though water intake is critical in maintaining fluid balance, it is not precisely controlled in humans. We usually drink when we are thirsty, but we often drink even when we are not thirsty because, for example, we are on a coffee break.

With water intake being inadequately controlled and sometimes even contributing to water imbalances in the body, the primary factor involved in maintaining water balance is urinary output regulated by the kidneys. Accordingly, *vasopressin-controlled H_2O reabsorption is of primary importance in regulating ECF osmolarity*.

Before we shift attention to acid–base balance, examine Table 14-5, which summarizes the regulation of ECF volume and osmolarity, the two factors important in maintaining fluid balance.

Check Your Understanding 14.2

1. Make a chart showing the percentage of body H_2O distributed among the major body fluid compartments.
2. Compare how ECF volume and ECF osmolarity are regulated, and discuss why it is important that each is regulated.
3. Compare the effect of ECF hypertonicity and hypotonicity on cell volume.

TABLE 14-5 Summary of the Regulation of ECF Volume and Osmolarity

Regulated Variable	Need to Regulate the Variable	Outcomes If the Variable Is Not Normal	Mechanism for Regulating the Variable
ECF Volume	Important in the long-term control of arterial blood pressure	↓ ECF volume → ↓ arterial blood pressure ↑ ECF volume → ↑ arterial blood pressure	Maintenance of salt balance; salt osmotically “holds” H_2O, so the Na^+ load determines the ECF volume Accomplished primarily by aldosterone-controlled adjustments in urinary Na^+ excretion
ECF Osmolarity	Important to prevent detrimental osmotic movement of H_2O between the ECF and ICF	↑ ECF osmolarity (hypotonicity) → H_2O enters the cells → cells swell ↓ ECF osmolarity (hypertonicity) → H_2O leaves the cells → cells shrink	Maintenance of free H_2O balance Accomplished primarily by vasopressin-controlled adjustments in excretion of H_2O in the urine

14.3 | Acid–Base Balance

The term **acid–base balance** refers to the precise regulation of **free hydrogen ion (H^+) concentration** in the body fluids. To indicate the concentration of a chemical, its symbol is enclosed in square brackets: $[]$. Thus, $[H^+]$ designates H^+ concentration.

Acids liberate H^+ ; bases accept them

Acids are a special group of hydrogen-containing substances that *dissociate*, or separate, when in solution, liberating free H^+ and anions. Many other substances (e.g., carbohydrates) also contain hydrogen, but they are not classified as acids, because the hydrogen is tightly bound within their molecular structure and is never liberated as free H^+ .

A strong acid has a greater tendency to dissociate in solution than a weak acid. This means that a greater percentage of strong acid molecules separate into free H^+ and anions. Hydrochloric acid (HCl) is an example of a strong acid. Every HCl molecule dissociates into free H^+ and Cl^- (chloride) when dissolved in H_2O . Carbonic acid (H_2CO_3) is an example of a weak acid, and only a portion of these molecules dissociate in solution into H^+ and HCO_3^- (bicarbonate anions). The rest of the H_2CO_3 molecules remain intact. *Only the free H^+ contribute to the acidity of a solution.* This makes H_2CO_3 a weaker acid than HCl, since only a portion of H_2CO_3 molecules dissociate in solution to make free H^+ (► Figure 14-5).

The extent of dissociation for a given acid is always constant. When in solution, the same proportion of the molecules of the acid always separate to liberate free H^+ , and the other portion always remains intact. The constant degree of dissociation for a particular acid (in this example, H_2CO_3) is expressed by the **dissociation constant, K**. Consider the following chemical equation:

The dissociation constant is calculated as

$$[H^+][HCO_3^-]/[H_2CO_3] = K$$

where $[H^+][HCO_3^-]$ represents the concentration of ions resulting from $[H_2CO_3]$ dissociation, and $[H_2CO_3]$ represents the concentration of intact (undissociated) molecules. This dissociation constant varies for different acids.

A **base** is a substance that can combine with a free H^+ and thus remove it from solution. The stronger the base, the more readily it can bind to free H^+ in solution.

The pH designation

The $[H^+]$ in the ECF is normally 4×10^{-8} or 0.00000004 equivalents per litre. The concept of pH was developed to express $[H^+]$ more conveniently. Specifically, **pH** equals the logarithm (log) to the base 10 of the reciprocal of the hydrogen ion concentration:

$$pH = \log 1/[H^+] \quad (\text{or } pH = -\log[H^+])$$

► **FIGURE 14-5** Comparison of a strong and a weak acid. (a) Five molecules of a strong acid. A strong acid, such as HCl (hydrochloric acid), completely dissociates into free H^+ and anions in solution. (b) Five molecules of a weak acid. A weak acid, such as H_2CO_3 (carbonic acid), only partially dissociates into free H^+ and anions in solution.

Two important points should be noted about this formula:

1. Since $[H^+]$ is in the denominator, a high $[H^+]$ corresponds to a low pH, and a low $[H^+]$ corresponds to a high pH.
2. Since pH represents a base-10 logarithmic relationship, every unit change in pH actually represents a tenfold change in free $[H^+]$. A log to the base 10 indicates how many times 10 must be multiplied by itself to produce a given number. For example, the log of $10 = 1$, whereas the log of $100 = 2$. The number 10 must be multiplied by itself twice to yield 100 ($10 \times 10 = 100$). Numbers less than 10 have a log of less than 1. Numbers between 10 and 100 have logs between 1 and 2, and so on. Accordingly, each unit of change in pH indicates a tenfold change in free $[H^+]$. For example, a solution with a pH of 7 has a $[H^+]$ that is 10 (10^1) times less than that of a solution with a pH of 6 (a 1 pH-unit difference) and 100 (10^2) times less than that of a solution with a pH of 5 (a 2 pH-unit difference). For further discussion on pH, see Concepts, Challenges, and Controversies.

ACIDIC AND BASIC SOLUTIONS IN CHEMISTRY

The pH of pure water is 7.0, which is considered chemically neutral. An extremely small proportion of H_2O molecules dissociate into H^+ and OH^- (hydroxide ions). Although OH^- is

Acid–Base Balance: The Physico-chemical Approach

ACID–BASE BALANCE IS ONE OF THE MORE—if not most—difficult topics in physiology. Not only is it seemingly arbitrary and empirical, it is also highly quantitative. Moreover, it relies on pH, a system in which the H^+ concentration $[H^+]$ and its changes are not intuitively comprehensible. For example, if the control pH is 7.4 and the $[H^+]$ doubles, what is the new pH? If you are still trying to calculate this, try this version: if the control $[H^+]$ is 40 nEq/L and the $[H^+]$ doubles, what is the new $[H^+]$? The relative ease of answering the latter question illustrates this point.

In the early 1980s, Peter Stewart (1921–1993), a Winnipeg-born physiologist working at Brown University in Rhode Island, changed our approach to acid–base physiology, using the principles of physico-chemistry. One of Stewart’s most important contributions is that he distinguishes between independent and dependent variables. In traditional acid–base physiology, if one adds hydrochloric acid to water, the pH decreases (becomes more acidic) because the acid immediately dissociates into H^+ and Cl^- , and the increased $[H^+]$ accounts for the increased acidity (drop in pH). But because $[H^+]$ is the dependent

variable, how can the addition of the dependent variable (the H^+ in HCl) change itself? In physico-chemistry, it is the addition of Cl^- that changes the acidity of the solution.

Stewart uses physico-chemistry to show that three independent variables determine the acidity of a physiological solution: the P_{CO_2} , the net charge of strong ions (i.e., ones that easily dissociate: Na^+ , K^+ , Cl^- , and lactate), and total weak acid (typically proteins, such as albumin). Note that H^+ is not listed because it is, as mentioned, the dependent variable.

Stewart’s approach is unassailably correct, even though some traditional physiologists protested. Nevertheless, the pH approach is so thoroughly entrenched that it remains the one described by all current texts, including this edition.

Those interested in Stewart’s approach can consult the Internet; start with his Wikipedia entry, and then www.acidbase.org, where you click on “read the book.” It is a challenging read, but Stewart’s work is of enormous perception and importance.

considered basic since it has the ability to bind with H^+ , an equal number of H^+ are produced from dissociation of water. This makes water neutral: neither acidic nor basic. Solutions having a pH less than 7.0 contain a higher $[H^+]$ than pure water and are considered **acidic**. Conversely, solutions with a pH value of greater than 7.0 have a lower $[H^+]$ and are considered **basic**, or **alkaline** (► Figure 14-6a). ► Figure 14-7 compares the pH values of common solutions.

ACIDOSIS AND ALKALOSIS IN THE BODY

The pH of arterial blood is normally 7.45, and the pH of venous blood is 7.35, for an average blood pH of 7.4. The pH of skeletal muscle is about 7.15, making it slightly more acidic than either arterial or venous blood. The pH value of skeletal muscle decreases with greater intensity of exercise and is attributed to an increase in lactate generated during increased muscular effort. Venous blood is normally slightly more acidic than arterial blood because it contains more CO_2 . This is because CO_2 reacts with H_2O to generate more H_2CO_3 , carbonic acid—a weak acid. As a result, there is slightly more free H^+ in solution and, therefore, an increase in acidity (decreased pH).

Many disease processes cause deviations from the normal plasma pH range of 7.35–7.45. The term **acidaemia** is used to describe a plasma pH that is below 7.35. The suffix *-aemia* means blood, so this term literally means “acidic blood.” The general term **acidosis** refers to an overall acidic state in the body. Likewise, the term **alkalaemia** is used to describe a plasma pH that is above 7.45. Similar to acidaemia, alkalaemia literally means “alkaline blood.” The general term **alkalosis** refers to an overall

alkalotic or basic state in the body. In most instances, a state of acidosis results in an acidaemia, and a state of alkalosis results in an alkalaemia. For this reason, in the rest of the chapter we use the terms acidosis and alkalosis when referring to abnormalities in plasma pH below 7.35 or above 7.45, respectively. (See ► Figure 14-6b.) Note that the reference point for determining the body’s acid–base status is not the chemically neutral pH of 7.0; rather, it is the normal plasma pH of 7.4. Thus, a plasma pH of 7.2, for example, is considered a state of acidosis in the body, even though in chemistry a pH of 7.2 is considered basic or alkaline.

Even very minor deviations (few hundredths of a point) from the normal pH range can result in serious illness. An arterial pH of less than 6.8 or greater than 8.0 signifies an emergency and must be corrected immediately, as it is not compatible with life for any extended period of time. Since death will occur with an arterial pH outside the range of 6.8–8.0, the $[H^+]$ in the body fluids must be carefully regulated.

FLUCTUATIONS IN $[H^+]$

Even small changes in $[H^+]$ have dramatic effects on normal cell function. The main consequences of fluctuations in $[H^+]$ outside of the narrow normal range (7.35–7.45) include the following:

1. Changes in excitability of nerve and muscle cells
 - States of acidosis in the body lead to an overall depression of the central nervous system. Individuals in a state of acidosis often become disoriented and, in severe cases, eventually die in a comatose state.

► **FIGURE 14-6 pH considerations in chemistry and physiology.** (a) Relationship of pH to the relative concentrations of H^+ and base (OH^-) under chemically neutral, acidic, and alkaline conditions. (b) Plasma pH range under normal, acidosis, and alkalosis conditions

3. *Influence on K^+ levels in the body.* When reabsorbing Na^+ from the filtrate, the renal tubular cells secrete either K^+ or H^+ in exchange (p. 583). Normally, they secrete a preponderance of K^+ compared with H^+ . As a result of this intimate relationship between secretion of H^+ and K^+ by the kidneys, an increased rate of secretion of one of these ions is accompanied by a decreased rate of secretion of the other. For example, if more H^+ than normal is eliminated by the kidneys (as occurs in states of acidosis), less K^+ than usual can be excreted. The resulting K^+ retention can affect cardiac function, among other detrimental consequences.

Hydrogen ions

As with any other constituent, the input of hydrogen ions must be balanced by an equal output to maintain a constant $[H^+]$ in the body fluids. Only a small percentage of the acid in our body comes from the foods we eat or fluids we drink. Most ingested acids are weak and therefore only release a small amount of H^+ as a result of dis-

sociation. An example of this is the weak citric acid found in oranges. Most H^+ in the body fluids is generated internally from metabolic activities.

SOURCES OF H^+ IN THE BODY

Normally, H^+ is continually added to the body fluids from the three following sources:

1. *Carbonic acid formation.* The major source of H^+ is through H_2CO_3 formation from metabolically produced CO_2 . Cellular oxidation of nutrients yields energy, but also CO_2 and H_2O as end products. CO_2 and H_2O , in the presence of *carbonic anhydrase (ca)*, forms H_2CO_3 . This partially dissociates to liberate free H^+ and HCO_3^- .

This reaction is reversible because it can proceed in either direction. The direction depends on the concentrations of the substrates involved, as dictated by the *law of mass action* (p. 532). Within the systemic capillaries, the CO_2 level in the blood increases as metabolically produced CO_2 enters

- States of alkalosis lead to an overall hyperexcitability of the nervous system. The sensory component of the peripheral nervous system is often affected first. Patients often complain of **paraesthesias** (a sensation of pins-and-needles) in the extremities. This is thought to be the result of the nerves becoming so excitable that they fire even in the absence of normal stimuli. Motor nerves can also be affected and begin to twitch and, in severe cases, will spasm. Death can occur in extreme states of alkalosis because muscle spasms in the muscles of respiration lead to a serious impairment to breathing. Also, patients in severe states of alkalosis may die from uncontrollable convulsions as a result of hyperexcitability of the central nervous system (CNS).

2. *A marked influence on enzyme activity.* Most enzymes have very narrow pH range where enzyme activity is optimal. Changes in pH on either side of this narrow range produce low or high reaction rates. This occurs because some of the forces holding the enzyme (protein) in its normal conformation depend on charged groups, such as H^+ .

➤ FIGURE 14-7 Comparison of pH values of common solutions

from the tissues. Initially, this drives the reaction to the acid side, generating H^+ and HCO_3^- . However, in the lungs, the CO_2 diffuses from the blood in pulmonary capillaries into the alveoli (air sacs). The resultant reduction in blood CO_2 reverses the initial change and drives the reaction back toward the CO_2 side. Overall, there is no change in overall blood $[H^+]$ and therefore no change in pH. When the rate of CO_2 removal by the lungs does not match the rate of CO_2 production at the tissue level, however, the resulting change in CO_2 leads to an overall change in the free H^+ in the body fluids.

2. **Inorganic acids produced during breakdown of nutrients.** Dietary proteins found abundantly in meat protein contain a large quantity of sulphur and phosphorus. When these nutrient molecules are broken down, sulphuric acid and phosphoric acid are produced as by-products. Being moderately strong acids, these two inorganic acids largely dissociate, liberating free H^+ into the body fluids. In contrast, breakdown of fruits and vegetables produce various bases that neutralize the acids derived from protein metabolism. Generally, more acids than bases are

produced during breakdown of ingested food, leading to an excess of these acids.

3. **Organic acids resulting from intermediary metabolism.** Numerous organic acids are produced during normal intermediary metabolism. For example, fatty acids are produced during fat metabolism, and lactic acid is produced by muscles during heavy exercise. These acids partially dissociate to yield free H^+ .

Hydrogen ion generation therefore normally goes on continuously as a result of metabolism. In certain disease states, additional acids may be produced that further contribute to the total body pool of H^+ . In untreated insulin-dependent diabetes mellitus, large quantities of ketoacids are produced and released into the plasma from abnormal fat metabolism. Also, certain acid-producing medications can add to the total $[H^+]$ in the body.

The input of H^+ is unceasing, highly variable, and essentially unregulated. For this reason, the body has several mechanisms to help maintain a normal plasma pH.

THREE LINES OF DEFENCE AGAINST CHANGES IN $[H^+]$

The generated free H^+ must be largely removed from solution in the body and ultimately must be eliminated so that the pH of body fluids can remain within the narrow normal range of 7.35–7.45. Mechanisms must also exist to compensate rapidly for the occasional situation in which the ECF becomes too alkaline.

Three lines of defence against changes in $[H^+]$ operate to maintain $[H^+]$ of body fluids at a nearly constant level despite unregulated input. These include (1) the *chemical buffer systems*, (2) the *respiratory mechanism of pH control*, and (3) the *renal mechanism of pH control*.

Chemical buffer systems

A **chemical buffer system** is a mixture in a solution of two chemical compounds that minimize pH changes when either an acid or a base is added to or removed from the solution. A buffer system consists of a pair of substances involved in a reversible reaction. One of these substances must yield free H^+ if the $[H^+]$ falls, and the other must bind with free H^+ if the $[H^+]$ rises.

An important example of such a buffer system is the carbonic acid:bicarbonate ($H_2CO_3 : HCO_3^-$) buffer pair involved in the following reversible reaction:

When a strong acid, such as HCl, is added to an unbuffered solution, all the dissociated H^+ remains free in the solution (➤ Figure 14-8a). In contrast, when HCl is added to a solution containing the $H_2CO_3 : HCO_3^-$ buffer pair, the HCO_3^- immediately binds with the free H^+ to form H_2CO_3 (➤ Figure 14-8b). This weak H_2CO_3 dissociates only slightly compared with the complete dissociation of HCl that occurred when the buffer system was not present. In the opposite case, when the pH of the solution starts to rise due to the addition of base or loss of acid, H_2CO_3 releases H^+ to minimize the rise in pH.

FIGURE 14-8 Action of chemical buffers. (a) All the added hydrogen ions (H⁺) remain free and contribute to the acidity of the solution. (b) Bicarbonate ions (HCO₃⁻), the basic member of the buffer pair, bind with some of the added H⁺ and remove them from solution so that they do not contribute to its acidity.

The body has four buffer systems and each serves a different important role in the body: (1) the (H₂CO₃:HCO₃⁻) buffer system, (2) the protein buffer system, (3) the haemoglobin buffer system, and (4) the phosphate buffer system. (Table 14-6).

The H₂CO₃:HCO₃⁻ buffer pair

The (H₂CO₃:HCO₃⁻) buffer pair is the most important buffer system in the ECF for buffering pH changes brought about by causes other than fluctuations in CO₂-generated H₂CO₃. This buffer pair is a very effective ECF buffer system for two reasons. First, H₂CO₃ and HCO₃⁻ are abundant in the ECF and are therefore readily available to resist changes in pH. Second, each component of this buffer system is closely regulated. The respiratory system closely regulates CO₂ (ultimately generating H₂CO₃), and the kidneys closely regulate [HCO₃⁻]. Thus, the (H₂CO₃:HCO₃⁻) buffer system involves CO₂, via the following reaction:

When new H⁺ is added to the plasma from any source other than CO₂ (e.g., lactic acid release into the ECF from exercising muscles), the preceding reaction is driven toward the left side of the equation. The extra H⁺ binds with HCO₃⁻ and therefore no longer contributes to the acidity of body fluids. In contrast, a decrease in [H⁺] for a reason other than a reduction in CO₂ (e.g., loss of plasma-derived HCl in the gastric juices during vomiting), the reaction is driven toward the right side of the equation. Dissolved CO₂ and H₂O in the plasma form H₂CO₃, which generates additional H⁺ to make up for the H⁺ deficit. In so doing, the H₂CO₃:HCO₃⁻ buffer system resists the fall in [H⁺].

It is very important to note that this system cannot buffer changes in pH induced by fluctuations in HCO₃⁻, CO₂, or H₂CO₃. A buffer system cannot buffer itself. Consider, for example, the situation in which the plasma [H⁺] is elevated by CO₂ retention due to a breathing problem. According to the law of mass action, the rise in CO₂ drives the reaction to the right, thereby elevating [H⁺]. The increase in [H⁺] occurs because the reaction is driven to the *right* by an increase in CO₂. The elevated [H⁺] cannot drive the reaction to the *left* to buffer the increase in [H⁺] because the elevated [H⁺] is due to a rightward shift of the reaction. The H₂CO₃:HCO₃⁻ buffer is only effective against increases [H⁺] brought about by mechanisms other than an increase CO₂ content. In the opposite situation, the H₂CO₃:HCO₃⁻ buffer system cannot compensate for a reduction in [H⁺] from

TABLE 14-6 Chemical Buffers and Their Primary Roles

Buffer System	Major Functions
Carbonic acid: Bicarbonate buffer system	Primary ECF buffer against noncarbonic acid changes
Protein buffer system	Primary ICF buffer; also buffers ECF
Haemoglobin buffer system	Primary buffer against carbonic acid changes
Phosphate buffer system	Important urinary buffer; also buffers ICF

a deficit of CO_2 , for the similar reason outlined above. Changes in pH caused by fluctuations in CO_2 levels can be regulated, but a different mechanism is required.

THE HENDERSON-HASSELBALCH EQUATION AND NORMAL PLASMA PH OF 7.4

The relationship between $[\text{H}^+]$ and the members of a buffer pair can be expressed according to the **Henderson-Hasselbalch equation**. For the $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ buffer system, the equation is as follows:

$$\text{pH} = \text{pK} + \log[\text{HCO}_3^-]/[\text{H}_2\text{CO}_3]$$

Although you do not need to know the mathematical manipulations involved, it is helpful to understand how this formula is derived. Recall that the dissociation constant K for H_2CO_3 is

$$[\text{H}^+][\text{HCO}_3^-]/[\text{H}_2\text{CO}_3] = K$$

and the relationship between pH and $[\text{H}^+]$ is

$$\text{pH} = \log 1/[\text{H}^+] \text{ or } \text{pH} = -\log[\text{H}^+]$$

Like pH, pK is the negative logarithm of K . Notice that in both cases, the negative log function is replaced by the letter p . Solving the dissociation constant equation for $[\text{H}^+]$ gives the following:

$$[\text{H}^+] = K \times [\text{H}_2\text{CO}_3]/[\text{HCO}_3^-]$$

By taking the negative log of each side, the formula becomes

$$-\log[\text{H}^+] = -\log\{K \times [\text{H}_2\text{CO}_3]/[\text{HCO}_3^-]\}$$

Using the mathematical principles of logarithms, this equation can be simplified to

$$-\log[\text{H}^+] = -\log(K) + \log([\text{HCO}_3^-]/[\text{H}_2\text{CO}_3])$$

The final manipulation of the above expression required in order to obtain the Henderson-Hasselbalch equation is to replace the negative log functions with the letter p :

$$\text{pH} = \text{pK} + \log[\text{HCO}_3^-]/[\text{H}_2\text{CO}_3]$$

Practically speaking, $[\text{H}_2\text{CO}_3]$ directly reflects the concentration of dissolved CO_2 because CO_2 in the plasma is converted into H_2CO_3 . Replacing $[\text{H}_2\text{CO}_3]$ with $[\text{CO}_2]$, the equation becomes

$$\text{pH} = \text{pK} + \log[\text{HCO}_3^-]/[\text{CO}_2]$$

The pK value always remains a constant for any given acid. For example, the pK of H_2CO_3 is 6.1. Since pK is always a constant, changes in pH are associated with changes in the ratio between $[\text{HCO}_3^-]$ and $[\text{CO}_2]$.

- Under normal circumstances, the ratio between $[\text{HCO}_3^-]$ and $[\text{CO}_2]$ in the ECF is 20:1. If we substitute the ratio of 20:1 and solve for pH, we obtain the following:

$$\begin{aligned}\text{pH} &= \text{pK} + \log[\text{HCO}_3^-]/[\text{CO}_2] \\ &= 6.1 + \log 20/1\end{aligned}$$

- $\log(20) = 1.3$. Therefore, $\text{pH} = 6.1 + 1.3 = 7.4$, which is the normal pH of plasma.

- When the ratio of $[\text{HCO}_3^-]:[\text{CO}_2]$ increases to values above 20:1, pH rises. This occurs with either a rise in $[\text{HCO}_3^-]$ or a fall in $[\text{CO}_2]$.
- In contrast, when the ratio of $[\text{HCO}_3^-]:[\text{CO}_2]$ decreases to values below 20:1, pH falls. This occurs with either a decrease in $[\text{HCO}_3^-]$ or increase in $[\text{CO}_2]$.

The $[\text{HCO}_3^-]$ is regulated by the kidneys and $[\text{CO}_2]$ is regulated by the lungs. This means that the pH of the plasma can be shifted up and down by altering $[\text{HCO}_3^-]$ at the level of the kidneys and/or the $[\text{CO}_2]$ at the level of the lungs. The kidneys and lungs regulate pH (and thus free $[\text{H}^+]$) largely by controlling plasma $[\text{HCO}_3^-]$ and $[\text{CO}_2]$, respectively, to restore their ratio to normal. Accordingly, the pH of the plasma is related to the plasma $[\text{HCO}_3^-]$ and $[\text{CO}_2]$ based on the following relationship:

$$\text{pH} \propto \frac{[\text{HCO}_3^-] \text{ controlled by kidney function}}{[\text{CO}_2] \text{ controlled by respiratory function}}$$

Although the kidneys and the lungs are crucial to maintaining normal plasma pH, there are disease states where the kidney or respiratory tract are unable to properly regulate $[\text{HCO}_3^-]$ or $[\text{CO}_2]$. This leads to conditions that are collectively referred to as **acid-base disorders**. They occur as a result of alterations in the ratio of $[\text{HCO}_3^-]:[\text{CO}_2]$. We explore these disorders in relation to respiratory and renal control of pH and acid-base disturbances in the section on Acid-Base Imbalances.

The protein buffer system

The most plentiful buffers of the body fluids are the proteins. These include both intracellular proteins and the plasma proteins. Proteins are excellent buffers because they contain both acidic and basic groups that can give up or take up H^+ . Quantitatively, due to the sheer abundance of intracellular proteins, the protein system is most important in buffering changes in $[\text{H}^+]$ in the ICF.

The haemoglobin buffer system

Haemoglobin buffers the H^+ generated from the metabolically produced CO_2 that travels between the tissues and lungs. At the level of the systemic capillaries, CO_2 continuously diffuses into the blood from the tissue cells where it is produced. The greatest percentage of this CO_2 forms H_2CO_3 , which partially dissociates into H^+ and HCO_3^- . As discussed, free H^+ produced from H_2CO_3 cannot be buffered by HCO_3^- . Instead, the free $[\text{H}^+]$ becomes bound to Hb and no longer contributes to the acidity of body fluids. Were it not for Hb, blood would become much too acidic after picking up CO_2 at the tissues. With the tremendous buffering capacity of the Hb system, venous blood is only slightly more acidic than arterial blood, despite the large volume of free H^+ produced from CO_2 carried in venous blood. At the lungs, the reactions are reversed, and the resulting CO_2 is exhaled.

The phosphate buffer system

Since phosphates are most abundant intracellularly, this system contributes significantly to intracellular buffering—rivalled only by the more plentiful intracellular proteins.

The phosphate buffer system consists of an acidic phosphate salt (NaH_2PO_4) that can donate a free H^+ when the $[\text{H}^+]$ falls and a basic phosphate salt (Na_2HPO_4) that can accept a free H^+ when the $[\text{H}^+]$ rises. The buffer pair NaH_2PO_4 : Na_2HPO_4 can alternately switch a H^+ for a Na^+ as demanded by the $[\text{H}^+]$:

Despite the phosphate salt pair being a good buffer, its concentration in the ECF is rather low, so it is not very important as an ECF buffer.

Even more importantly, the phosphate system serves as an excellent urinary buffer. Humans normally consume more phosphate than needed. Any excess phosphate filtered through the kidneys is not reabsorbed because the renal threshold for phosphate has been exceeded (p. 580). Therefore, the excess phosphate remains in the tubular fluid and can buffer any H^+ secreted into the tubular fluid until it is eventually excreted in the urine. This ensures that the free $[\text{H}^+]$ in the tubular fluid remains low, and the pH of the urine does not change significantly. The excess H^+ ingested and created in the body can therefore continue to be secreted and excreted in the amounts required to maintain a normal plasma pH. Unlike the other buffers discussed, this is the only one present in the tubular fluid that buffers urine during its formation.

Chemical buffer systems: The first line of defence

All chemical buffer systems act immediately (within fractions of a second) to minimize changes in pH. Accordingly, the buffer systems are considered the *first line of defence* against changes in $[\text{H}^+]$ in the body because they are the first mechanisms to respond.

Through the mechanism of buffering, most excess H^+ seem to disappear from the body fluids. It must be emphasized, however, that none of the chemical buffer systems actually eliminate H^+ from the body. Buffered H^+ is merely removed from solution by being incorporated within one member of the buffer pair, preventing H^+ from contributing to the acidity

of the body's fluid. Although effective, each buffer system has a limited capacity to soak up H^+ . Since H^+ is unceasingly produced in the body, it must ultimately be removed. If H^+ were not eventually eliminated, all of the buffers would become bound with H^+ , effectively stopping all further buffering ability. The body therefore requires other lines of defence against changes in $[\text{H}^+]$, specifically, lines of defence with an ability to eliminate excess H^+ .

The respiratory and renal systems can very effectively eliminate acid from the body, instead of merely suppressing it, but the trade-off is their slower response compared to chemical buffer systems.

The respiratory system and $[\text{H}^+]$

The respiratory system plays an important role in acid–base balance through its ability to alter pulmonary ventilation and consequently to alter excretion of CO_2 . The level of respiratory activity is governed in part by arterial $[\text{H}^+]$ through the following mechanism (■ Table 14-7):

- When arterial $[\text{H}^+]$ increases as the result of a *nonrespiratory* cause, the respiratory centre in the brain stem is reflexively stimulated to increase pulmonary ventilation (the rate at which gas is exchanged between the lungs and the atmosphere) (p. 548). As the rate and depth of breathing increase, more CO_2 than usual is exhaled. This means that less CO_2 is available to react with H_2O in the blood and less H_2CO_3 is produced. Therefore, removal of CO_2 helps to remove excess acid from nonrespiratory sources in the body.
- Conversely, when arterial $[\text{H}^+]$ falls, pulmonary ventilation is reduced. As a result of slower and shallower breathing, less CO_2 is removed from the body by the lungs. Metabolically produced CO_2 therefore accumulates in the blood. This CO_2 reacts with H_2O to produce H_2CO_3 , restoring $[\text{H}^+]$ toward normal.

The lungs are extremely important in maintaining $[\text{H}^+]$. Every day they remove from body fluids what amounts to 100 times more H^+ derived from carbonic acid as the kidneys remove from sources other than carbonic acid. Furthermore, the

■ TABLE 14-7 Respiratory Adjustments to Acidosis and Alkalosis Induced by Nonrespiratory Causes

Respiratory Compensations	ACID–BASE STATUS		
	Normal (pH 7.4)	Nonrespiratory (metabolic) Acidosis (pH 7.1)	Nonrespiratory (metabolic) Alkalosis (pH 7.7)
Ventilation	Normal	↑	↓
Rate of CO_2 Removal	Normal	↑	↓
Rate of H_2CO_3 Formation	Normal	↓	↑
Rate of H^+ Generation from CO_2	Normal	↓	↑

respiratory system, through its ability to regulate arterial $[\text{CO}_2]$, can adjust the amount of H^+ added to body fluids as needed to restore a normal pH.

The respiratory system: The second line of defence

If deviations in $[\text{H}^+]$ are not swiftly and completely corrected by the buffer systems, the respiratory system comes into action. Unlike the immediate response of the buffer systems of the body, adjustments in ventilation require a few minutes to be initiated. This makes it the *second line of defence* against changes in $[\text{H}^+]$ in the body.

The respiratory system can compensate only for non-respiratory changes to plasma pH. Furthermore, it can only partially correct these abnormalities in pH (50 to 75 percent). There are two main reasons for this. First, the peripheral chemoreceptors and central chemoreceptors change pulmonary ventilation using different mechanisms. The peripheral chemoreceptors increase ventilation in response to an elevated arterial $[\text{H}^+]$, and the central chemoreceptors increase ventilation in response to a rise in $[\text{CO}_2]$ (p. 545). Consider the example of an acidosis arising from a nonrespiratory cause. When the peripheral chemoreceptors detect the increase in arterial $[\text{H}^+]$, they reflexively *stimulate* the respiratory centre to increase ventilation, allowing for more CO_2 to be blown off. The $[\text{CO}_2]$ therefore decreases, and the central chemoreceptors *inhibit* the respiratory centre. By opposing the action of the peripheral chemoreceptors, the central chemoreceptors stop the compensatory increase in ventilation short of restoring pH back to the normal range.

Second, as the pH moves toward normal, the driving force for the compensatory increase in ventilation is diminished. Ventilation is increased by the peripheral chemoreceptors in response to a rise in arterial $[\text{H}^+]$, but as the $[\text{H}^+]$ is gradually reduced, so is the enhanced response in ventilation.

When changes in $[\text{H}^+]$ stem from $[\text{CO}_2]$ fluctuations arising from respiratory abnormalities, the respiratory mechanism does not contribute to pH control. Take for instance an acidosis that exists because of CO_2 accumulation due to a lung disease. It was the initial impairment in the lungs that led to an increased CO_2 , and so the lungs cannot possibly compensate by increasing CO_2 removal. The buffer systems (other than the H_2CO_3 : HCO_3^- pair) plus renal regulation are the only mechanisms available for defending against respiratory-induced acid–base disturbances.

The kidneys and plasma pH control

The kidneys control the pH of body fluids by adjusting three interrelated factors: (1) H^+ excretion, (2) HCO_3^- excretion, and (3) ammonia NH_3 secretion.

Acids are continuously being added to body fluids as a result of metabolic activities, yet the generated H^+ must not be allowed to accumulate. Although the body's buffer systems can resist changes in pH by removing H^+ from solution, the

persistent production of acidic metabolic products would eventually overwhelm the capacity of these buffers. Therefore, the constantly generated H^+ must ultimately be eliminated from the body. The lungs can remove only carbonic acid by eliminating CO_2 . The task of eliminating H^+ derived from sulphuric, phosphoric, lactic, and other acids rests with the kidneys. Furthermore, the kidneys can also eliminate extra H^+ derived from carbonic acid.

MECHANISM OF RENAL H^+ EXCRETION AND SECRETION

Recall that the filtration rate of H^+ equals plasma $[\text{H}^+]$ multiplied by GFR. Since normal plasma $[\text{H}^+]$ is extremely low (less than in pure H_2O), the filtration rate of H^+ is also extremely low. Although the filtered H^+ is normally eliminated in the urine, it only accounts for a very minute fraction of the excreted H^+ . The vast majority of excreted H^+ is secreted into the filtrate at various places across the nephron. These locations include the proximal tubule, distal tubule, and collecting duct. Since the normal tendency of the kidney is to remove excess H^+ by excretion, urine is usually acidic (pH ~ 6.0).

The H^+ secretory process begins in the tubular cells with CO_2 from three sources: CO_2 diffused into the tubular cells from (1) plasma, (2) tubular fluid, or (3) CO_2 metabolically produced within the tubular cells. Catalyzed by carbonic anhydrase, CO_2 and H_2O form H_2CO_3 , which dissociates into H^+ and HCO_3^- . The produced H^+ is secreted by two main mechanisms. First, an energy-dependent carrier on the luminal surface can transport H^+ out of the cell into the tubule lumen. Second, the proximal tubule utilizes a *luminal $\text{Na}^+ - \text{H}^+$ antiporter*. The net effects of this antiporter include H^+ secretion into the lumen and Na^+ reabsorption into the peritubular capillaries (► Figure 14-9). Furthermore, the HCO_3^- produced is reabsorbed into the peritubular capillaries. This means that Na^+ reabsorption and plasma pH regulation (by way of renal H^+ secretion) are partially linked. In fact, this proximal tubule antiporter is responsible for the majority of the Na^+ reabsorption in this region of the kidneys.

FACTORS INFLUENCING THE RATE OF H^+ SECRETION

The magnitude of H^+ secretion depends primarily the acid–base status of the plasma and the effect it has on the tubular cells of the kidney (► Figure 14-10). There are no neural or hormonal controls involved.

- When the $[\text{H}^+]$ of the plasma passing through the peritubular capillaries is elevated above normal, the tubular cells respond by secreting a greater-than-usual amount of H^+ from the plasma into the tubular fluid.
- Conversely, when plasma $[\text{H}^+]$ is lower than normal, the kidneys conserve H^+ by reducing secretion and the subsequent excretion in the urine.
- Since H^+ secretion in the kidneys begins with CO_2 , its rate of secretion is also influenced by the $[\text{CO}_2]$.

► **FIGURE 14-9** The $\text{Na}^+ - \text{H}^+$ exchanger (NHE) of the proximal tubule

- When plasma $[\text{CO}_2]$ increases, these reactions proceed more rapidly, and the rate of H^+ secretion also increases (Figure 14-10).
- Conversely, when plasma $[\text{CO}_2]$ decreases, these reactions proceed less rapidly and the rate of H^+ secretion also decreases.

These responses are extremely important in terms of how the kidney compensates for acid–base abnormalities involving a change in H_2CO_3 caused by respiratory dysfunction. Therefore, the kidneys can adjust H^+ excretion to compensate for changes in both carbonic and noncarbonic acids.

The kidneys and HCO_3^- excretion

Before being eliminated by the kidneys, the H^+ generated from noncarbonic acids is buffered to a large extent by plasma HCO_3^- (see Why It Matters, p. 629). Therefore, renal handling

of acid–base balance also involves adjustment of HCO_3^- excretion, depending on the H^+ load in the plasma (Figure 14–10).

The kidneys regulate plasma $[\text{HCO}_3^-]$ by two interrelated mechanisms: (1) variable reabsorption of filtered HCO_3^- back into the plasma, and (2) variable addition of new HCO_3^- to the plasma. Both of these mechanisms are inextricably linked with H^+ secretion by the kidney tubules. Each H^+ secreted into the tubular fluid results in the simultaneous transfer of a HCO_3^- into the peritubular capillary plasma. Whether a filtered HCO_3^- is reabsorbed or a new HCO_3^- is added to the plasma in accompaniment with H^+ secretion depends on whether filtered HCO_3^- is present in the tubular fluid to react with the secreted H^+ .

COUPLING OF HCO_3^- REABSORPTION WITH H^+ SECRETION

Bicarbonate is freely filtered, but because the luminal membranes of tubular cells are impermeable to filtered HCO_3^- , it cannot diffuse into these cells. In fact, HCO_3^- is not freely permeable to membranes in general. Therefore, reabsorption of HCO_3^- must occur via an indirect mechanism (► Figure 14-11). H^+ secreted into the tubular fluid combines with filtered HCO_3^- to form H_2CO_3 . Under the influence of carbonic anhydrase, which is present on the surface of the luminal membrane, H_2CO_3 decomposes into CO_2 and H_2O within the filtrate. Unlike HCO_3^- , the CO_2 can easily penetrate tubular cell membranes. Once it is intracellular, cytoplasmic carbonic anhydrase helps the CO_2 react with H_2O to form H_2CO_3 which dissociates into H^+ and HCO_3^- . Since HCO_3^- can permeate the basolateral membrane of the tubule cells, it passively diffuses out of the cells and into the peritubular capillary plasma. Meanwhile, the generated H^+ is actively secreted. Notice that the disappearance of a HCO_3^- from the tubular fluid is coupled with the appearance of another HCO_3^- in the plasma. In effect, a HCO_3^- has been “reabsorbed.” Even though the HCO_3^- entering the plasma is not the same one that was filtered, the net result is the same as if HCO_3^- were directly reabsorbed.

Under normal circumstances, the amount of H^+ secreted is greater than the amount of HCO_3^- filtered. Accordingly, all the filtered HCO_3^- is usually reabsorbed. By far, most of the secreted H^+ combines with HCO_3^- and is “used up” in HCO_3^- reabsorption rather than excreted. However, the slight excess of secreted H^+ that is not matched by filtered HCO_3^- is excreted in urine.

Secretion H^+ that is *excreted* is generally coupled with the *addition of new* HCO_3^- to the plasma. This H^+ is generated by CO_2 from cellular metabolism, or by the CO_2 that diffuses from the plasma and into the tubular cell (► Figure 14-12). The CO_2 reacts with H_2O in the cell to produce H^+ and HCO_3^- . The HCO_3^- is absorbed into the peritubular capillaries. This HCO_3^- is considered “new” because it is not associated with the reabsorption of filtered HCO_3^- . The H^+ is secreted, combines with urinary buffers, especially basic phosphate (HPO_4^{2-}), and is ultimately excreted in the urine.

► **FIGURE 14-10** Control of the rate of tubular H^+ secretion

► **FIGURE 14-11 Hydrogen ion secretion coupled with bicarbonate reabsorption.** Because the disappearance of a filtered HCO_3^- from the tubular fluid is coupled with the appearance of another HCO_3^- in the plasma, HCO_3^- is considered to have been reabsorbed.

RENAL HANDLING OF H^+ AND HCO_3^- DURING ACIDOSIS AND ALKALOSIS

When plasma $[\text{H}^+]$ is elevated during acidosis, more H^+ is secreted than normal. At the same time, less plasma $[\text{HCO}_3^-]$ is filtered than normal because more of it is used up in buffering the excess H^+ in the ECF. This imbalance between filtered HCO_3^- and secreted H^+ has two consequences. First, more of the secreted H^+ is excreted in the urine because more H^+ are entering the tubular fluid at a time when fewer are needed to reabsorb the reduced quantities of filtered HCO_3^- . This extra H^+ makes the urine more acidic than normal. Second, the increased excretion of H^+ is linked with the addition of new HCO_3^- to the plasma. This additional HCO_3^- is available to buffer excess H^+ present in the body.

In the situation of alkalosis, the rate of H^+ secretion diminishes, and the rate of HCO_3^- filtration increases. When plasma $[\text{H}^+]$ is below normal, a smaller proportion of the HCO_3^- pool is tied up buffering H^+ . This causes the plasma $[\text{HCO}_3^-]$ to increase. As a result, the rate of HCO_3^-

filtration correspondingly increases. Not all of the filtered HCO_3^- is reabsorbed because HCO_3^- is in excess of secreted H^+ in the tubular fluid. Since HCO_3^- cannot be reabsorbed without first

► **FIGURE 14-12 Hydrogen ion secretion and excretion coupled with the addition of new HCO_3^- to the plasma.** Secreted H^+ does not combine with filtered HPO_4^{2-} and is not subsequently excreted until all the filtered HCO_3^- has been reabsorbed, as depicted in Figure 14-11. Once all the filtered HCO_3^- has combined with secreted H^+ , further secreted H^+ is excreted in the urine, primarily in association with urinary buffers such as basic phosphate. Excretion of H^+ is coupled with the appearance of new HCO_3^- in the plasma. The new HCO_3^- represents a net gain rather than merely a replacement for filtered HCO_3^- .

Why is bicarbonate transport important? Aside from acting as a buffer in skeletal muscle and other tissues, bicarbonate is important to diseases such as cystic fibrosis (CF). Normal pancreatic secretion of a 140 mM HCO_3^- solution is frequently disrupted in CF patients, and that loss of

HCO_3^- secretion capacity correlates strongly with disease severity in CF. Thus, there is a defect in the transport of HCO_3^- . This has raised the question as to whether delivering HCO_3^- to diseased tissues can someday be used to lessen the effects of CF in patients and even extend their lives.

reacting with H^+ , there is incomplete reabsorption of HCO_3^- . Excess HCO_3^- remains in the tubular fluid and is excreted in urine. The net effects of this excretion include alkalinization of the urine and an overall reduction in plasma HCO_3^- .

In summary, when plasma $[\text{H}^+]$ increases above normal during *acidosis*, renal compensation includes the following (■ Table 14-8):

1. Increased secretion and excretion of H^+ in the urine, which eliminates the excess H^+ and decreases plasma $[\text{H}^+]$
2. Reabsorption of all the filtered HCO_3^- and the addition of new HCO_3^- to the plasma, resulting in increased plasma $[\text{HCO}_3^-]$

When plasma $[\text{H}^+]$ falls below normal during *alkalosis*, renal compensation includes the following:

1. Decreased secretion and excretion of H^+ in the urine, which conserves H^+ and increases plasma $[\text{H}^+]$
2. Incomplete reabsorption of filtered HCO_3^- and subsequent increased excretion of HCO_3^- , resulting in decreased plasma $[\text{HCO}_3^-]$.

Note that in states of acidosis, the kidneys acidify urine (by secreting extra H^+) and alkalinize plasma (by conserving HCO_3^-) to bring pH back to normal. In states of alkalosis, the kidneys alkalinize the urine (by eliminating excess HCO_3^-) and acidify plasma (by reducing secretion of H^+) to bring pH back to normal.

The kidneys and ammonia

The energy-dependent H^+ carriers in the tubular cells can secrete H^+ against a concentration gradient until the tubular

fluid becomes 800 times as acidic as the plasma. At this point, further H^+ secretion stops because the gradient becomes too great for the secretory process to continue. The kidneys cease to secrete H^+ when urinary pH becomes 4.5. Only about 1 percent of the excess free H^+ secreted daily can acidify the urine to this pH. This means the other 99 percent of the normally secreted H^+ load could not be eliminated—an intolerable situation. For H^+ secretion to proceed, therefore, most secreted H^+ must be buffered in the tubular fluid so that it does not exist as free H^+ and, accordingly, not contribute to tubular acidity.

Bicarbonate is unable to buffer urinary H^+ as it does H^+ in the ECF because it is not excreted in the urine simultaneously with H^+ . (Whichever of these substances is in excess in the plasma is excreted in the urine.) There are, however, two important urinary buffers that help remove free H^+ : (1) filtered phosphate buffers, and (2) secreted ammonia.

FILTERED PHOSPHATE AS A URINARY BUFFER

Normally, secreted H^+ is first buffered by the phosphate buffer system. Phosphate is present in the tubular fluid only because of dietary excess, not because of any specific mechanism for buffering secreted H^+ . Phosphate just happens to have buffering capacity. Furthermore, tubular fluid contains phosphate levels above the transport maximum. Above this level excess phosphate remains in the tubular fluid. The basic member of this buffer pair binds with secreted H^+ . When H^+ secretion is high, the buffering capacity of urinary phosphates is exceeded. As soon as all the basic phosphate ions that are coincidentally excreted have soaked up H^+ , the acidity of the tubular fluid quickly rises as

■ TABLE 14-8 Summary of Renal Responses to Acidosis and Alkalosis

Acid–Base Abnormality	H^+ Secretion	H^+ Excretion	HCO_3^- Reabsorption and Addition of New HCO_3^- to Plasma	HCO_3^- Excretion	pH of Urine	Compensatory Change in Plasma pH
Acidosis	↑	↑	↑	Normal (zero; all filtered is reabsorbed)	Acidic	Alkalinization toward normal
Alkalosis	↓	↓	↓	↑	Alkaline	Acidification toward normal

more H^+ is secreted. Without additional buffering capacity from another source, H^+ secretion would soon halt abruptly because the free $[\text{H}^+]$ in the tubular fluid can quickly rise to the critical limiting level (pH 4.5).

SECRETED NH_3 AS A URINARY BUFFER

When acidosis exists, the tubular cells secrete **ammonia** (NH_3) into the tubular fluid once the normal urinary phosphate buffers are saturated. This NH_3 enables the kidneys to continue secreting additional H^+ ions because NH_3 combines with free H^+ in the tubular fluid to form **ammonium ion** (NH_4^+), as follows:

The tubular membranes are not very permeable to NH_4^+ , so NH_4^+ remains in the tubular fluid and is subsequently lost in urine. Each molecule of NH_4^+ eliminated takes an H^+ with it. NH_3 secreted during acidosis allows for the necessary increased buffering capacity in the tubular fluid, so large amounts of H^+ can be secreted. Were it not for NH_3 secretion, the extent of H^+ secretion would be limited to whatever phosphate-buffering capacity coincidentally happened to be present as a result of dietary excess.

In contrast to the urinary phosphate buffer system, which is in the tubular fluid because the phosphate have been filtered but not reabsorbed, NH_4^+ is deliberately synthesized from the amino acid *glutamine* within the proximal tubular cells (▶ Figure 14-13a). Once synthesized, NH_4^+ is absorbed into the tubular lumen. In the thick ascending limb of the loop of Henle, NH_4^+ can take the place of K^+ and be reabsorbed into the renal interstitium via the $\text{Na}^+ - \text{K}^+ - 2 \text{Cl}^-$ transporter. The relative pH of the renal interstitium is high. NH_4^+ therefore liberates

a H^+ to the interstitium and becomes NH_3 . Unlike NH_4^+ , NH_3 readily diffuses passively into cells down its concentration gradient. This allows NH_3 to diffuse into the collecting duct of the nephron. Here it combines with a free H^+ and is excreted as NH_4^+ (▶ Figure 14-13b). The rate of NH_3 secretion by the tubular cells varies directly based on the excess H^+ needing to be secreted. When someone has been in a state of acidosis for more than two or three days, the rate of NH_3 production increases substantially. This extra NH_3 provides additional buffering capacity and contributes to renal compensation for acidosis.

▶ **FIGURE 14-13a** Ammonium production from glutamine metabolism in the proximal tubule cell. NH_4^+ from glutamine metabolism is secreted into the tubule lumen and travels to the loop of Henle. The bicarbonate molecules produced in the process are reabsorbed into the peritubular capillaries and constitute new bicarbonate ions.

▶ **FIGURE 14-13b** Ammonium and ammonia movement through the loop of Henle and distal nephron. Ammonium takes the place of K^+ on the $\text{Na}^+ - \text{K}^+ - 2 \text{Cl}^-$ transporter and enters the renal interstitium. The relatively high pH of the renal interstitium causes NH_4^+ to liberate a H^+ . The resultant NH_3 diffuses through the collecting duct cell and into the tubular lumen, where it combines with a metabolically produced free H^+ . The NH_4^+ becomes trapped in the lumen and is excreted in the urine.

The kidneys: A powerful third line of defence

The kidneys require hours to days to compensate for changes in body-fluid pH, compared with the immediate responses of the buffer systems and the few minutes of delay before the respiratory system responds. Therefore, they are the *third line of defence* against $[H^+]$ changes in body fluids. However, the kidneys are considered the most potent acid–base regulatory organs. Not only can they vary the degree to which removal of H^+ occurs from any source, they can also variably conserve or eliminate HCO_3^- , depending on the acid–base status of the body. For example, during renal compensation for acidosis, each H^+ excreted in urine results in a new HCO_3^- added to the plasma to buffer (by means of the $H_2CO_3 : HCO_3^-$ system) another H^+ that remains in body fluids. By simultaneously removing acid (H^+) from and adding base (HCO_3^-) to body fluids, the kidneys can restore the pH toward normal more effectively than the lungs, which adjust only the amount of H^+ -generating CO_2 in the body.

Also contributing to the kidneys' acid–base regulatory potency is their ability to return pH almost exactly to normal. Compared to the respiratory system that can only partially compensate for a pH abnormality, the kidneys continue to change pH until compensation is essentially complete.

Acid–base imbalances

Deviations from normal acid–base status can be divided into four general categories based on the source and direction of the abnormal change in $[H^+]$. These categories are *respiratory acidosis*, *respiratory alkalosis*, *metabolic acidosis*, and *metabolic alkalosis*.

As you have learned, changes in plasma $[H^+]$ are reflected by changes in the ratio of $[HCO_3^-]$ to $[CO_2]$. Recall that the normal ratio is 20/1. Using the Henderson–Hasselbalch equation with this ratio and the pK value of 6.1, we arrive at a normal plasma pH of 7.4. Compared to taking direct measurements of $[H^+]$ alone, we can find more important clues about the underlying factors responsible for acid–base disturbances by focusing on the changes in specific values for $[HCO_3^-]$ and $[CO_2]$. The following rules of thumb apply when examining acid–base imbalances *before any compensations take place*:

1. A change in pH that has an underlying respiratory cause is associated with a change in $[CO_2]$. For example, a respiratory acidosis is caused by an increase in $[CO_2]$, and a respiratory alkalosis is caused by a decrease in $[CO_2]$. Both of these scenarios result in a change in free H^+ that is derived from H_2CO_3 . In contrast, a pH deviation of metabolic origin is associated with an abnormal $[HCO_3^-]$. A metabolic acidosis results in a low plasma $[HCO_3^-]$, and a metabolic alkalosis results in a high $[HCO_3^-]$. These changes are caused by an inequality between the amount of HCO_3^- available and the amount of H^+ generated from noncarbonic acid sources that the HCO_3^- must buffer.

2. Observing how the overall ratio changes $[HCO_3^-]/[CO_2]$ helps us determine whether an acidotic or alkalotic state exists. When the ratio falls below 20/1, an acidosis exists. Mathematically, this makes sense. The log of any number lower than 20 is less than 1.3 and, when added to the pK of 6.1, yields an acidotic pH < 7.4 . Likewise, when the ratio exceeds 20/1, an alkalosis exists. The log of any number greater than 20 is more than 1.3 and, when added to the pK of 6.1, yields an alkalotic pH > 7.4 .
3. We now have enough information to determine which of the four categories an acid–base disturbance falls into:
 - *Respiratory acidosis* has a ratio of less than 20/1 due to an elevation in $[CO_2]$.
 - *Respiratory alkalosis* has a ratio greater than 20/1 due to a decrease in $[CO_2]$.
 - *Metabolic acidosis* has a ratio of less than 20/1 due to a decrease in $[HCO_3^-]$.
 - *Metabolic alkalosis* has a ratio greater than 20/1 due to an elevation in $[HCO_3^-]$.

Next we examine each of these categories in more detail, paying particular attention to possible causes and compensations, and using the examples in ▶ Figure 14-14 (a–i). In this figure the “balance beam” concept and the Henderson–Hasselbalch equation will help you better visualize the contributions of the lungs and kidneys to the causes of and compensations for various acid–base disorders. The normal situation is represented in ▶ Figure 14-14a.

Respiratory acidosis and an increase in $[CO_2]$

Respiratory acidosis occurs when CO_2 builds up in the blood as a result of hypoventilation (p. 540). This leads to an increased production of H_2CO_3 and therefore increased free H^+ in the plasma, causing the pH to become more acidic (pH < 7.4).

CAUSES OF RESPIRATORY ACIDOSIS

Respiratory acidosis is commonly caused by pulmonary conditions (p. 516–517), including emphysema, chronic bronchitis, asthma, and severe pneumonia. It may also be triggered by metabolic alkalosis.

In uncompensated respiratory acidosis, $[CO_2]$ is elevated, whereas $[HCO_3^-]$ is normal. In our example in ▶ Figure 14-14b, the $[CO_2]$ is doubled, so the ratio becomes 20/2 (or 10/1). It may appear that $[H^+]$ and $[HCO_3^-]$ should increase proportionally because an elevated $[CO_2]$ drives the reaction $CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$ to the right. This is not the case, however, because the $[HCO_3^-]$ is normally 600 000 times that of $[H^+]$. Take for example, a situation where there is 1 H^+ and 600 000 HCO_3^- present in the ECF. The generation of 1 additional H^+ will double its concentration, but one extra HCO_3^- only increases the HCO_3^- by 0.00017 percent (from 600 000 to 600 001 ions). Therefore, an elevation in

Figure 14-14 Schematic representation of the relationship of $[\text{HCO}_3^-]$ and $[\text{CO}_2]$ to pH in various acid–base statuses. (a) Normal acid–base balance. The $[\text{HCO}_3^-] / [\text{CO}_2]$ ratio is 20/1. (b) Uncompensated respiratory acidosis. The $[\text{HCO}_3^-] / [\text{CO}_2]$ ratio is reduced (20/2), because CO_2 has accumulated. (c) Compensated respiratory acidosis. Compensatory retention of $[\text{HCO}_3^-]$ to balance the CO_2 accumulation restores the $[\text{HCO}_3^-] / [\text{CO}_2]$ ratio to a normal equivalent (40/2). (d) Uncompensated respiratory alkalosis. The $[\text{HCO}_3^-] / [\text{CO}_2]$ ratio is increased (20/0.5) by a reduction in CO_2 . (e) Compensated respiratory alkalosis. Compensatory elimination of $[\text{HCO}_3^-]$ to balance the CO_2 deficit restores the $[\text{HCO}_3^-] / [\text{CO}_2]$ ratio to a normal equivalent (10/0.5). (f) Uncompensated metabolic acidosis. The $[\text{HCO}_3^-] / [\text{CO}_2]$ ratio is reduced (10/1) by a $[\text{HCO}_3^-]$ deficit. (g) Compensated metabolic acidosis. Conservation of $[\text{HCO}_3^-]$, which partially makes up for the $[\text{HCO}_3^-]$ deficit, and a compensatory reduction in CO_2 restore the $[\text{HCO}_3^-] / [\text{CO}_2]$ to a normal equivalent (15/0.75). (h) Uncompensated metabolic alkalosis. The $[\text{HCO}_3^-] / [\text{CO}_2]$ ratio is increased (40/1) by excess $[\text{HCO}_3^-]$. (i) Compensated metabolic alkalosis. Elimination of some of the extra $[\text{HCO}_3^-]$ and a compensatory increase in CO_2 restore the ratio $[\text{HCO}_3^-] / [\text{CO}_2]$ to a normal equivalent (25/1.25).

[CO₂] brings about a pronounced increase in [H⁺], but [HCO₃⁻] remains essentially normal.

COMPENSATIONS FOR RESPIRATORY ACIDOSIS

Compensatory measures act to restore pH to normal.

- The chemical buffers immediately take up additional H⁺.
- The respiratory mechanism usually cannot respond with compensatory increased ventilation, because impaired respiration is the reason for the abnormality in the first place.
- The kidneys are therefore most important in compensating for respiratory acidosis. They reabsorb all the filtered HCO₃⁻ and add new HCO₃⁻ to the plasma, and simultaneously they secrete and excrete more H⁺.

As a result, HCO₃⁻ stores in the body rise. In ▶ Figure 14-14c, the plasma [HCO₃⁻] is doubled, so the [HCO₃⁻]/[CO₂] ratio becomes 40/2 rather than 20/2. A ratio of 40/2 is equivalent to a normal 20/1 ratio, so pH returns to the normal 7.4. Enhanced renal conservation of HCO₃⁻ and new HCO₃⁻ formation has fully compensated for CO₂ accumulation, although both [CO₂] and [HCO₃⁻] are now distorted. Note that maintenance of normal pH depends on preserving a normal ratio between [HCO₃⁻] and [CO₂], no matter what the absolute values of each of these buffer components are. Although the occurrence of complete compensation to the point that pH returns exactly to the normal state of 7.4 is extremely rare, in each example in ▶ Figure 14-14 we assume full compensation for ease of mathematical calculations. Also note that the values used in these examples represent hypothetical situations. Deviations in pH actually occur over a wide range, and the degree to which compensation can be accomplished varies considerably (e.g., HCO₃⁻ may rise or fall only by one or two points).

Respiratory alkalosis and a decrease in [CO₂]

Respiratory alkalosis results from hyperventilation, and is a condition in which the amount of CO₂ normally found in the blood decreases. This leads to an overall decrease in H⁺ and hence an elevated plasma pH. Common causes of hyperventilation include fever, anxiety, and serious infections. Other stresses to the body, including pregnancy or high altitude, can cause respiratory alkalosis. It may also be triggered by metabolic acidosis.

Looking at the biochemical abnormalities in uncompensated respiratory alkalosis, as shown in Figure 14-14d, we find the increase in pH reflects a reduction in [CO₂] (half the normal value in this example), whereas [HCO₃⁻] remains normal. This yields a ratio of 20/0.5 (or 40/1), which will cause an overall increase in plasma pH.

COMPENSATIONS FOR RESPIRATORY ALKALOSIS

Compensatory measures act to shift pH back toward normal.

- The chemical buffer systems begin to liberate H⁺ to diminish the severity of the alkalosis.
- As plasma [CO₂] and [H⁺] fall below normal because of excessive ventilation, two of the normally potent stimuli for

driving ventilation are removed. This effect tends to limit the extent to which a nonrespiratory factor, such as fever or anxiety, can cause hyperventilation.

- If the situation continues for a few days, the kidneys compensate by conserving H⁺ and excreting more HCO₃⁻.

In Figure 14-14e, HCO₃⁻ stores are reduced to half (by loss in the urine) to compensate for the loss in [CO₂]. The [HCO₃⁻]/[CO₂] ratio becomes 10/0.5 (equivalent to the normal 20/1), and pH is restored to normal.

Metabolic acidosis and a fall in [HCO₃⁻]

Metabolic acidosis (also known as **nonrespiratory acidosis**) encompasses all types of acidosis besides that caused by excess CO₂ in body fluids. In the uncompensated state, metabolic acidosis is characterized by a reduction in plasma [HCO₃⁻], whereas [CO₂] remains normal. In ▶ Figure 14-14f, [HCO₃⁻] is halved and [CO₂] remains normal, producing a [HCO₃⁻]/[CO₂] ratio of 10/1. A metabolic acidosis may arise from an excessive loss of body fluids rich in HCO₃⁻ or from an accumulation of noncarbonic acids. In the latter case, plasma HCO₃⁻ is used up in buffering the additional H⁺.

SERUM ANION GAP

A relatively simple measurement can be used to determine the cause of metabolic acidosis: the **anion gap**. The serum is uncharged or electro-neutral, meaning that the number of anions and number of cations are equal. The anion gap is a mathematical way of determining the difference in laboratory-measured anions (negatively charged ions) and laboratory-measured cations (positively charged ions) in serum. Therefore, to determine the anion gap, look at the ions that are *measured* in the serum, and this gives you an idea of the amount of *unmeasured* anions.

The equation for calculating the anion gap is as follows:

$$\text{anion gap} = ([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-])$$

This is generally shortened to

$$\text{anion gap} = [\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$$

As serum potassium is generally very low, it does not greatly affect the calculation.

The normal value of serum anion gap is considered 12 mEq/L, but typically its range is 8–16 mEq/L. This number represents the main unmeasured anions that are normally present in the plasma: phosphate, citrate, sulphate, and protein (▶ Figure 14-15). When the anion gap increases, this generally indicates there is an excess of one or more of these unmeasured anions. It can also mean that other anions, such as lactate or keto acids, have been added to the plasma. Some diseases, extreme exercise, alcohol abuse, or even septic shock can cause unmeasured anions to increase. These anions are generally acidic and, as such, cause a decrease in serum bicarbonate by the action of chemical buffering.

In cases of a normal anion-gap metabolic acidosis, the disturbance is often due to a loss of bicarbonate (e.g., diarrhoea and some renal diseases). To maintain an electrically neutral serum, the loss in bicarbonate is generally countered by an increase in serum chloride.

► FIGURE 14-15 Serum anion gap

CAUSES OF METABOLIC ACIDOSIS

Severe diarrhoea. During digestion, a digestive juice rich in HCO_3^- is normally secreted into the digestive tract and is later reabsorbed back into the plasma when digestion is completed. During diarrhoea, this HCO_3^- is lost from the body before it can be reabsorbed. Consequently, less HCO_3^- is available to buffer H^+ , which leads to more free H^+ in the body fluids. Also, the loss of HCO_3^- shifts the $\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}^+ + \text{HCO}_3^-$ reaction to the right to compensate for the HCO_3^- deficit. This increases $[\text{H}^+]$ above normal.

1. **Diabetes mellitus.** The absence of insulin results in an inability for cells to use glucose for metabolic processes. As a result, abnormal fat metabolism leads to the formation of excess keto acids whose dissociation increases plasma $[\text{H}^+]$. These excess keto acids cause a high anion gap.
2. **Strenuous exercise.** When muscles resort to anaerobic glycolysis during strenuous exercise, excess lactic acid is produced, raising plasma $[\text{H}^+]$ (p. 317). The excess lactic acid causes a high anion gap.
3. **Uraemic acidosis.** In severe kidney failure (uraemia), the kidneys cannot rid the body of normal amounts of metabolically generated H^+ from noncarbonic acid sources. H^+ therefore begins to accumulate in the body fluids. Furthermore, the dysfunction results in an inability to conserve adequate amounts of HCO_3^- .

COMPENSATIONS FOR METABOLIC ACIDOSIS

Except in uraemic acidosis, metabolic acidosis is compensated for by both respiratory and renal mechanisms as well as by chemical buffers.

- The buffers take up extra H^+ .
- The lungs blow off additional H^+ -generating CO_2 .
- The kidneys excrete more H^+ and conserve more HCO_3^- .

In ► Figure 14-14f, g), these compensatory measures restore the ratio to normal by reducing $[\text{CO}_2]$ and by raising $[\text{HCO}_3^-]$. In this example, the ratio is brought to 15/0.75, which is equivalent to 20/1.

Note that in compensating for metabolic acidosis, the lungs deliberately change $[\text{CO}_2]$ to levels that deviate from normal in an attempt to restore a normal $[\text{H}^+]$. In respiratory-induced acid–base disorders, on the other hand, the abnormal $[\text{CO}_2]$ is the *cause* of the $[\text{H}^+]$ imbalance.

When kidney disease causes metabolic acidosis, complete compensation is not possible because the renal mechanism is not available for pH regulation. Recall that the respiratory system can compensate only up to 75 percent of the way toward normal. Uraemic acidosis is very serious because the kidneys cannot help restore pH all the way to normal.

Clinical Connections

Without insulin production, Diane's energy metabolism shifts to a catabolic state.

This leads to the breakdown of lipids and proteins and induces an overall energy deficient state, increasing hunger and food intake (*polyphagia*). Although caloric intake increases, it is usually insufficient to counterbalance the overall catabolic state, and weight loss ensues.

The fatty acids from lipid catabolism are converted in the liver to the ketones β -hydroxybutyric acid and acetoacetic acid. These two metabolically produced compounds are acidic, which leads to a decrease in the plasma pH and a state of metabolic acidosis. Furthermore, these compounds are anionic and increase the number of unmeasured anions in the plasma, thereby elevating the plasma anion gap. These two features help define the specific acid–base disturbance seen in DKA: an elevated plasma anion-gap metabolic acidosis.

In DKA, the increase in buffering activity related to the high $[\text{H}^+]$ in the plasma results in a decrease in plasma bicarbonate. Furthermore, the respiratory system attempts to compensate for the high $[\text{H}^+]$ by increasing the rate and depth of breathing to remove CO_2 . This is reflected in a decreased pCO_2 level. Although these compensatory mechanisms attempt to correct the acid–base disturbance, the condition will worsen without emergent medical intervention.

Definitive treatment of DKA requires fluid replacement, correction of electrolyte disturbances, administration of insulin, and correction of the acidotic state in the body. Prior to exogenous insulin injections, new-onset Type I DM was a universally fatal condition.

Now, with injectable exogenous insulin available, the prompt identification of new-onset Type I DM and effective treatment of DKA can help make Type I DM a chronic illness that can be effectively managed with insulin and careful blood glucose monitoring.

Metabolic alkalosis and an elevation in $[\text{HCO}_3^-]$

Metabolic alkalosis is a reduction in plasma $[\text{H}^+]$ caused by a relative deficiency of noncarbonic acids. This acid–base disturbance is associated with an increase in $[\text{HCO}_3^-]$, which, in the uncompensated state, is not accompanied by a change in $[\text{CO}_2]$. In Figure 14-14h, $[\text{HCO}_3^-]$ is doubled, producing an alkalotic ratio of 40/1.

CAUSES OF METABOLIC ALKALOSIS

1. *Vomiting* causes abnormal loss of $[H^+]$ from the body as a result of lost acidic gastric juices. Hydrochloric acid is secreted into the stomach lumen in preparation for and during digestion. Bicarbonate is added to the plasma during gastric HCl secretion. This HCO_3^- is neutralized by H^+ as the gastric secretions are eventually reabsorbed back into the plasma, so normally there is no net addition of HCO_3^- to the plasma from this source. However, when this acid is lost from the body during vomiting, not only is plasma $[H^+]$ decreased, but reabsorbed H^+ is no longer available to neutralize the HCO_3^- entering the plasma during gastric HCl secretion. Thus, loss of HCl in effect increases plasma $[HCO_3^-]$. Less frequently, vomiting can have deeper effects; that is, it can cause the loss of HCO_3^- from the digestive juices in the upper intestine. In these instances, vomiting can result in a metabolic acidosis instead of metabolic alkalosis.
2. *Ingestion of alkaline drugs* can produce alkalosis, such as when baking soda ($NaHCO_3$, which dissociates in solution into Na^+ and HCO_3^-) is used as a self-administered remedy for treating gastric hyperacidity. Although HCO_3^- neutralizes excess acid in the stomach and helps relieve the symptoms heartburn, there is a risk that more HCO_3^- than needed may be ingested. The extra HCO_3^- absorbed from the digestive tract increases the plasma $[HCO_3^-]$. Ultimately, the increased HCO_3^- binds with more of the free H^+ than usual, and so the amount of free $[H^+]$ decreases. Commercially available alkaline products for treating gastric hyperacidity are generally not absorbed from the digestive tract to any extent and therefore do not alter the body's acid-base status.

COMPENSATIONS FOR METABOLIC ALKALOSIS

- In metabolic alkalosis, chemical buffer systems immediately liberate H^+ .
- Ventilation is reduced so that extra H^+ -generating CO_2 is retained in the body fluids.
- If the condition persists for several days, the kidneys conserve H^+ and excrete the excess HCO_3^- in the urine.

In Figure 14-14i, there is a compensatory increase in $[CO_2]$ and a partial reduction in $[HCO_3^-]$. Together they help restore the $[HCO_3^-]/[CO_2]$ ratio back to the equivalent of 20/1.

OVERVIEW OF COMPENSATED ACID-BASE DISORDERS

An individual's acid-base status cannot be assessed on the basis of pH alone. Uncompensated acid-base abnormalities can readily be distinguished on the basis of deviations of either $[CO_2]$ or $[HCO_3^-]$ from normal (Table 14-9). However, when compensation has been accomplished and pH is essentially normal, determinations of $[HCO_3^-]$ and $[HCO_3^-]$ can reveal an acid-base disorder, but the type of disorder is more difficult to distinguish. The procedures for making these distinctions are beyond the scope of this textbook. For example, in both compensated respiratory acidosis and compensated metabolic alkalosis, $[CO_2]$ and $[HCO_3^-]$ are both above normal. Similarly, compensated respiratory alkalosis and compensated metabolic acidosis share similar patterns of $[CO_2]$ and $[HCO_3^-]$. A full medical history and examination are often extremely helpful in determining the particular type of acid-base disorder that exists. In addition, many clinicians use a specific device called a nomogram to determine which type of acid-base disorder their patients have (Figure 14-16). With this device, the arterial blood levels for pH, pCO_2 , and HCO_3^- are mapped on a graph. The type of acid-base disorder is determined by the point at which the test results show up on the graph—that is, within which of the highlighted sections as shown in Figure 14-16.

TABLE 14-9 Summary of $[CO_2]$, $[HCO_3^-]$ and pH in Uncompensated and Compensated Acid-Base Abnormalities

Acid-Base Status	pH	$[CO_2]$ (Compared with Normal)	$[HCO_3^-]$ (Compared with Normal)	$HCO_3^-/[CO_2]$
Normal	Normal	Normal	Normal	20/1
Uncompensated Respiratory Acidosis	Decreased	Increased	Normal	20/2 (10/1)
Compensated Respiratory Acidosis	Normal	Increased	Increased	40/2 (20/1)
Uncompensated Respiratory Alkalosis	Increased	Decreased	Normal	20/0.5 (40/1)
Compensated Respiratory Alkalosis	Normal	Decreased	Decreased	10/0.5 (20/1)
Uncompensated Metabolic Acidosis	Decreased	Normal	Decreased	10/1
Compensated Metabolic Acidosis	Normal	Decreased	Decreased	15/0.75 (20/1)
Uncompensated Metabolic Alkalosis	Increased	Normal	Increased	40/1

FIGURE 14-16 A nomogram for acid-base disorders. This nomogram is used to determine the type of acid-base disorder based on the patient's arterial pH, pCO_2 , and HCO_3^- .

Check Your Understanding 14.3

1. Explain why only a narrow pH range is compatible with life.
2. If a person has severe diarrhoea, what type of acid-base abnormality will likely result? Describe the compensatory responses of the three lines of defence against this change in $[H^+]$.

Chapter in Perspective: Focus on Homeostasis

Homeostasis depends on maintaining a balance between the input and output of all constituents present in the internal fluid environment. Regulation of fluid balance involves two separate components: control of salt balance and control of water balance. Control of salt balance is primarily important in the long-term regulation of arterial blood pressure, because the

body's salt load affects the osmotic determination of the ECF volume, of which plasma volume is a part. An increased salt load in the ECF leads to an expansion in ECF volume, including plasma volume, which in turn causes a rise in blood pressure. Conversely, a reduction in the ECF salt load brings about a fall in blood pressure. Salt balance is maintained by constantly adjusting salt output in the urine to match unregulated, variable salt intake.

Control of water balance is important in preventing changes in ECF osmolarity, which induces detrimental osmotic shifts of H_2O between the cells and ECF. Such shifts of H_2O into or out of the cells cause the cells to swell or shrink, respectively. Cells, especially brain neurons, do not function normally when swollen or shrunken. Water balance is largely maintained by controlling the volume of free H_2O (H_2O not accompanied by solute) lost in the urine to compensate for uncontrolled losses of variable volumes of H_2O from other avenues, such as through sweating or diarrhoea, and for poorly regulated H_2O intake. Even though a thirst mechanism exists to control H_2O intake based on need, the amount a person drinks is often influenced by social custom and habit instead of thirst alone.

A balance between input and output of H^+ is critical to maintaining the body's acid-base balance within the narrow limits compatible with life. Deviations in pH of the internal fluid environment lead to altered neuromuscular excitability, changes in enzymatically controlled metabolic activity, and $[K^+]$ imbalances. Imbalances in $[K^+]$ can cause cardiac arrhythmias. These effects are fatal if the pH falls outside the range of 6.8–8.0.

Hydrogen ions are uncontrollably and continually added to the body fluids as a result of ongoing metabolic activities, yet the ECF's pH must be kept constant at a slightly alkaline level of 7.4 for optimal body function. Like salt and water balance, control of H^+ output by the kidneys is the main regulatory factor in achieving H^+ balance. The lungs, which can adjust their rate of excretion of H^+ -generating CO_2 , also help eliminate H^+ from the body. Furthermore, chemical buffer systems can take up or liberate H^+ , transiently keeping its concentration constant within the body until its output can be brought into line with its input. Such a mechanism is not available for salt or water balance.

REVIEW EXERCISES

Objective Questions (Answers in Appendix E, p. A-50)

- The only avenue by which materials can be exchanged between the cells and the external environment is the ECF. (*True or false?*)
- Water is driven into the cells when the ECF volume is expanded by an isotonic fluid gain. (*True or false?*)
- Salt balance in humans is poorly regulated because of our hedonistic salt appetite. (*True or false?*)
- An unintentional increase in CO_2 is a cause of respiratory acidosis, but a deliberate increase in CO_2 compensates for metabolic alkalosis. (*True or false?*)
- The largest body-fluid compartment is the _____
- Of the two members of the $H_2CO_3 : HCO_3^-$ buffer system, _____ is regulated by the lungs and _____ is regulated by the kidneys.
- Which individuals would have the lowest percentage of body H_2O ?
 - a chubby baby
 - a well-proportioned female university student
 - a well-muscled male university student
 - an obese elderly woman
 - a lean elderly man
- Which of the following factors does NOT increase vasopressin secretion?
 - ECF hypertonicity
 - alcohol
 - stressful situations
 - ECF volume deficit
 - angiotensin II
- Which of the following statements about pH are correct? (*Indicate all correct answers.*)
 - It equals $\log 1/[H^+]$.
 - It equals $pK + \log[CO_2]/[HCO_3^-]$.
 - It is high in acidosis.
 - It falls as $[H^+]$ increases.
 - It is normal when the $[HCO_3^-]/[CO_2]$ ratio is 20/1.
- Which of the following statements about acidosis are correct? (*Indicate all correct answers.*)
 - It causes overexcitability of the nervous system.
 - It exists when the plasma pH falls below 7.35.
 - It occurs when the $[HCO_3^-]/[CO_2]$ ratio exceeds 20/1.
 - It occurs when CO_2 is blown off more rapidly than it is being produced by metabolic activities.
 - It occurs when excessive bicarbonate is lost from the body, as in diarrhoea.
- Why do the kidney tubular cells secrete NH_3 ? (*Indicate all correct answers.*)
 - because the urinary pH becomes too high
 - because the body is in a state of alkalosis
 - to enable further renal secretion of H^+
 - to buffer excess filtered HCO_3^-
 - because there is excess NH_3 in the body fluids
- Complete the following chart:

$\frac{[HCO_3^-]}{[CO_2]}$	Uncompensated Abnormality	Possible Cause	pH
10/1	1. _____	2. _____	3. _____
20/0.5	4. _____	5. _____	6. _____
20/2	7. _____	8. _____	9. _____
40/1	10. _____	11. _____	12. _____

Written Questions

1. Explain the balance concept.
2. Outline the distribution of body H_2O .
3. Define *transcellular fluid*, and identify its components. Does the transcellular compartment as a whole reflect changes in the body's fluid balance?
4. Compare the ionic composition of plasma, interstitial fluid, and intracellular fluid.
5. What factors are regulated to maintain the body's fluid balance?
6. Why is regulation of ECF volume important? How is it regulated?
7. Why is regulation of ECF osmolarity important? How is it regulated? What are the causes and consequences of ECF hypertonicity and ECF hypotonicity?
8. Outline the sources of input and output in a daily salt balance and a daily H_2O balance. Which are subject to control to maintain the body's fluid balance?
9. Distinguish between an acid and a base.
10. What is the relationship between $[H^+]$ and pH?
11. What is the normal pH of body fluids? How does this compare with the pH of H_2O ?
12. Define *acidosis* and *alkalosis*.
13. What are the consequences of fluctuations in $[H^+]$?

14. What are the body's sources of H^+ ?
15. Describe the three lines of defence against changes in $[H^+]$ in terms of their mechanisms and speed of action.
16. List and indicate the functions of each of the body's chemical buffer systems.
17. What are the causes of the four categories of acid–base imbalances?
18. Why is uraemic acidosis so serious?

Quantitative Exercises (Solutions in Appendix E, p. A-50)

1. Given that plasma pH is 7.4, arterial $P_{CO_2} = 40$ mmHg, and each mmHg partial pressure of CO_2 is equivalent to a plasma $[CO_2]$ of 0.03 mM, what is the value of plasma $[HCO_3^-]$?
2. Death occurs if the plasma pH falls outside the range of 6.8–8.0 for an extended time. What is the concentration range of H^+ represented by this pH range?
3. A person drinks 1 L of distilled water. Use the data in Table 14-1 to calculate the resulting percentage increase in total body water (TBW), ICF, ECF, plasma, and interstitial fluid. Repeat the calculations for ingestion of 1 L of isotonic NaCl. Which solution would be better at expanding plasma volume in a patient who has just haemorrhaged?

POINTS TO PONDER

(Explanations in Appendix E, p. A-51)

1. Alcoholic beverages inhibit vasopressin secretion. Given this fact, predict the effect of alcohol on the rate of urine formation. Predict the actions of alcohol on ECF osmolarity. Explain why a person still feels thirsty after excessive consumption of alcoholic beverages.
2. If a person loses 1500 mL of salt-rich sweat and drinks 1000 mL of water during the same time period, what will happen to vasopressin secretion? Why is it important to replace both the water and the salt?
3. If a solute that can penetrate the plasma membrane, such as dextrose (a type of sugar), is dissolved in sterile water at a concentration equal to that of normal body fluids and then is injected intravenously, what is the impact on the body's fluid balance?
4. Explain why it is safer to treat gastric hyperacidity with antacids that are poorly absorbed from the digestive tract than with baking soda, which is a good buffer for acid but is readily absorbed.
5. Which would buffer the acidosis accompanying severe pneumonia?
 - a. $H^+ + HCO_3^- \rightarrow H_2CO_3 \rightarrow CO_2 + H_2O$
 - b. $CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$
 - c. $H^+ + Hb \rightarrow HHb$
 - d. $HHb \rightarrow H^+ + Hb$
 - e. $NaH_2PO_4 + Na^+ \rightarrow Na_2HPO_4 + H^+$

14

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-51)

Marilyn Y. has had pronounced diarrhoea for more than a week as a result of having acquired *salmonellosis*, a bacterial intestinal infection, from improperly handled food. What impact has this

prolonged diarrhoea had on her fluid and acid–base balance? In what ways has Marilyn's body been trying to compensate for these imbalances?

Altitude Adaptation

When a person travels to or lives at altitude, the cardiorespiratory system adapts. These changes can occur quickly (seconds) or take many months; some changes eventually become part of the genetic makeup of individuals whose ancestors have lived at altitude for generations.

Altitude generally refers to an elevation of ≥ 1500 m (4921 ft). As altitude increases, barometric pressure falls. As a result, so does the prevailing partial pressure of oxygen (P_{O_2}). At altitudes greater than 2500 m, this results in alveolar hypoxia and, assuming gas exchange across the alveolar–capillary membrane is normal, arterial hypoxaemia. Because a major function of the cardiorespiratory system is to deliver oxygen to tissues to maintain cellular metabolism, the fall of arterial P_{O_2} reduces O_2 delivery to tissues, thereby compromising cellular function. To prevent this, the body compensates for (adapts to) altitude-induced hypoxia.

How much oxygen is delivered to the tissues depends on two factors: the concentration (or content) of oxygen in the blood and perfusion (for the whole body, this is the cardiac output). Cardiorespiratory adjustments, therefore, represent the body's efforts to increase these two factors. The study of responses to altitude is clinically relevant because these responses are similar in patients whose disease state is hypoxaemic.

In terms of the arterial O_2 content, adaptation starts immediately upon ascent to altitude and is especially noticeable if the ascent is rapid, as when one travels by air. The carotid chemoreceptors are immediately activated upon exposure to a hypoxic environment: for example, at 3000 m, where barometric P_{O_2} is 525 mmHg, and ambient, inspired, and alveolar P_{O_2} are approximately 110, 100, and 50 mmHg, respectively, in a healthy person. Due to the arterial hypoxaemia, the person hyperventilates. (By definition, a drop in the alveolar P_{O_2} and arterial P_{O_2} at the same metabolic CO_2 production indicates hyperventilation.) The fall in alveolar P_{O_2} , according to the alveolar gas equation (p. 525), increases alveolar P_{O_2} . Even if the increase is only a few mmHg, this can substantially increase the O_2 saturation and, therefore, arterial O_2 content when the body is functioning on the steep part of the O_2 dissociation curve (p. 532). The hypoxia-induced increase in ventilation, however, is blunted by the accompanying hypocapnia and the resulting respiratory alkalosis (pp. 540).

Over the next few days of acclimatization, ventilation gradually increases, for reasons that are still incompletely understood. The classical explanation is that the kidneys compensate for the alkalosis by not reabsorbing bicarbonate (HCO_3^-). The loss of HCO_3^- occurs in all body compartments, including the cerebral spinal fluid (CSF) to which the central chemoreceptors are exposed. Thus, as the pH of the CSF gradually returns toward normal (i.e., re-acidifies), ventilation increases and, accompanying it, the arterial P_{O_2} and arterial O_2 content. An alternate explanation for this acclimatization is an increase in peripheral

chemoreceptor sensitivity to hypoxia. This is based on findings (primarily in research on goats) that the acclimatization occurs even when only the carotid bodies, not the rest of the body (including the brain), are exposed to hypoxic blood. In humans, acclimatization still occurs even if hypocapnia and respiratory alkalosis are prevented through the addition of carbon dioxide to the inspired gas.

The arterial O_2 content also increases rapidly at altitude because of a decrease in plasma volume, which is increased urine production and/or a shift of fluid to the interstitial and intracellular compartments. If a greater proportion of the blood is occupied by red blood cells (i.e., an increase in haematocrit), then for a given blood flow, more oxygen is delivered to the tissues.

The arterial hypoxaemia associated with altitude also stimulates, via activation of hypoxia-inducible factor, the release of erythropoietin, the protein that controls the production of red blood cells. Although earlier work indicated that the primary site of erythropoietin production was the kidneys and liver, more recent work indicates that many tissues, including the heart and diaphragm, contain the mRNA for erythropoietin. Although the red blood cells that are released may be immature, the haematocrit increases, thereby increasing the O_2 -carrying capacity of the blood. This response takes about three to four weeks to become fully effective.

Increases in arterial O_2 content are, however, ineffective in maintaining O_2 delivery if perfusion to tissues is inadequate. At altitude, aortic chemoreceptors are stimulated by the decreased arterial O_2 content (not by the decreased arterial P_{O_2}) and reflexively stimulate the heart (increased heart rate), thereby increasing its output.

Many vascular beds of the systemic vasculature, especially those in the brain and heart, are sensitive to the prevailing blood gases. Hypoxaemia causes arterioles to dilate, increasing perfusion. This effect, however, is blunted by the hypocapnia resulting from altitude-induced hyperventilation; as a result, vascular resistance depends on the net effect of the opposing vasodilator and vasoconstrictor stimuli. In addition to arterial P_{O_2} and P_{O_2} , other circulating factors (pH, adrenaline, angiotensin II, and adenosine) determine the vascular resistance. Many factors derived from the endothelium affect vascular smooth muscle, including nitric oxide and prostaglandins (vasodilators) and endothelin-1 and superoxides (vasoconstrictors). To these must be added the mechanical effects of changes in blood pressure and viscosity. Research to determine how all these factors interact—and change over time as the cardiorespiratory system responds—to control vascular resistance at altitude is in the early stages.

The vasculature in the lung responds differently to changes in arterial P_{O_2} . As described elsewhere (p. 539), hypoxia causes constriction, not dilation, of the pulmonary vasculature. Ordinarily, this is useful because *regional* constriction would force pulmonary blood flow to other, presumably better-ventilated

regions with higher regional alveolar P_{O_2} s. At altitude, however, the entire lung will be hypoxic (even though regional variations in ventilation/perfusion ratio will persist and, along with it, regional variations in alveolar P_{O_2}). As a result, pulmonary vascular resistance increases, causing an increase in the pressure generated by the right ventricle. At moderate altitudes, this is innocuous, but at higher altitudes the increased pressure can cause fluid to leak from the pulmonary blood vessels into the lung: a condition known as *high altitude pulmonary edema* (HAPE). There is considerable variation among individuals in terms of susceptibility to HAPE and, as yet, no way to predict who will suffer from it. The best way to prevent HAPE is by gradual ascent to altitude. Treatment involves administration of supplemental oxygen and descent.

Long-term adaptations once thought to include increased capillary density and mitochondria—both of which would improve O_2 delivery and utilization—have not been confirmed by later research. Indeed, mountain climbers, experience decreases in both body and muscle mass. Because the number of muscle capillaries does not change, the increase in capillary density is an artefact related to the loss of muscle mass. In fact, the ratio of capillaries to muscle fibres does not change.

Understandably, researchers and clinicians concentrate on oxygen and its delivery to tissues. As a result, much less attention has been given to the effects of changes in carbon dioxide on adaptation to altitude. Among the Quechua people of South America, who reside above 4000 m, new mothers swaddle their newborns, including their heads, even though this decreases the P_{O_2} of the air inhaled by the infants (E.Z. Tronick et al. [1994]. The Quechua manta pouch: A caretaking practice for buffering the Peruvian infant against the multiple stressors of high altitude, *Child Dev*, 65: 1005–13). Although newborns have fetal haemoglobin, which has an O_2 dissociation curve displaced to the left (i.e., it binds oxygen more avidly than adult haemoglobin, making it better at taking up oxygen in the lung), the investigators did not measure the P_{O_2} of the inhaled gas. It is possible that a higher P_{O_2} would help dilate (or prevent as much vasoconstriction of) systemic blood vessels, thereby increasing blood flow and, therefore, O_2 delivery, despite a lower inspired P_{O_2} . A higher arterial P_{O_2} would also help unload oxygen to tissues. It is unclear if the practice is actually beneficial; it has not been described in the few other societies that live at high altitude. Moreover, if this practice is beneficial, why do adults not use it? Perhaps they no longer need it because they are fully adapted.

Altitude Training for Performance Enhancement

Formal altitude training has been used since the 1968 Olympic Games in Mexico City, Mexico. The many benefits associated with training at altitude (i.e., altitude training) result from the reduction in air density and partial pressure of oxygen (P_{O_2}), which stimulates increased red blood cell (RBC) production and leads to improved sea-level endurance performance.

Those who live well above sea level (≥ 2500 m) have an advantage over athletes who reside at sea level, and their acclimatization is due to their chronic exposure to moderate-to-high-altitude

hypoxia. The acclimatized person has high O_2 -carrying capacity (high haematocrit, haemoglobin, and erythrocyte count), similar to that observed in chronic polycythaemia. Increases in the levels of endogenous erythropoietin (EPO)—released principally from the kidneys, but with small amounts from the liver—increase the RBC volume and gradually reduce the increased ventilation and cardiac frequency that typically accompany acute moderate-to-high-altitude exposure. In response to hypoxic pulmonary vasoconstriction, other long-term physiological changes associated with the cardiovascular system include increases in blood volume, pulmonary arterial wall thickness, and right ventricular muscle mass. If the person does not respond well to altitude, the hypoxic vasoconstriction may lead to pulmonary hypertension, and right ventricular failure can develop, as seen in chronic mountain illness.

However, for most athletes, exposure to an altitude of 1500–2500 m for training purposes is physiologically manageable and has been shown by some research to be beneficial to athletic performance. Many sports teams train at an altitude of 2500 m. Two of the most common altitude training methodologies are “live high, train high” and “live high, train low.” The latter is arguably the most frequently used and effective method even though its effectiveness has recently been questioned. Nonetheless, our discussion will focus on this strategy.

The basic guidelines for altitude-training camp (for eating and sleeping) state that an elevation of approximately 2500 m above sea level is required to stimulate an increase in RBC production and thus improve aerobic performance. At this height, the amount of oxygen available is about 25 percent less than at sea level. A minimum altitude exposure of about 8 to 10 hours per day, for 10 to 14 days, is needed in order to stimulate the adaptations necessary to increase the number of RBCs and thus changes in haematocrit and haemoglobin, which are essential to increasing the O_2 transport ability of the blood. These changes, along with changes in skeletal muscle mitochondria and oxidative enzymes improve endurance performance. Four weeks of training is typically recommended.

Recent research has advanced the development of successful altitude training protocols. Benjamin D. Levine and James Stray-Gundersen (1997) developed the basic protocol for the “live high, train low” approach (Living high-training low: Effect of moderate-altitude acclimatization with low-altitude training on performance. *J Appl Physiol*, 83: 102–12). They used college-level competitive runners as the participants. The benefit associated with their method was not only to expose the athletes to the hypoxic environment long enough to stimulate an increase in haematocrit but also to allow the athletes to maintain training intensity by training at low altitude. Recall that upon exposure to moderate to high altitude, many physiological and performance measures decrease, an effect known as *detraining*; this is due to the reduced inspired P_{O_2} . Upon acute exposure to altitude (2300 m), athletes demonstrated a 14 percent drop in maximum oxygen consumption ($\dot{V}O_{2\max}$), an 8 percent slower 1.5 km run time, and a 10 percent slower 5 km run time.

After four weeks of “live high, train low,” Levine and Stray-Gundersen recorded an improvement in sea-level 5000 m time trials (13.4 s), and increases in RBC volume (9%), O_2 max

(5%), and maximal running speed at O_2 max. The improvements in O_2 max, RBC volume, and time trial performance were roughly proportional, indicating the importance of haematocrit to endurance performance.

These two researchers later repeated the study using elite male and female runners ([2001] *J Appl Physiol*, 91: 1113–20). The purpose was to determine if elite runners who were likely near their maximal structural and functional adaptive capacity (near their genetic ceiling) would be able to improve performance similarly to that of the college-level distance runners in the earlier 1997 study. The results indicated that elite distance runners improved their 3000 m run time by an average of 1.1 percent, which is a meaningful improvement at the world-class level. O_2 max also improved by 3 percent. The physiological changes following acclimatization to moderate altitude were an almost doubling of circulating EPO levels and a 10 g/L increase in haemoglobin concentration. These results indicate that the natural stimulation of the kidneys, liver, heart, and diaphragm to produce endogenous EPO could improve sea-level endurance performance in

both well-trained and elite distance runners. Other researchers have observed similar improvements. However, as previously mentioned, a recent study suggests that part or all of the improvement in performance may be related to a placebo effect (C. Siebenmann et al., “Live high-train low” using normobaric hypoxia: A double-blinded, placebo-controlled study. *J Appl Physiol* [2011] doi:10.1152/jappphysiol.00388.2011).

On return to sea level, the body returns to homeostatic conditions associated with sea level. In the first two weeks, there is, typically, a decrease in haematocrit and an increase in plasma volume, and erythrocyte (RBC) formation in bone marrow is depressed. However, for competitive purposes, coaches suggest that when altitude-trained endurance athletes travel to sea-level competitions, they will have a higher RBC concentration for about 10 to 14 days, and this gives the athlete a competitive advantage. Approximately two months following the return from moderate-to-high-altitude training, total blood volume decreases and haematocrit is normal or slightly below normal. These adjustments gradually return the body to sea-level homeostasis.

The Digestive System

Body systems maintain homeostasis

Digestive system

Cells make up body systems

Homeostasis

The digestive system contributes to homeostasis by transferring nutrients, water, and electrolytes from the external environment to the internal environment.

Homeostasis is essential for survival of cells

Garry DeLong/Getty Images

Photomicrograph of the pylorus

To maintain homeostasis, nutrient molecules used for energy production must continually be replaced by new, energy-rich nutrients. As well, nutrient molecules, especially proteins, are needed for ongoing synthesis of new cells and cell parts in the course of tissue turnover and growth. Similarly, water and electrolytes constantly lost in urine and sweat and through other avenues must be replenished regularly. The

digestive system contributes to homeostasis by transferring nutrients, water, and electrolytes from the external environment to the internal environment. The digestive system does not directly regulate the concentration of any of these constituents in the internal environment. It does not vary nutrient, water, or electrolyte uptake based on body needs (with few exceptions); rather, it optimizes conditions for digesting and absorbing what is ingested.

Clinical Connections

Cathy is 40 years old and has recently complained of a burning sensation in her abdomen. The pain, which occurs between meals and generally subsides while she is eating, has not been relieved by NSAIDs but is partially relieved by antacids. She has frequent belching, feels bloated, and has a general fatigue. She has also recently experienced a noticeable weight loss. When her vitals were taken, she was hypotensive and had tachycardia. A fecal occult blood test was positive. She underwent endoscopy that visualized a peptic ulcer, and a biopsy from the site tested positive for *H. pylori*.

15.1 | Introduction

The primary function of the **digestive system** is to transfer nutrients, water, and electrolytes from the food we eat into the body's internal environment. The digestive system is a series of hollow organs that are joined together. It begins with the mouth and terminates at the anus. Ingested food is essential as an energy source, or fuel, from which the cells can generate ATP to carry out their particular energy-dependent activities, such as active transport, contraction, synthesis, and secretion. Food is also a source of building supplies for the renewal and addition of body tissues.

The act of eating does not automatically make the preformed organic molecules in food available to the body cells as a source of fuel or as building blocks. First, the food must be digested, that is, biochemically broken down, into small, simple molecules that can be absorbed from the digestive tract into the circulatory system for distribution to the cells. Normally, about 95 percent of the ingested food is made available for the body's use. The sequence in nutrient acquisition is ingestion, digestion, absorption, distribution, and usage.

We first provide an overview of the digestive system, examining the common features of the various components of the system, and then we begin a detailed tour of the tract from beginning to end.

Four digestive processes

There are four basic digestive processes: *motility*, *secretion*, *digestion*, and *absorption*.

MOTILITY

The term **motility** refers to the muscular contractions that mix and move forward the contents of the digestive tract. Like vascular smooth muscle, the smooth muscle in the walls of the digestive tract maintains a constant low level of contraction known as tone. Tone is important in maintaining a steady pressure on the contents of the digestive tract as well as in preventing its walls from remaining permanently stretched following distension.

Two basic types of digestive motility are superimposed on this ongoing tonic activity: propulsive movements and mixing movements. *Propulsive movements* propel, or push, the contents forward through the digestive tract; the rate of propulsion varies depending on the functions of the different regions. That is, the contents move forward in a given segment at a velocity that's appropriate for that segment to fulfill its role in digestion. *Mixing movements* serve a twofold function. First, by mixing food with the digestive juices, these movements promote digestion of the food. Second, they facilitate absorption by exposing all parts of the intestinal contents to the absorbing surfaces of the digestive tract.

Contraction of the smooth muscle within the walls of the digestive organs accomplishes movement of material through most of the digestive tract. The exceptions occur at the ends of the tract—the mouth through the early part of the oesophagus at the beginning and the external anal sphincter at the end. In these regions, the acts of chewing, swallowing, and defecation have voluntary components, and thus use skeletal muscle. By contrast, motility accomplished by smooth muscle throughout the rest of the tract is controlled by complex involuntary mechanisms.

SECRETION

A number of digestive juices are secreted into the digestive tract lumen by exocrine glands (p. 7) along the route, each with its own specific secretory product. Each **digestive secretion** consists of water, electrolytes, and specific organic constituents important in the digestive process, such as enzymes, bile salts, or mucus. The secretory cells extract from the plasma large volumes of water and the raw materials necessary to produce their particular secretion.

Secretion of all digestive juices requires energy, both for active transport of some of the raw materials into the cell (others diffuse in passively) and for synthesis of secretory products by the endoplasmic reticulum. On appropriate neural or hormonal stimulation, the secretions are released into the digestive tract lumen. Normally, there is no net loss of water as the digestive secretions are reabsorbed in one form or another back into the blood after their participation in digestion. However, in the case of vomiting or diarrhoea, the digestive secretions are not fully reabsorbed, resulting in a net loss of the water that had initially been borrowed from the plasma. This can lead to dehydration.

Furthermore, endocrine cells located in the digestive tract wall secrete into the blood the gastrointestinal hormones (e.g., gastrin, secretin, motilin) that help control digestive motility and exocrine gland secretion.

DIGESTION

Humans consume three different biochemical categories of energy-rich foodstuffs: *carbohydrates*, *proteins*, and *fats*. These large molecules cannot cross plasma membranes intact to be absorbed from the lumen of the digestive tract into the blood or lymph. The term **digestion** refers to the biochemical breakdown of the structurally complex foodstuffs of the diet into smaller, absorbable units by the enzymes produced within the digestive system, as follows:

1. The simplest form of **carbohydrates** is the simple sugars or **monosaccharides** (one-sugar molecules), such as **glucose**, **fructose**, and **galactose**, very few of which are normally found in the diet (Appendix B, p. A-11). Most ingested carbohydrate is in the form of **polysaccharides** (many-sugar molecules), which consist of chains of interconnected glucose molecules. The most common polysaccharide consumed is **starch** derived from plant sources. In addition, meat contains **glycogen**, the polysaccharide storage form of glucose in muscle. **Cellulose**, another dietary polysaccharide, found in plant walls, cannot be digested into its constituent monosaccharides by the digestive juices humans secrete; it represents the indigestible *fibre*, or the bulk, in our diets. Besides polysaccharides, a lesser source of dietary carbohydrate is in the form of **disaccharides** (two-sugar molecules), including **sucrose** (table sugar, which consists of one glucose and one fructose molecule) and **lactose** (milk sugar made up of one glucose and one galactose molecule). Through the process of digestion, starch, glycogen, and disaccharides are converted into monosaccharides, principally glucose with small amounts of fructose and galactose. These monosaccharides are the absorbable units for carbohydrates.
2. The sources of dietary **protein** are meats, legumes, eggs, grains, and dairy products. Dietary proteins consist of various combinations of **amino acids** held together by peptide bonds (Appendix B, p. A-14). Through the process of digestion, proteins are degraded primarily into their constituent amino acids as well as a few **small polypeptides** (several amino acids linked by peptide bonds), both of which are the absorbable units for protein.

3. Most dietary **fats** are in the form of **triglycerides**, which are neutral fats, each consisting of a glycerol with three **fatty acid** molecules attached (*tri* means “three”) (Appendix B, p. A-12). During digestion, two of the fatty acid molecules are split off, leaving a **monoglyceride**—a glycerol molecule with one fatty acid molecule attached (*mono* means “one”). Thus, the end products of fat digestion are monoglycerides and free fatty acids, which are the absorbable units of fat.

Digestion is accomplished by enzymatic **hydrolysis** (break-down by water; Appendix B, p. A-15). By adding water at the bond site, enzymes in the digestive secretions break down the bonds that hold the small molecular subunits within the nutrient molecules together, thus setting the small molecules free (▶ Figure 15-1). The removal of water at the bond sites (dehydration synthesis) originally joined these small subunits to form nutrient molecules. Hydrolysis replaces the water and frees the small absorbable units. Digestive enzymes are specific in the type of bonds they can hydrolyze. As food moves through the digestive tract, it is subjected to various enzymes, each of which breaks down the food molecules even further. In this way, large food molecules are converted to simple absorbable units in a progressive, stepwise fashion, like an assembly line in reverse, as the digestive tract contents are propelled forward.

ABSORPTION

In the small intestine, digestion is completed and most absorption occurs. Through the process of **absorption**, the small absorbable units that result from digestion, along with water, vitamins, and electrolytes, are transferred from the digestive tract lumen into the blood or lymph. As we examine the digestive tract from beginning to end, we will discuss the four processes of motility, secretion, digestion, and absorption as they take place within each digestive organ (see ■ Table 15-1).

The digestive tract and accessory organs

The digestive system consists of the *digestive* (or *gastrointestinal*) *tract* plus the accessory digestive organs (*gastro* means “stomach”). The **accessory digestive organs** include the *salivary glands*, the *exocrine pancreas*, and the *biliary system*, which is composed of the *liver* and *gallbladder*. These exocrine organs lie outside the digestive tract and empty their secretions through ducts into the digestive tract lumen.

▶ **FIGURE 15-1** An example of hydrolysis. In this example, the disaccharide maltose (the intermediate breakdown product of polysaccharides) is broken down into two glucose molecules by the addition of H₂O at the bond site.

The **digestive tract** is a tube about 4.5 m in length in its normal contractile state (in the uncontracted state of a cadaver the tract is 9 m long). Running through the middle of the body, the digestive tract includes the following organs (■ Table 15-1): *mouth*; *pharynx* (throat); *oesophagus*; *stomach*; *small intestine* (consisting of the *duodenum*, *jejunum*, and *ileum*); *large intestine* (the *cecum*, *appendix*, *colon*, and *rectum*); and *anus*. Although these organs are continuous with one another, they are considered separate entities because of regional modifications that allow for specialized activities. Because the digestive tract is continuous from the mouth to the anus, like the lumen of a straw, it is continuous with the external environment. As a result, the contents within the lumen of the digestive tract are technically outside the body, just as the liquid you suck through a straw is not a part of the straw. Only after a substance has been absorbed from the lumen across the digestive tract wall is it considered part of the body. This is important, because conditions essential to digestion can be tolerated in the digestive tract lumen, but not in the body proper. Consider the following examples:

- The pH of the stomach contents is ≤ 2 as a result of the gastric secretion of hydrochloric acid (HCl), yet the body fluid’s pH in other regions ranges between 6.8 and 8.0.
- The digestive enzymes that hydrolyze the protein in food could also destroy the body’s own tissues (proteins) that produce them. Therefore, once these enzymes are synthesized in inactive form, they are not activated until they reach the lumen, where they actually attack the food outside the body (i.e., within the lumen), thereby protecting the body tissues against self-digestion.
- In the lower intestine exist quadrillions of living microorganisms that are normally harmless and even beneficial, yet if these same microorganisms enter the body proper (as may happen with a ruptured appendix), they may be extremely harmful or even lethal.

The digestive tract wall

The digestive tract wall has the same general structure throughout most of its length, from oesophagus to anus, with some local variations characteristic of each region. A cross-section of the digestive tube reveals four major tissue layers (▶ Figure 15-2). From the innermost layer outward they are the *mucosa*, the *submucosa*, the *muscularis externa*, and the *serosa*.

MUCOSA

The **mucosa** lines the luminal surface of the digestive tract, as well as other body cavities that are exposed to the external environment and internal organs. It is divided into three layers:

- The primary component is the **mucous membrane**, an inner epithelial layer that serves as a protective surface. It is modified in particular areas for secretion and absorption. The mucous membrane contains

■ **TABLE 15-1** Anatomy and Functions of Components of the Digestive System

Digestive Organ	Motility
Mouth and Salivary Glands	Chewing
Pharynx and Oesophagus	Swallowing
Stomach	Receptive relaxation; peristalsis
Exocrine Pancreas	Not applicable
Liver	Not applicable
Small Intestine	Segmentation; migrating motility complex
Large Intestine	Haustral contractions, mass movements

Secretion	Digestion	Absorption
Saliva • Amylase • Mucus • Lysozyme	Carbohydrate digestion begins	No foodstuffs; a few medications—for example, nitroglycerin
Mucus	None	None
Gastric Juice • HCl • Pepsin • Mucus • Intrinsic factor	Carbohydrate digestion continues in body of stomach; protein digestion begins in antrum of stomach	No foodstuffs; a few lipid-soluble substances, such as alcohol and aspirin
Pancreatic Digestive Enzymes • Trypsin, chymotrypsin, carboxypeptidase • Amylase • Lipase	These pancreatic enzymes accomplish digestion in duodenal lumen	Not applicable
Pancreatic aqueous NaHCO₃ secretion		
Bile • Bile salts • Alkaline secretion • Bilirubin	Bile does not digest anything, but bile salts facilitate fat digestion and absorption in duodenal lumen	Not applicable
Succus Entericus		
Mucus		
Salt (Small intestine enzymes—disaccharidases and aminopeptidases—are not secreted but function within the brush-border membrane.)	In lumen, under influence of pancreatic enzymes and bile, carbohydrate and protein digestion continues, and fat digestion is completely accomplished; in brush border, carbohydrate and protein digestion is completed.	All nutrients, most electrolytes, and water
Mucus	None	Salt and water, converting contents to feces

exocrine gland cells for secretion of digestive juices, *endocrine gland cells* for secretion of blood-borne gastrointestinal hormones, and *epithelial cells* specialized for absorbing digested nutrients.

- The **lamina propria** is a thin middle layer of connective tissue on which the epithelium rests. It houses the **gut-associated lymphoid tissue (GALT)**, which is important in the defence against disease-causing intestinal bacteria (p. 464).
- The **muscularis mucosa**, a sparse layer of smooth muscle, is the outermost mucosal layer that lies adjacent to the submucosa.

The mucosal surface is generally highly folded (ridged), which greatly increases the surface area available for absorption. The degree of folding varies depending on the region of the tract; it is most extensive in the small intestine, where maximum absorption occurs, and least in the oesophagus, which merely serves as a transit tube. The pattern of surface folding can be modified by contraction of the muscularis mucosa.

SUBMUCOSA

The **submucosa** (under the mucosa) is a thick layer of connective tissue that supports the mucosa and provides the digestive tract with its distensibility and elasticity. It contains larger blood and lymph vessels, both of which send branches inward to the mucosal layer and outward to the surrounding thick muscle layer. Also, a nerve network known as the *submucosal plexus* lies within the submucosa (*plexus* means “network”).

MUSCULARIS EXTERNA

The **muscularis externa**, the major smooth muscle coat of the digestive tube, surrounds the submucosa. In most parts of the tract, the muscularis externa consists of two layers: an *inner circular layer* (encircle) and an *outer longitudinal layer*. Contraction of these circular fibres decreases the lumen diameter, constricting the tube at the point of contraction. Contraction of the fibres in the outer layer (longitudinally), shortens the tube. Together, contractile activity of these smooth muscle layers produces the propulsive and mixing movements. Another nerve network, the *myenteric plexus*, lies between the two muscle layers (*myo* means “muscle”; *enteric* means “intestine”). Together the submucosal and myenteric plexuses, along with hormones and local chemical mediators, help regulate local gut activity.

SEROSA

The outer connective tissue covering of the digestive tract is the **serosa (serous membrane)**, which secretes a watery fluid (**serous fluid**) that lubricates to reduce friction between the digestive organs and surrounding viscera. Throughout much of the tract, the serosa is continuous with the **mesentery**, which suspends the digestive organs from the inner wall of the abdominal cavity like a sling (► Figure 15-2). This attachment provides relative fixation, supporting the digestive organs in proper position, while still allowing them freedom for mixing and propulsive movements.

© 2016 Cengage

► **FIGURE 15-2** Layers of the digestive tract wall. The digestive tract wall consists of four major layers: from the innermost out, they are the mucosa, submucosa, muscularis externa, and serosa.

Regulation of digestive function

Digestive motility and secretion are carefully regulated to maximize digestion and absorption of ingested food. Four factors are involved in regulating digestive system function: (1) autonomous smooth muscle function, (2) intrinsic nerve plexuses, (3) extrinsic nerves, and (4) gastrointestinal hormones.

AUTONOMOUS SMOOTH MUSCLE FUNCTION

Similar to some self-excitable cardiac muscle cells, some smooth muscle cells are pacemaker cells that display rhythmic, spontaneous variations in membrane potential. The prominent type of self-induced electrical activity in digestive smooth muscle is slow-wave potentials (p. 331), alternatively referred to as the digestive tract's **basic electrical rhythm (BER)**. Muscle-like but noncontractile cells known as the **interstitial cells of Cajal** are the pacemaker cells that instigate cyclic slow-wave activity. These pacemaker cells lie at the boundary between the longitudinal and circular smooth muscle layers. Slow waves are not action potentials and do not directly induce muscle contraction; they are rhythmic, wavelike fluctuations in membrane potential that cyclically bring the membrane closer to or farther from threshold potential. These slow-wave oscillations are believed to be due to cyclic variations in calcium release from the endoplasmic reticulum and calcium uptake by the mitochondria of the pacemaker cell. If these waves reach threshold at the peaks of

depolarization, a volley of action potentials is triggered at each peak, resulting in rhythmic cycles of muscle contraction.

Like cardiac muscle, smooth muscle cells are connected by gap junctions, through which charge-carrying ions can flow (p. 36). In this way, electrical activity initiated in a digestive tract pacemaker cell spreads to the adjacent contractile smooth muscle cells. New evidence suggests that this electrical activity may also spread via the enteric nervous system, described shortly. Thus, the whole muscle sheet behaves like a functional syncytium, becoming excited and contracting as a unit at threshold (p. 328). If threshold is not achieved, the oscillating slow-wave sweeps across the muscle sheet without being accompanied by contractile activity.

Whether threshold is reached depends on various mechanical, neural, and hormonal factors that influence the starting point around which the slow-wave rhythm oscillates. If the starting point is nearer the threshold level, as it is when food is present in the digestive tract, the depolarizing slow-wave peak reaches threshold, so action potential frequency and its accompanying contractile activity increase. Conversely, if the starting point is farther from threshold, as when no food is present, there is a lower likelihood of reaching threshold.

The *rate* (frequency) of self-induced rhythmic digestive contractile activities, such as peristalsis in the stomach, segmentation in the small intestine, and haustral contractions in the large intestine, depends on the inherent rate established by

the involved pacemaker cells. The *intensity* (strength) of these contractions depends on the number of action potentials that occur when the slow-wave potential reaches threshold, which in turn depends on how long threshold is sustained. At threshold, voltage-gated Ca^{2+} channels are activated (p. 58), resulting in Ca^{2+} influx into the smooth muscle cell. The resultant Ca^{2+} entry has two effects: (1) it is responsible for the rising phase of an action potential, with the falling phase being brought about as usual by K^{+} efflux; and (2) it triggers a contractile response (p. 329). The greater the number of action potentials that take place, the higher the cytosolic Ca^{2+} concentration, the greater the cross-bridge activity, and the stronger the contraction. Other factors that influence contractile activity also do so by altering the cytosolic Ca^{2+} concentration. Consequently, the level of contractility can range from low-level tone to vigorous mixing and propulsive movements due to the variations in cytosolic Ca^{2+} concentration.

INTRINSIC NERVE PLEXUSES

The **intrinsic nerve plexuses** are the two major networks of nerve fibres—the submucosal plexus and the **myenteric plexus**—that lie entirely within the digestive tract wall and run its entire length. This means the digestive tract has its own intramural nervous system, which contains as many neurons as the spinal cord and endows the tract with a considerable degree of self-regulation. These two plexuses are often termed the **enteric nervous system**. However, the enteric nervous system does receive substantial input from the autonomic nervous system.

The intrinsic plexuses influence all facets of digestive tract activity. Various types of neurons are present in the intrinsic plexuses. Some are sensory, and these have receptors that respond to specific local stimuli in the digestive tract. Other local neurons innervate the smooth muscle cells and the exocrine and endocrine cells of the digestive tract to directly affect digestive tract motility, secretion of digestive juices, and secretion of gastrointestinal hormones. As with the CNS, the enteric nervous system is linked by interneurons; some neurons are excitatory, and some are inhibitory. For example, neurons that release *acetylcholine* promote smooth muscle contraction, whereas *nitric oxide* and *vasoactive intestinal peptide* cause relaxation. These intrinsic nerve networks primarily coordinate local activity within the digestive tract. To illustrate, if a large piece of food gets stuck in the oesophagus, the intrinsic plexuses coordinate local responses to push the food forward. Intrinsic nerve activity can, in turn, be influenced by the extrinsic nerves.

EXTRINSIC NERVES

The **extrinsic nerves** are the nerve fibres from both branches of the ANS that originate outside the digestive tract and innervate the various digestive organs. The autonomic nerves influence digestive tract motility and secretion either by modifying ongoing activity in the intrinsic plexuses, altering the level of gastrointestinal hormone secretion, or, in some instances, acting directly on the smooth muscle and glands.

Recall that, in general, the sympathetic and parasympathetic nerves supplying any given tissue exert opposing actions on that tissue. The sympathetic nervous system tends to inhibit

or slow down digestive tract contraction and secretion. This action is appropriate, considering that digestive processes are not of highest priority when the body faces an emergency. The parasympathetic nervous system dominates when general maintenance types of activities, such as digestion, can proceed optimally. Accordingly, the parasympathetic nerve fibres supplying the digestive tract tend to increase smooth muscle motility and promote secretion of digestive enzymes and hormones. A unique parasympathetic nerve supply of the digestive tract—the post-ganglionic parasympathetic nerve fibres—is actually a part of the intrinsic nerve plexuses, which secrete acetylcholine within the plexuses. Accordingly, acetylcholine is released in response to local reflexes coordinated entirely by the intrinsic plexuses as well as to vagal stimulation, which acts through the intrinsic plexuses.

In addition to being called into play during generalized sympathetic or parasympathetic discharge, the autonomic nerves, especially the vagus nerve, can be discretely activated to modify digestive activity only. One of the major purposes of specific activation of extrinsic innervation is to coordinate activity between different regions of the digestive system. For example, the act of chewing food reflexly increases not only salivary secretion but also stomach, pancreatic, and liver secretion via vagal reflexes in anticipation of the arrival of food.

Swallowing can become a great concern for the elderly, because such diseases as Alzheimer's can interfere with the autonomic nervous system. It is important to correct this condition, since it affects the same neuromuscular structures that influence speech. Hospitals often use speech therapists to work with Alzheimer's patients.

GASTROINTESTINAL HORMONES

Tucked within the mucosa of certain regions of the digestive tract are endocrine gland cells that release hormones into the blood. These **gastrointestinal hormones** are carried through the blood to other areas of the digestive tract, where they exert either excitatory or inhibitory influences on smooth muscle and exocrine gland cells; for example, gastrin stimulates the release of gastric juices (acid) by the stomach. Interestingly, many of these same hormones are released from neurons in the brain, where they act as neurotransmitters and neuromodulators. During embryonic development, certain cells of the developing neural tissue migrate to the digestive system, where they become endocrine cells.

Receptor activation

The digestive tract wall contains three types of sensory receptors that respond to local changes in the digestive tract: (1) *chemoreceptors* sensitive to chemical components within the lumen, (2) *mechanoreceptors* sensitive to stretch or tension within the wall, and (3) *osmoreceptors* sensitive to the osmolarity of the luminal contents.

Stimulation of these receptors elicits neural reflexes or secretion of hormones, both of which alter the level of activity in the digestive system's effector cells. These effector cells include smooth muscle cells (for modifying motility),

exocrine gland cells (for controlling secretion of digestive juices), and endocrine gland cells (for varying secretion of gastrointestinal hormones (► Figure 15-3). Receptor activation may bring about two types of neural reflexes: short reflexes and long reflexes. When the intrinsic nerve networks influence local motility or secretion in response to specific local stimulation, all elements of the reflex are located within the wall of the digestive tract itself; that is, a **short reflex** takes place. Extrinsic autonomic nervous activity can be superimposed on the local controls to modify smooth muscle and glandular responses, either to correlate activity between different regions of the digestive system or to modify digestive system activity in response to external influences. Because the autonomic reflexes involve long pathways between the central nervous system and digestive system, they are known as **long reflexes**. In addition to these neural reflexes, digestive system activity is coordinated by the gastrointestinal hormones, which are released in response to local changes in the digestive tract or by short or long reflexes.

Sensory receptors within the digestive tract wall monitor luminal content and wall tension. Receptor proteins within the plasma membranes of the digestive system's effector cells bind with and respond to gastrointestinal hormones, neurotransmitters, and local chemical mediators.

From this overview, you can see that regulation of gastrointestinal function is very complex, influenced by many synergistic, interrelated pathways that are designed to ensure that the appropriate responses occur to digest and absorb the ingested food. In no other system of the body is there so much overlapping control.

Next we take a tour of the digestive tract, beginning with the mouth and ending with the anus. Along the way, we will examine each digestive organ in terms of the four basic digestive processes of motility, secretion, digestion, and absorption.

■ Table 15-1 summarizes these activities and serves as a useful reference throughout the rest of the chapter.

Check Your Understanding 15.1

1. Draw a cross-section of the digestive tract, and label the following: mucosa, submucosa, muscularis externa, serosa, submucosal plexus, and myenteric plexus.
2. Describe how pacemaker activity affects smooth muscle function.
3. Describe how the sympathetic and parasympathetic nervous systems regulate smooth muscle motility.

15.2 | Mouth

The oral cavity

Entry to the digestive tract is through the **mouth (oral cavity)**. The opening is formed by the muscular **lips**, which help procure, guide, and hold the food in the mouth. The lips also serve non-digestive functions: for example, in speech, which depends on particular lip formations, and in interpersonal relationships, such as in kissing when the lips serve as a sensory receptor.

The **palate**, which forms the arched roof of the oral cavity, separates the mouth from the nasal passages. It allows breathing and chewing or sucking to take place simultaneously. Hanging down from the palate in the rear of the throat is the **uvula**, which plays an important role in sealing off the nasal passages during swallowing.

The **tongue** forms the floor of the oral cavity, is composed of voluntarily controlled skeletal muscle, and contains the majority of the **taste buds** (p. 181). Movements of the tongue guide food within the mouth for chewing and swallowing, and are also important in speech.

► FIGURE 15-3 Summary of pathways controlling digestive system activities

The **pharynx** is the cavity at the rear of the throat. It acts as a common passageway for both the digestive system (links the mouth and oesophagus) and the respiratory system. This arrangement necessitates mechanisms to guide food and air into the proper passageways beyond the pharynx. Within the side walls of the pharynx are the **tonsils**, lymphoid tissues that are part of the immune system.

The teeth

Mastication (chewing) is the motility of the mouth that involves the slicing, tearing, grinding, and mixing of ingested food by the **teeth**. The teeth are embedded in and protrude from the jawbones. The exposed part of a tooth is covered by **enamel**, the hardest structure of the body, which forms before the tooth's eruption.

The upper and lower teeth normally fit together when the jaws are closed. This **occlusion** allows food to be ground and crushed between the tooth surfaces. The teeth can exert great forces during eating; an adult male can exert up to 90 kg. This is sufficient to crack a hard nut. However, the degree of occlusion is most important in determining the efficiency of chewing.

When the teeth do not make proper contact (**malocclusion**) they cannot accomplish their normal cutting and grinding action. This occurs due to abnormal positioning of the teeth, often caused by either overcrowding of teeth or displacement of the jaw in relation one another. Malocclusion can cause abnormal wearing of affected tooth surfaces and dysfunction and pain of the **temporomandibular joint (TMJ)**, where the jawbones articulate with each other. Malocclusion is often corrected by braces, which exert prolonged gentle pressure against the teeth to move them gradually into position.

The functions of chewing are (1) to grind and break food up for swallowing and increase the food surface area on which salivary enzymes act, (2) to mix food with saliva, and (3) to stimulate the taste buds. The third function not only gives rise to the pleasurable subjective sensation of taste, but also reflexively increases salivary, gastric, pancreatic, and bile secretion to prepare for the arrival of food.

The act of chewing can be voluntary, but most chewing during a meal is a rhythmic reflex brought about by activation of the skeletal muscles of the jaws, lips, cheeks, and tongue in response to the pressure of food against the oral tissues.

Saliva

Saliva secretion is produced largely by three major pairs of salivary glands that lie outside the oral cavity and discharge saliva through short ducts into the mouth. It is stimulated by both the parasympathetic and sympathetic nervous systems.

Saliva is about 99.5 percent water and 0.5 percent electrolytes and protein, and approximately 1 to 1.5 L/day is secreted. Saliva secretions range from a basal rate of 0.5 mL/min to a maximum flow rate of about 5 mL/min in response to a potent stimulus (e.g., sucking a lemon). The salivary salt (NaCl) concentration is only one-seventh of that in the plasma, which is important in perceiving salty tastes. Similarly, discrimination of sweet tastes

is enhanced by the absence of glucose in the saliva. The most important salivary proteins are *amylase*, *mucus*, and *lysozyme*. They contribute to the functions of saliva as follows:

1. Saliva begins digestion of carbohydrate in the mouth via **salivary amylase**, an enzyme that breaks polysaccharides down into **maltose**, a disaccharide (see ▶ Figure 15-1).
2. Saliva facilitates swallowing by moistening food particles, holding them together, and by providing lubrication by the **mucus**.
3. Saliva exerts some antibacterial action—first, by **lysozyme**, an enzyme that destroys certain bacteria by breaking down their cell walls; and second, by rinsing away material that may serve as a food source for bacteria.
4. Saliva serves as a solvent for molecules; only molecules in solution can react with taste bud receptors. Self-demonstration: Dry your tongue and then drop some sugar on it—you cannot taste the sugar until it is moistened.
5. Saliva aids speech by facilitating movements of the lips and tongue.
6. Saliva plays an important role in oral hygiene by helping keep the mouth and teeth clean. The constant flow of saliva helps flush away food residues, foreign particles, and old epithelial cells that have shed from the oral mucosa.
7. Saliva is rich in bicarbonate buffers, which neutralize acids in food as well as acids produced by bacteria in the mouth, thereby helping prevent dental caries (this is the correct term for what is commonly referred to as tooth decay or dental cavities).

Despite these many functions, saliva is not essential for digesting and absorbing foods, because enzymes produced by the pancreas and small intestine can complete food digestion even in the absence of salivary and gastric secretion.

The main problems associated with diminished salivary secretion, a condition known as **xerostomia**, are difficulty in chewing and swallowing, inarticulate speech unless frequent sips of water are taken when talking, and a rampant increase in dental caries unless special precautions are taken.

Salivary secretion

Basal secretions brought on by low-level stimulation by the parasympathetic nervous system are important in keeping the mouth and throat moist at all times. In addition to this continuous, low-level secretion, salivary secretion may be increased by two types of salivary reflexes: the simple and conditioned salivary reflexes (▶ Figure 15-4).

SIMPLE AND CONDITIONED SALIVARY REFLEXES

The **simple salivary reflex** occurs when chemoreceptors and pressure receptors within the oral cavity respond to the presence of food. On activation, these receptors initiate impulses in afferent nerve fibres that carry the information to the **salivary centre**, which is located in the medulla of the brain stem, as are

© 2016 Cengage

FIGURE 15-4 Control of salivary secretion

all the brain centres that control digestive activities. The salivary centre, in turn, sends impulses via the extrinsic autonomic nerves to the salivary glands to promote increased salivation.

With the **conditioned (acquired) salivary reflex**, salivation occurs without oral stimulation. Just thinking about, seeing, smelling, or hearing the preparation of pleasant food initiates salivation through this reflex. All of us have experienced such “mouth-watering” in anticipation of something delicious to eat. This reflex is a learned response based on previous experience. Through functions of the cerebral cortex, our mental associations with the pleasure of eating stimulate the medullary salivary centre.

AUTONOMIC INFLUENCE ON SALIVARY SECRETION

The salivary centre controls the degree of salivary output by means of the autonomic nerves that supply the salivary glands. Unlike the autonomic nervous system elsewhere in the body, sympathetic and parasympathetic responses in the salivary glands are not antagonistic. Both sympathetic and parasympathetic stimulation increase salivary secretion, but the quantity, characteristics, and mechanisms are different. Parasympathetic stimulation, which exerts the dominant role in salivary secretion, produces a prompt and abundant flow of watery saliva that is rich in enzymes. Sympathetic stimulation, by contrast, produces a much smaller volume of thick saliva that is rich in mucus. Because sympathetic stimulation elicits a smaller volume of saliva, the mouth feels drier than usual during circumstances when the sympathetic system is dominant, such as stress situations (giving a speech).

Salivary secretion is the only digestive secretion entirely under neural control. All other digestive secretions are regulated by both nervous system reflexes and hormones.

Digestion

Digestion in the mouth involves the hydrolysis of polysaccharides into disaccharides by amylase. However, most digestion by this enzyme is accomplished in the body of the stomach after

the food mass and saliva have been swallowed. Acid inactivates amylase, but in the centre of the food mass, where stomach acid has not yet reached, this salivary enzyme continues to function for several more hours.

No absorption of foodstuff occurs from the mouth. Importantly, some drugs can be absorbed by the oral mucosa; a prime example is *nitroglycerin*, a vasodilator drug sometimes used by cardiac patients to relieve anginal attacks (p. 378) associated with myocardial ischemia (p. 360).

Check Your Understanding 15.2

1. State the functions of salivary mucus, amylase, and lysozyme.
2. Compare the effects of parasympathetic versus sympathetic stimulation of the salivary glands.

15.3 | Pharynx and Oesophagus

The motility associated with the pharynx and oesophagus is **swallowing**. Most of us think of swallowing as the limited act of moving food out of the mouth into the oesophagus. However, swallowing actually is the entire process of moving food from the mouth through the oesophagus into the stomach.

Swallowing: A programmed all-or-none reflex

Swallowing is initiated when a **bolus**, or ball of chewed or liquid food, is voluntarily forced by the tongue to the rear of the mouth into the pharynx (Figure 15-5a). Swallowing is a complex task requiring a coordinated effort of 25 pairs of muscles. The pressure of the bolus stimulates pharyngeal pressure receptors, which send afferent impulses to the **swallowing centre** located in the medulla of the brain stem. The swallowing centre then reflexly activates in

the appropriate sequence the muscles involved in swallowing. Swallowing is the most complex reflex in the body. Multiple highly coordinated responses are triggered in a specific all-or-none pattern over a period of time to accomplish the act of swallowing. Swallowing is initiated voluntarily, but once begun it cannot be stopped. Perhaps you have experienced this when a large piece of hard candy inadvertently slipped to the rear of your throat, triggering an unintentional swallow.

The stages of swallowing

Swallowing is divided into the oropharyngeal stage and the esophageal stage. The **oropharyngeal stage** lasts about one second and consists of moving the bolus from the mouth through the pharynx and into the oesophagus. When the bolus enters the pharynx, it must be directed into the oesophagus and prevented from entering the other openings that communicate with the pharynx (i.e., the trachea). All of this is managed by the following coordinated activities (► Figure 15-5b):

- The position of the tongue against the hard palate keeps food from reentering the mouth during swallowing.
- The uvula is elevated and lodges against the back of the throat, sealing off the nasal passages.
- Food is prevented from entering the trachea primarily by elevation of the larynx and tight closure of the vocal folds across the laryngeal opening, or **glottis** (► Figure 15-5c). The first part of the trachea is the *larynx*, or *voice box*, across which are stretched the *vocal folds*. Contraction of laryngeal muscles aligns the vocal folds in tight apposition to each other, thus sealing the glottis entrance. Also, the bolus tilts a small flap of cartilage, the **epiglottis** (*epi* means “upon”), backward over the closed glottis, thereby protecting the respiratory airways. It is the glottis that is closed by the epiglottis during the valsalva manoeuvre, which is used to stabilize the core area during heavy lifting.
- The respiratory passages are temporarily sealed off during swallowing, because the swallowing centre briefly inhibits the nearby respiratory centre.
- With the larynx and trachea sealed off, pharyngeal muscles contract to force the bolus into the oesophagus.

The pharyngoesophageal sphincter

The oesophagus is a fairly straight muscular tube that extends between the pharynx and stomach (see ■ Table 15-1). Lying for the most part in

► FIGURE 15-5 Oropharyngeal and esophageal stages of swallowing

the thoracic cavity, it penetrates the diaphragm and joins the stomach in the abdominal cavity. The oesophagus is guarded at both ends by sphincters (ringlike muscle). The sphincter when closed prevents passage through the tube. The upper esophageal sphincter is the *pharyngoesophageal sphincter*, and the lower esophageal sphincter is the *gastroesophageal sphincter*.

Because the oesophagus is exposed to subatmospheric intrapleural pressure as a result of respiratory activity (p. 513), a pressure gradient exists between the atmosphere and the oesophagus. Except during a swallow, the **pharyngoesophageal sphincter** keeps the entrance to the oesophagus closed to prevent air from entering the oesophagus and stomach during breathing. Otherwise, the digestive tract would be subjected to large volumes of gas, which would lead to excessive **eructation** (burping). During swallowing, this sphincter opens and allows the bolus to pass into the oesophagus. Once the bolus has entered the oesophagus, the pharyngoesophageal sphincter closes and breathing resumes.

Peristaltic waves

The **esophageal stage** of the swallow now begins (► Figure 15-5d). The swallowing centre triggers a **primary peristaltic wave** that sweeps from the beginning to the end of the oesophagus, forcing the bolus ahead of it through the oesophagus to the stomach. The term **peristalsis** refers to ringlike contractions of the circular smooth muscle that move progressively forward (► Figure 15-5e). The peristaltic wave takes about five to nine seconds to reach the lower end of the oesophagus. Progression of the wave is controlled by the swallowing centre, with innervation by means of the vagus.

If a large or sticky swallowed bolus, such as a bite of peanut butter sandwich, fails to be carried along to the stomach, the lodged bolus distends the oesophagus, stimulating pressure receptors within its walls. A second more forceful peristaltic wave is initiated, mediated by the intrinsic nerve plexuses at the level of the distension. These **secondary peristaltic waves** do not involve the swallowing centre, nor is the person aware of their occurrence. Distension of the oesophagus also reflexly increases salivary secretion. The trapped bolus is eventually dislodged and moved forward. Esophageal peristalsis is so effective you could eat an entire meal while you were upside down and it would all promptly be pushed to the stomach.

THE GASTROESOPHAGEAL SPHINCTER

The **gastroesophageal sphincter** is a highly muscular sphincter in the lower oesophagus that remains constricted at all times, except during either swallowing or vomiting. As the peristaltic wave sweeps down the oesophagus, the gastroesophageal sphincter relaxes reflexly so that the bolus can pass into the stomach (► Figure 15-5e). After the bolus has entered the stomach, the gastroesophageal sphincter again contracts.

It is essential that the gastroesophageal sphincter stays contracted to maintain a barrier between the stomach and oesophagus, thereby reducing the risk of reflux of acidic gastric contents into the oesophagus. If gastric contents do flow backward past the sphincter—called gastroesophageal reflux (**gastric reflux**)—the acidity of these contents irritates the oesophagus,

causing discomfort known as **heartburn**. (The heart itself is not involved.) The acidity of the contents can damage the esophageal lining if the reflux occurs on a regular basis (i.e., >1/week). Regular gastric reflux can lead to serious disorders, such as esophageal ulcers or esophageal cancer.

ESOPHAGEAL SECRETION

Mucus is secreted throughout the length of the digestive tract by mucus-secreting glands in the mucosa. By lubricating the passage of food, esophageal mucus reduces the likelihood of damage by sharp edges in the entering food. It also protects the esophageal wall from acid and enzymes in gastric juice if gastric reflux occurs.

The entire transit time in the pharynx and oesophagus averages a mere 6 to 10 seconds, too short a time for any digestion or absorption to occur. Let's now move on to examine the stomach.

Check Your Understanding 15.3

1. Describe how the pharynx prevents food entry into the trachea during a swallow.
2. State the function of the pharyngoesophageal sphincter.

15.4 | Stomach

The **stomach** is a J-shaped saclike chamber lying between the oesophagus and the small intestine. It has three sections based on anatomic, histological, and functional distinctions (► Figure 15-6). The **fundus** is the part of the stomach that lies above the esophageal opening. The middle or main part of the stomach is the **body**. The smooth muscle layers in the fundus and body are relatively thin, but the lower part of the stomach, the **antrum**, has much heavier musculature. This difference in muscle thickness plays an important role in gastric motility in these two regions. There are also glandular differences in the mucosa of these regions. The terminal portion of the stomach is the **pyloric sphincter**, which acts as a barrier between the stomach and the upper part of the small intestine, the duodenum.

Food storage and protein digestion

The stomach performs three main functions:

1. The stomach's most important function is to store ingested food until it can be emptied into the small intestine at a rate appropriate for optimal digestion and absorption. Because the small intestine is the primary site for this digestion and absorption, it is important that the stomach store the food and meter it into the duodenum at a rate that does not exceed the small intestine's capacities.
2. The stomach secretes hydrochloric acid (HCl) and enzymes that begin protein digestion. The stomach is capable of secreting about 3 L of gastric juice each day.

© 2016 Cengage

► **FIGURE 15-6 Anatomy of the stomach.** The stomach is divided into three sections based on structural and functional distinctions: the fundus, body, and antrum. Based on differences in glandular secretion, the mucosal lining of the stomach is divided into the oxyntic mucosa and the pyloric gland area.

- Through the stomach's mixing movements, the ingested food is pulverized and mixed with gastric secretions to produce a thick liquid known as **chyme**. The stomach contents must be converted to chyme before they can be emptied into the duodenum.

We next discuss these stomach functions in terms of the four basic digestive processes—motility, secretion, digestion, and absorption. Starting with motility, gastric motility is complex and subject to multiple regulatory inputs. The four aspects of gastric motility are (1) filling, (2) storage, (3) mixing, and (4) emptying. We begin with gastric filling.

Gastric filling

When empty, the stomach's volume is about 50 mL, but it can expand to a capacity of about 1000 mL (twentyfold increase) during a meal, and can be physically distended to as much as 4000 mL. The stomach accommodates this change in volume with little change in tension and intragastric pressure by means of the following mechanism. The interior of the stomach has deep folds. During a meal, the folds get smaller and nearly flatten out as the stomach relaxes with each mouthful. This reflex relaxation of the stomach is called **receptive relaxation**; it enhances the stomach's ability to accommodate the extra volume of food with little rise in stomach pressure. Receptive relaxation is triggered by eating and is mediated by the vagus nerve. If too much food is consumed, the stomach becomes overdistended and intragastric pressure rises along with discomfort.

Gastric storage

Pacemaker cells located in the fundus region generate slow-wave potentials that sweep down the length of the stomach toward the pyloric sphincter at a rate of three per minute. This rhythmic spontaneous depolarization—the basic electrical rhythm (BER) of the stomach—occurs continuously and may or may not be accompanied by contraction of the stomach's circular smooth muscle layer. Depending on the level of smooth muscle excitability, smooth muscle cells may be brought to threshold by this flow of current and undergo action potentials, which in turn initiate peristaltic waves that sweep over the stomach in pace with the BER.

Once initiated, the peristaltic wave spreads over the fundus and body to the antrum and pyloric sphincter. When the waves reach the antrum they become much stronger and more vigorous, because the muscle there is much thicker than that of the fundus and body. Because weak mixing movements occur in the fundus and body, food delivered to the stomach is stored in the relatively quiet body without being mixed. The fundic area contains only a pocket of gas. Food is gradually fed from the body into the antrum, where mixing does take place.

Gastric mixing

The strong antral peristaltic contractions mix the food with gastric secretions to produce chyme. Each antral peristaltic wave propels chyme forward toward the pyloric sphincter. Tonic contraction of the pyloric sphincter keeps it almost, but not completely, closed. The small opening is large enough for water and other fluids to pass through but too small for the thicker chyme, except when a strong antral peristaltic contraction pushes it through. Before more chyme can be squeezed out, the peristaltic wave reaches the pyloric sphincter and causes it to contract more forcefully, closing the exit and blocking further passage into the duodenum. The bulk of the antral chyme that was being propelled forward but failed to be pushed into the duodenum is stopped at the closed sphincter and folds back into the antrum, only to be propelled forward and tumbled back again as the new peristaltic wave advances (► Figure 15-7). This process, called **retropulsion**, thoroughly mixes the chyme in the antrum and thoroughly shears and grinds the chyme until the particles are small enough for emptying.

Clinical Connections

Cathy has a peptic ulcer, which essentially is damage to the stomach lining. While her stomach is empty she feels pain because the stomach acids irritate the ulcer area. With food in her stomach, the acids are essentially neutralized, so the irritation is not felt. The ulcer, if severe enough, can cause bleeding. This bleeding can be detected with a fecal occult blood test. The loss of blood could also account for her hypertension and reflex tachycardia.

Gastric emptying

In addition to mixing gastric contents, the antral peristaltic contractions are the driving force for gastric emptying. Of the 30 mL of chyme that the antrum can hold, usually only a few millilitres

- 1 A peristaltic contraction originates in the upper fundus and sweeps down toward the pyloric sphincter.
- 2 The contraction becomes more vigorous as it reaches the thick-muscled antrum.
- 3 The strong antral peristaltic contraction propels the chyme forward.
- 4 A small portion of chyme is pushed through the partially open sphincter into the duodenum. The stronger the antral contraction, the more chyme is emptied with each contractile wave.

- 5 When the peristaltic contraction reaches the pyloric sphincter, the sphincter is tightly closed and no further emptying takes place.
- 6 When chyme that was being propelled forward hits the closed sphincter, it is tossed back into the antrum. Mixing of chyme is accomplished as chyme is propelled forward and tossed back into the antrum with each peristaltic contraction, a process called retropulsion.

© 2016 Cengage

FIGURE 15-7 Gastric emptying and mixing as a result of antral peristaltic contractions

of antral contents are pushed into the duodenum with each peristaltic wave. However, the amount of chyme that escapes into the duodenum before the pyloric sphincter tightly closes depends largely on the strength of peristalsis. The intensity of antral peristalsis can vary markedly under the influence of different signals from both the stomach and the duodenum; thus, gastric emptying is regulated by both gastric and duodenal factors (Table 15-2). These factors influence the stomach's excitability by slightly depolarizing or hyperpolarizing the gastric smooth muscle. This excitability is a determinant of the degree of antral peristaltic activity. The greater the excitability, the more frequently the BER will generate action potentials, the greater the degree of peristaltic activity in the antrum, and the faster the rate of gastric emptying.

FACTORS IN THE STOMACH THAT INFLUENCE THE RATE OF GASTRIC EMPTYING

The main gastric factor that influences the strength of contraction is the amount of chyme in the stomach. Other things being equal, the stomach empties at a rate proportional to the volume of chyme in it at any given time. Stomach distension triggers increased gastric motility through a direct effect of stretch on the smooth muscle as well as through involvement of the intrinsic plexuses, the vagus nerve, and the stomach hormone *gastrin*. (The source, control, and other functions of this hormone are described in Section 15.8.)

Furthermore, the degree of fluidity of the chyme in the stomach influences gastric emptying. The stomach contents

must be converted into a finely divided, thick liquid form before emptying. The sooner the appropriate degree of fluidity can be achieved, the more rapidly the contents are ready to be evacuated.

FACTORS IN THE DUODENUM THAT INFLUENCE THE RATE OF GASTRIC EMPTYING

Despite these gastric influences, factors in the duodenum are of primary importance in controlling the rate of gastric emptying. The duodenum must be ready to receive the chyme and can delay gastric emptying by reducing peristaltic activity in the stomach until the duodenum is ready to accommodate more chyme. Even if the stomach is distended and its contents are in a liquid form, it cannot empty until the duodenum is ready to deal with the chyme.

The four most important duodenal factors that influence gastric emptying are *fat*, *acid*, *hypertonicity*, and *distension*. The presence of one or more of these stimuli in the duodenum activates the appropriate duodenal receptors, which trigger either a neural or a hormonal response that reduces gastric motility by reducing the excitability of the gastric smooth muscle. The subsequent reduction in antral peristaltic activity slows down the rate of gastric emptying.

- The *neural* response is mediated through both the intrinsic nerve plexuses (short reflex) and the autonomic nerves (long reflex). Collectively, these reflexes are called the **enterogastric reflex**.

■ **TABLE 15-2** Factors Regulating Gastric Motility and Emptying

Factors	Mode of Regulation	Effects on Gastric Motility and Emptying
Within the Stomach		
Volume of chyme	Distension has a direct effect on gastric smooth muscle excitability, as well as acting through the intrinsic plexuses, the vagus nerve, and gastrin	Increased volume stimulates motility and emptying
Degree of fluidity	Direct effect; contents must be in a fluid form to be evacuated	Increased fluidity allows more rapid emptying
Within the Duodenum		
Presence of fat, acid, hypertonicity, or distension	Initiates the enterogastric reflex or triggers the release of enterogastrones (cholecystokinin, secretin)	These factors in the duodenum inhibit further gastric motility and emptying until the duodenum has coped with factors already present
Within the Intestine		
Glucagon-like peptide-1 (GLP-1)	Inhibits gastric secretions, delays carbohydrate absorption	Slows motility and gastric emptying in the stomach
Gastric inhibitory peptide (GIP)	Possibly inhibits acid secretions	No effect on motility or emptying
Outside the Digestive System		
Emotion	Alters autonomic balance	Stimulates or inhibits motility and emptying
Intense pain	Increases sympathetic activity	Inhibits motility and emptying

© 2016 Cengage

- The *hormonal response* involves the release from the duodenal mucosa of several hormones collectively known as **enterogastrones**. The blood carries these hormones to the stomach, where they inhibit antral contractions to reduce gastric emptying. The two most important enterogastrones are **secretin** and **cholecystokinin (CCK)**. Secretin was the first hormone discovered (in 1902). Because it was a secretory product that entered the blood, it was termed *secretin*. The name *cholecystokinin* derives from the fact that this same hormone also causes contraction of the bile-containing gallbladder (*chole* means “bile”; *cysto* means “bladder”; and *kinin* means “contraction”). Secretin and CCK are major gastrointestinal hormones that perform other important functions in addition to serving as enterogastrones.

Let’s examine why it is important that each of these stimuli in the duodenum (fat, acid, hypertonicity, and distension) delays gastric emptying (acting through the enterogastric reflex or one of the enterogastrones).

- **Fat.** Fat is digested and absorbed more slowly than the other nutrients. Furthermore, fat digestion and absorption take place only within the lumen of the small intestine. Therefore, when fat is already in the duodenum, further gastric emptying of more fatty stomach contents into the duodenum is prevented until the small intestine has processed the fat that’s already there. In fact, fat is the most potent stimulus for inhibition of gastric motility. This is evident when you compare the rate of emptying of a high-fat meal (after six hours some of a bacon-and-eggs meal may still be in the stomach) with

that of a protein and carbohydrate meal (a meal of lean meat and potatoes may empty in three hours).

- **Acid.** Because the stomach secretes hydrochloric acid (HCl), highly acidic chyme is emptied into the duodenum, where it is neutralized by the sodium bicarbonate (NaHCO_3) secreted into the duodenal lumen, primarily from the pancreas. Unneutralized acid irritates the duodenal mucosa and inactivates the pancreatic digestive enzymes that are secreted into the duodenal lumen. Appropriately, therefore, unneutralized acid in the duodenum inhibits further emptying of acidic gastric contents until complete neutralization can be accomplished.
- **Hypertonicity.** As molecules of protein and starch are digested in the duodenal lumen, large numbers of amino acid and glucose molecules are released. If absorption of these amino acid and glucose molecules does not keep pace with the rate at which protein and carbohydrate digestion proceeds, these large numbers of molecules remain in the chyme and increase the osmolarity of the duodenal contents. Osmolarity depends on the number of molecules present, not on their size, and one protein molecule may be split into several hundred amino acid molecules, each of which has the same osmotic activity as the original protein molecule. The same holds true for one large starch molecule, which yields many smaller but equally osmotically active glucose molecules. Because water is freely diffusible across the duodenal wall, it enters the duodenal lumen from the plasma as the duodenal osmolarity rises. Large volumes of water entering

the intestine from the plasma lead to intestinal distension, and, more important, circulatory disturbances ensue because of the reduction in plasma volume. To prevent these effects, gastric emptying is reflexly inhibited when the osmolarity of the duodenal contents starts to rise. In this way, the amount of food entering the duodenum for further digestion into a multitude of osmotically active particles is reduced until absorption processes have had an opportunity to catch up.

- **Distension.** Too much chyme in the duodenum inhibits the emptying of even more gastric contents, giving the distended duodenum time to cope with the excess volume of chyme it already contains before it gets any more.

Gastric dumping syndrome (rapid gastric emptying) occurs when there is a rapid movement of stomach contents, mainly undigested, into the small intestine after eating. There are two types: early and late gastric dumping. Early gastric dumping begins during or right after a meal, with symptoms of nausea, vomiting, bloating, diarrhoea, dizziness, and fatigue. Late gastric dumping occurs one to three hours post-meal. Its symptoms include weakness, sweating, and dizziness.

It is not uncommon to have both types of gastric dumping problems, and the syndrome is typically diagnosed on the basis of symptoms. Gastric dumping syndrome is largely preventable, by avoiding certain foods and eating a balanced diet. Treatment includes adjustment to eating habits and medication. Severe conditions may be treated with medications that slow digestion, or with surgery as a last resort. This syndrome is most commonly associated with patients who have undergone gastric bypass surgery.

Emotions and gastric motility

Other factors unrelated to digestion, such as emotions, can also alter gastric motility by acting through the autonomic nerves to influence the degree of gastric smooth muscle excitability. Even though the effect of emotions on gastric motility varies from one person to another and is not always predictable, sadness and fear generally tend to decrease motility, whereas anger and aggression tend to increase it. In addition to emotional influences, intense pain from any part of the body tends to inhibit motility, not just in the stomach but throughout the digestive tract. This response is brought about by increased sympathetic activity.

Vomiting

The complex act of vomiting, also known as *emesis*, is coordinated by a **vomiting centre** in the medulla of the brain stem. Vomiting begins with a deep inspiration and closure of the glottis. The contracting diaphragm descends downward on the stomach while simultaneous contraction of the abdominal muscles compresses the abdominal cavity, increasing the intra-abdominal pressure and forcing the abdominal viscera upward. As the flaccid stomach is squeezed between the diaphragm from above and the compressed abdominal cavity from below, the gastric contents are forced upward through the relaxed sphincters

and oesophagus and out through the mouth. The glottis is closed, so vomited material does not enter the respiratory airways. Also, the uvula is raised to close off the nasal cavity. The vomiting cycle may be repeated several times until the stomach is emptied. Vomiting is usually preceded by profuse salivation, sweating, rapid heart rate, and the sensation of nausea, all of which are characteristic of a generalized discharge of the autonomic nervous system.

CAUSES OF VOMITING

Vomiting can be initiated by afferent input to the vomiting centre from a number of receptors throughout the body. The causes of vomiting include the following:

- Tactile (touch) stimulation of the back of the throat, which is one of the most potent stimuli. For example, sticking a finger in the back of the throat or even the presence of a tongue depressor or dental instrument in the back of the mouth is enough stimulation to cause gagging and even vomiting in some people.
- Irritation or distension of the stomach and duodenum
- Elevated intracranial pressure, such as that caused by cerebral haemorrhage. Thus, vomiting after a head injury is considered a bad sign; it suggests swelling or bleeding within the cranial cavity.
- Rotation or acceleration of the head producing dizziness, such as in motion sickness
- Chemical agents, including drugs or noxious substances that initiate vomiting (i.e., **emetics**) either by acting in the upper parts of the gastrointestinal tract or by stimulating chemoreceptors in a specialized **chemoreceptor trigger zone** next to the vomiting centre in the brain. Activation of this zone triggers the vomiting reflex. For example, chemotherapeutic agents used in treating cancer often cause vomiting by acting on the chemoreceptor trigger zone. As well, this region of the brain is associated with morning sickness during early pregnancy and vomiting during a hangover.
- Psychogenic vomiting induced by emotional factors, including those accompanying nauseating sights and odours and anxiety before taking an examination or in other stressful situations

EFFECTS OF VOMITING

With excessive vomiting, the body experiences large losses of secreted fluids and acids that normally would be reabsorbed. The resulting reduction in plasma volume can lead to dehydration and circulatory problems, and the loss of acid from the stomach can lead to metabolic alkalosis (p. 636).

Vomiting is not always harmful, however. Limited vomiting triggered by irritation of the digestive tract can be useful in removing noxious material from the stomach, rather than letting it stay and be absorbed. In fact, emetics are sometimes taken after accidental ingestion of a poison to quickly remove the offending substance from the body.

We have now completed our discussion of gastric motility and will shift to gastric secretion.

Gastric juice

The cells that secrete gastric juice are in the lining of the stomach, the gastric mucosa, which is divided into two distinct areas: (1) the **oxyntic mucosa**, which lines the body and fundus; and (2) the **pyloric gland area (PGA)**, which lines the antrum. The luminal surface of the stomach is pitted with deep pockets formed by infoldings of the gastric mucosa. The first part of these invaginations are called **gastric pits**, at the base of which lie the **gastric glands**. A variety of secretory cells line these invaginations, some exocrine and some endocrine or paracrine (■ Table 15-3). Let's look at the gastric exocrine secretory cells first.

Three types of gastric exocrine secretory cells are found in the walls of the pits and glands in the oxyntic mucosa.

- **Mucous cells** line the gastric pits and the entrance of the glands. They secrete a thin, watery *mucus*. (*Mucous* is the adjective; *mucus* is the noun.)
- The deeper parts of the gastric glands are lined by chief and parietal cells. The more numerous **chief cells** secrete the enzyme precursor *pepsinogen*.
- The **parietal (oxyntic) cells** secrete *HCl* and *intrinsic factor* (*oxyntic* means “sharp,” a reference to these cells’ potent *HCl* secretory product).
- These exocrine secretions are all released into the gastric lumen. Collectively, they make up the gastric digestive juice.

A few **stem cells** are also found in the gastric pits. These cells rapidly divide and serve as the parent cells of all new cells of the gastric mucosa. The daughter cells that result from cell division either migrate out of the pit to become surface epithelial cells or migrate down deeper to the gastric glands, where they differentiate into chief or parietal cells. Through this activity, the entire stomach mucosa is replaced about every three days. This frequent turnover is important, because the harsh acidic stomach contents expose the mucosal cells to lots of wear and tear.

Between the gastric pits, the gastric mucosa is covered by **surface epithelial cells**, which secrete a thick, viscous, alkaline mucus that forms a visible layer several millimetres thick over the surface of the mucosa.

The gastric glands of the PGA primarily secrete mucus and a small amount of pepsinogen; no acid is secreted in this area, in contrast to the oxyntic mucosa.

Let's consider these exocrine products and their roles in digestion in further detail.

Hydrochloric acid

The parietal cells actively secrete *HCl* into the lumen of the gastric pits, which in turn empty into the lumen of the stomach. As a result of this *HCl* secretion, the pH of the luminal contents falls as low as 2. Hydrogen ion (H^+) and chloride ion (Cl^-) are actively transported by separate pumps in the parietal cells’ plasma membrane. Hydrogen ion is actively transported against a tremendous concentration gradient, with the H^+ concentration being as much as 3 million times greater in the lumen than in the blood. Chloride is secreted by a secondary active transport

mechanism against a much smaller concentration gradient that's only 1.5 times greater in the lumen than in the blood.

MECHANISM OF H^+ AND Cl^- SECRETION

The secreted H^+ is not transported from the plasma but is derived instead from metabolic processes within the parietal cell (► Figure 15-8). Specifically, the H^+ to be secreted is derived from the breakdown of H_2O molecules into H^+ and OH^- (hydroxyl ions) within the parietal cells. This H^+ is secreted into the lumen by $\text{H}^+ - \text{K}^+$ **ATPase** in the parietal cell's luminal membrane. This primary active-transport carrier also pumps K^+ into the cell from the lumen—a mechanism similar to the $\text{Na}^+ - \text{K}^+$ ATPase pump you are already familiar with. The transported K^+ then passively leaks back into the lumen through luminal K^+ channels, leaving K^+ levels unchanged by the process of H^+ secretion.

Meanwhile, the OH^- generated by the breakdown of H_2O becomes neutralized through combining with a new H^+ generated from carbonic acid (H_2CO_3). The parietal cells contain an abundance of the enzyme *carbonic anhydrase*. In the presence of carbonic anhydrase, H_2O readily combines with CO_2 , which either has been produced within the parietal cell by metabolic processes or has diffused in from the blood. The combination of H_2O and CO_2 results in the formation of H_2CO_3 , which partially dissociates to yield H^+ and HCO_3^- . The generated H^+ in essence replaces the one secreted.

The generated HCO_3^- is moved into the plasma by a $\text{Cl}^- - \text{HCO}_3^-$ **exchanger** in the parietal cell's basolateral membrane. This exchanger transports Cl^- into the parietal cell by means of secondary active transport (p. 44). Driven by the gradient, this carrier moves HCO_3^- out of the cell into the plasma down its electrochemical gradient and simultaneously transports Cl^- from the plasma into the parietal cell against its electrochemical gradient. This exchanger builds up the concentration of Cl^- inside the parietal cell, establishing a Cl^- concentration gradient between the parietal cell and gastric lumen. Because of this concentration gradient and because the cell interior is negative compared with the luminal contents, the negatively charged Cl^- pumped into the cell by the basolateral exchanger diffuses out of the cell and moves down its electrochemical gradient through channels in the luminal membrane and into the gastric lumen—completing the Cl^- secretory process.

FUNCTIONS OF *HCL*

Hydrochloric acid performs the following specific functions that aid digestion:

1. Activates the enzyme precursor pepsinogen to become an active enzyme, pepsin, and provides an acid medium that is optimal for pepsin activity
2. Aids in the breakdown of connective tissue and muscle fibres, reducing large food particles into smaller particles
3. Denatures protein, that is, uncoils proteins from their highly folded final form, thus exposing more of the peptide bonds for enzymatic attack
4. Along with salivary lysozyme, kills most of the microorganisms ingested with food, although some escape and continue to grow and multiply in the large intestine

In oxyntic mucosa

In pyloric gland area

TABLE 15-3 Anatomy and Functions of Components of the Digestive System

Type of Secretory Cell	Product Secreted	Stimuli for Secretion	Function(s) of Secretory Product
Exocrine Cells			
Mucous cells	Alkaline mucus	Mechanical stimulation by contents	Protects mucosa against mechanical, pepsin, and acid injury
Chief cells	Pepsinogen	ACh, gastrin	When activated, begins protein digestion
Parietal cells	Hydrochloric acid	ACh, gastrin, histamine	Activates pepsinogen, breaks down connective tissue, denatures proteins, kills microorganisms
	Intrinsic factor		Facilitates absorption of vitamin B ₁₂
Endocrine/Paracrine Cells			
Enterochromaffin-like (ECL) cells	Histamine	ACh, gastrin	Stimulates parietal cells
G cells	Gastrin	Protein products, ACh	Stimulates parietal, chief, and ECL cells
D cells	Somatostatin	Acid	Inhibits parietal, G, and ECL cells

of mucus coating the stomach lining, but it does not affect pepsin activity in the lumen.

- Being alkaline, mucus helps protect against acid injury by neutralizing HCl in the vicinity of the gastric lining, but it does not interfere with the function of HCl in the lumen. Whereas the pH in the lumen may be as low as 2, the pH in the layer of mucus adjacent to the mucosal cell surface is about 7.

■ Clinical Connections

Mucus helps to protect the stomach wall from self-digestion. However, an *H. pylori* infection can compromise the protective mucus and cause a peptic ulcer. *H. pylori* can survive in the stomach by producing urease enzymes. These enzymes metabolize urea to carbon dioxide and ammonia. Excessive carbon dioxide production can lead to frequent belching, and the ammonia produced can help neutralize stomach acid. The ammonia also can damage the epithelial layer, which allows the *H. pylori* access to the underlying connective tissues. Once the mucous layer is compromised, pepsin and HCl can cause extensive damage to the stomach wall, creating the ulcer.

Intrinsic factor

Intrinsic factor, another secretory product of the parietal cells, is important in the absorption of vitamin B₁₂. This vitamin can be absorbed only when in combination with intrinsic factor. Binding of the intrinsic factor–vitamin B₁₂ complex with a special receptor located only in the terminal ileum—the last part of the small intestine—triggers the receptor-mediated endocytosis of the complex at this location.

Vitamin B₁₂ is essential for the normal formation of red blood cells.

Parietal and chief cells

In addition to the gastric exocrine secretory cells, certain secretory cells in the gastric glands release endocrine and paracrine regulatory factors, instead of products involved in the digestion of nutrients in the gastric lumen. The locations and secretions of these types of cells—G cells, enterochromaffin-like (ECL) cells, and D cells—are as follows (see also ■ Table 15-3):

- Endocrine cells known as **G cells** are found in the gastric pits only in the PGA; they secrete the hormone *gastrin* into the blood.
- **Enterochromaffin-like (ECL) cells** are dispersed among the parietal and chief cells in the gastric glands of the oxyntic mucosa; they secrete the paracrine *histamine*.
- **D cells** are scattered in glands near the pylorus but are more numerous in the duodenum; they secrete the paracrine *somatostatin*.

These three regulatory factors from the gastric pits, along with the neurotransmitter *acetylcholine* (ACh), primarily control the secretion of gastric digestive juices. Parietal cells have separate receptors for each of these chemical messengers. Three of

them—ACh, gastrin, and histamine—are stimulatory. They bring about increased secretion of HCl by promoting the insertion of additional H⁺–K⁺ ATPases into the parietal cells' plasma membranes. The fourth regulatory agent—somatostatin—inhibits HCl secretion. ACh and gastrin also increase pepsinogen secretion through their stimulatory effect on the chief cells. We now consider each of these chemical messengers in further detail (■ Table 15-3).

- Acetylcholine (ACh) is a neurotransmitter released from the intrinsic nerve plexuses in response to both short local reflexes and vagal stimulation. ACh stimulates both the parietal and chief cells as well as the G cells and ECL cells.
- The G cells secrete the hormone **gastrin** into the blood in response to protein products in the stomach lumen and in response to ACh. Like secretin and CCK, gastrin is a major gastrointestinal hormone. After being carried by the blood back to the body and fundus of the stomach, gastrin stimulates the parietal and chief cells, promoting secretion of a highly acidic gastric juice. In addition to directly stimulating the parietal cells, gastrin indirectly promotes HCl secretion by stimulating the ECL cells to release histamine. Gastrin is the main factor that brings about increased HCl secretion during meal digestion. Gastrin is also *trophic* (growth-promoting) to the mucosa of the stomach and small intestine, thereby maintaining their secretory capabilities.
- **Histamine**, a paracrine, is released from the ECL cells in response to ACh and gastrin. Histamine acts locally on nearby parietal cells to speed up HCl secretion.
- Somatostatin is released from the D cells in response to acid. It acts locally as a paracrine in negative-feedback fashion to inhibit secretion by the parietal cells, G cells, and ECL cells, thereby turning off the HCl-secreting cells and their most potent stimulatory pathway.

From this list, it is obvious not only that multiple chemical messengers influence the parietal and chief cells but also that these chemicals influence one another. Next, as we examine the phases of gastric secretion, you will see under what circumstances each of these regulatory agents is released.

Control of gastric secretion

The rate of gastric secretion can be influenced by (1) factors arising before food ever reaches the stomach, (2) factors resulting from the presence of food in the stomach, and (3) factors in the duodenum after food has left the stomach. Accordingly, gastric secretion is divided into three phases: the cephalic, gastric, and intestinal phases.

CEPHALIC PHASE

The *cephalic phase of gastric secretion* refers to the increased secretion of HCl and pepsinogen that occurs in feedforward fashion in response to various stimuli even before food reaches the stomach (*cephalic* means “head”). Thinking about, tasting, smelling, chewing, and swallowing food increase gastric secretion by vagal nerve activity in two ways. First, vagal stimulation

■ **TABLE 15-4** Stimulation of Gastric Secretion

© 2016 Cengage

of the intrinsic plexuses promotes increased secretion of ACh, which in turn leads to increased secretion of HCl and pepsinogen by the secretory cells. Second, vagal stimulation of the G cells within the PGA causes the release of gastrin, which in turn further enhances secretion of HCl and pepsinogen; the effect on HCl is strengthened due to gastrin promoting the release of histamine (■ Table 15-4).

GASTRIC PHASE

The *gastric phase of gastric secretion* begins when food actually reaches the stomach. Protein, especially peptide fragments, stomach distension, caffeine, and alcohol all act as stimuli in the stomach; they increase gastric secretion by way of overlapping efferent pathways. For example, protein in the stomach, the most potent stimulus, stimulates chemoreceptors that activate the intrinsic nerve plexuses, which in turn stimulate the secretory cells. Furthermore, protein brings about activation of the extrinsic vagal fibres to the stomach. Vagal activity further enhances intrinsic nerve stimulation of the secretory cells and triggers the release of gastrin. Protein also directly stimulates the release of gastrin. Gastrin, in turn, is a powerful stimulus for further HCl and pepsinogen secretion and also calls forth the release of histamine, which further increases HCl secretion. Through these synergistic and overlapping pathways, protein induces the secretion of a highly acidic, pepsin-rich gastric juice, which continues the digestion of the protein that first initiated the process (■ Table 15-4).

When the stomach is distended with protein-rich food that needs to be digested, these secretory responses are appropriate. Caffeine and, to a lesser extent, alcohol also stimulate the secretion of a highly acidic gastric juice, even when no food is present. This unnecessary acid can irritate the linings of the stomach and duodenum. For this reason, people with ulcers or gastric hyperacidity should avoid caffeinated and alcoholic beverages.

INTESTINAL PHASE

The *intestinal phase of gastric secretion* encompasses the factors originating in the small intestine that influence gastric secretion. Whereas the other phases are excitatory, this phase is inhibitory.

The intestinal phase is important in helping shut off the flow of gastric juices when chyme begins to be emptied into the small intestine, a topic to which we now turn.

Gastric secretion

You have learned about the factors that turn on gastric secretion before and during a meal, but how is the flow of gastric juices shut off when they are no longer needed? Gastric secretion is gradually reduced in three different ways as the stomach empties (■ Table 15-5):

- As the meal is gradually emptied into the duodenum, the major stimulus for enhanced gastric secretion—the presence of protein in the stomach—is withdrawn.
- After foods leave the stomach, gastric juices accumulate to such an extent that gastric pH falls very low. This fall in pH within the stomach lumen comes about largely because food proteins that had been buffering HCl are no longer present in the lumen as the stomach empties. (Recall that proteins serve as excellent buffers; p. 625.) Somatostatin is released in response to this high gastric acidity. In negative-feedback fashion, somatostatin's inhibitory effects bring about a decline in gastric secretion.
- The same stimuli that inhibit gastric motility (fat, acid, hypertonicity, or distension in the duodenum brought about by the emptying of stomach contents into the duodenum) inhibit gastric secretion as well. The enterogastric reflex and the enterogastrones suppress the gastric secretory cells, while they simultaneously reduce the excitability of the gastric smooth muscle cells. This inhibitory response is the intestinal phase of gastric secretion.

The gastric mucosal barrier

How can the stomach contain strong acid contents and proteolytic enzymes without destroying itself? Recall that mucus provides a protective coating. In addition, the mucosal lining provides other barriers to mucosal acid damage. First, the

luminal membranes of the gastric mucosal cells are almost impermeable to H^+ , so acid cannot penetrate into the cells and damage them. Furthermore, the lateral edges of these cells are joined near their luminal borders by tight junctions, so acid cannot diffuse between the cells from the lumen into the underlying submucosa (see ▶ Figure 15-2). The properties of the gastric mucosa that enable the stomach to contain acid without injuring itself constitute the **gastric mucosal barrier** (▶ Figure 15-10). These protective mechanisms are enhanced by the fact that the entire stomach lining is replaced every three days. Because of rapid mucosal turnover, cells are usually replaced before they are exposed to the wear and tear of harsh gastric conditions for long enough to suffer damage.

Despite the protection provided by mucus, the gastric mucosal barrier, and the frequent turnover of cells,

the protective barrier is occasionally broken, and the gastric wall is injured by the stomach's acidic and enzymatic contents. When this occurs, an erosion, or **peptic ulcer**, of the stomach wall results. Excessive gastric reflux into the oesophagus and dumping of excessive acidic gastric contents into the duodenum can lead to peptic ulcers in these locations as well. (For a further discussion of ulcers, see ▶ Concepts, Challenges, and Controversies, p. 670.)

We now turn to the remaining two digestive processes in the stomach, gastric digestion and absorption.

Carbohydrate digestion and protein digestion

Two separate digestive processes take place within the stomach. In the body of the stomach, food remains in a

The gastric mucosal barrier made up of the following components enables the stomach to contain acid without injuring itself:

- 1 The luminal membranes of the gastric mucosal cells are impermeable to H^+ so that HCl cannot penetrate into the cells.
- 2 The cells are joined by tight junctions that prevent HCl from penetrating between them.
- 3 A mucous coating over the gastric mucosa offers further protection.

FIGURE 15-10 Gastric mucosal barrier

semisolid mass, because peristaltic contractions in this region are too weak for mixing to occur. Because food is not mixed with gastric secretions in the body of the stomach, very little protein digestion occurs here. In the interior of the mass, however, carbohydrate digestion continues under the influence of salivary amylase. Even though acid inactivates salivary amylase, the unmixed interior of the food mass is free of acid.

Digestion by the gastric juice itself is accomplished in the antrum of the stomach, where the food is thoroughly mixed with HCl and pepsin, which begins protein digestion.

Alcohol and Aspirin absorption, but no food

No food or water is absorbed into the blood through the stomach mucosa. However, two noteworthy non-nutrient substances are absorbed directly by the stomach—*ethyl alcohol* and *aspirin*. Alcohol is somewhat lipid soluble, so it can diffuse through the lipid membranes of the epithelial cells that line the stomach and can enter the blood through the submucosal capillaries. Although alcohol can be absorbed by the gastric mucosa, it can be absorbed even more rapidly by the small-intestine mucosa, because the surface area for absorption in the small intestine is much greater than in the stomach. Therefore, alcohol absorption occurs more slowly if gastric emptying is delayed so that the alcohol remains longer in the more slowly absorbing stomach. Because fat is the most potent duodenal stimulus for inhibiting gastric motility, consuming fat-rich foods (e.g., whole milk, pizza, or nuts) before or during alcohol ingestion delays gastric emptying and prevents the alcohol from producing its effects as rapidly.

Another category of substances absorbed by the gastric mucosa includes weak acids, most notably *acetylsalicylic acid* (aspirin). In the highly acidic environment of the stomach lumen, weak acids are almost totally un-ionized; that is, the H^+ and the associated anion of the acid are bound together. In an un-ionized form, these weak acids are lipid soluble, so they can be absorbed quickly by crossing the plasma membranes of the epithelial cells that line the stomach. Most other drugs are not absorbed until they reach the small intestine, so they do not begin to take effect as quickly.

This completes our discussion of the stomach, and we now turn to the next part of the digestive tract—the small intestine and the accessory digestive organs that release their secretions into the small-intestine lumen.

Check Your Understanding 15.4

1. Describe the process of retropulsion, and explain what it accomplishes.
2. Discuss how food-related stimuli induce gastric secretions during the cephalic phase of gastric secretion.
3. Describe the mechanisms that protect the gastric mucosa from acid damage.

15.5 | Pancreatic and Biliary Secretions

When gastric contents are emptied into the small intestine, they are mixed not only with juice secreted by the small-intestine mucosa but also with the secretions of the exocrine pancreas and liver that are released into the duodenal lumen. Next we discuss the roles of each of these accessory digestive organs.

The pancreas

The pancreas is an elongated gland that lies behind and below the stomach, above the first loop of the duodenum (► Figure 15-11). This mixed gland contains both exocrine and endocrine tissue. The predominant exocrine part consists of grapelike clusters of secretory cells that form sacs known as **acini**, which connect to ducts that eventually empty into the duodenum. The smaller endocrine part consists of isolated islands of endocrine tissue, the islets of Langerhans, which are dispersed throughout the pancreas. The most important hormones secreted by the islet cells are insulin and glucagon (Chapter 6). The exocrine and endocrine pancreas are derived from different tissues during embryonic development and have only their location in common. Although both are involved with the metabolism of nutrient molecules, they have different functions under the control of different regulatory mechanisms.

THE EXOCRINE PANCREAS

The **exocrine pancreas** secretes a pancreatic juice consisting of two components: (1) *pancreatic enzymes* actively secreted by the *acinar cells* that form the acini, and (2) an *aqueous alkaline solution* actively secreted by the *duct cells* that line the pancreatic ducts. The aqueous (watery) alkaline component is rich in sodium bicarbonate ($NaHCO_3$).

Pancreatic enzymes, like pepsinogen, are stored within zymogen granules after being produced, then released by exocytosis as needed. These pancreatic enzymes are important because they can almost completely digest food in the absence of all other digestive secretions. The acinar cells secrete three different types of pancreatic enzymes capable of digesting all three categories of foodstuffs: (1) **proteolytic enzymes** for protein digestion, (2) **pancreatic amylase** for carbohydrate digestion, and (3) **pancreatic lipase** for fat digestion.

PANCREATIC PROTEOLYTIC ENZYMES

The three major pancreatic proteolytic enzymes are *trypsinogen*, *chymotrypsinogen*, and *procarboxypeptidase*, each of which is secreted in an inactive form. Of less importance are several nucleases and elastases. The most plentiful of these enzymes are trypsinogen (inactive) and trypsin (active). When **trypsinogen** is secreted into the duodenal lumen, it is activated to its active enzyme form, **trypsin**, by **enterokinase** (also known as **enteropeptidase**), an enzyme embedded in the luminal border of the cells that line the duodenal mucosa. Trypsin then autocatalytically activates more trypsinogen. Like pepsinogen, trypsinogen must remain inactive within the pancreas to prevent

© 2016 Cengage

► **FIGURE 15-11** Schematic representation of the exocrine and endocrine portions of the pancreas. The exocrine pancreas secretes into the duodenal lumen a digestive juice composed of digestive enzymes secreted by the acinar cells and an aqueous NaHCO_3 solution secreted by the duct cells. The endocrine pancreas secretes the hormones insulin and glucagon into the blood.

this proteolytic enzyme from digesting the proteins of the cells in which it is formed. Trypsinogen remains inactive, therefore, until it reaches the duodenal lumen, where enterokinase triggers the activation process, which then proceeds autocatalytically. As further protection, the pancreas also produces a chemical known as **trypsin inhibitor**, which blocks trypsin's actions if spontaneous activation of trypsinogen inadvertently occurs within the pancreas.

the pancreatic juice in an active form, because active amylase does not endanger the secretory cells. These cells do not contain any polysaccharides.

PANCREATIC LIPASE

Pancreatic lipase is extremely important because, throughout the entire digestive system, it is the only enzyme secreted that can digest fat. (Insignificant amounts of lipase are secreted in the

Chymotrypsinogen and **procarboxypeptidase**, the other pancreatic proteolytic enzymes, are converted by trypsin to their active forms, **chymotrypsin** and **carboxypeptidase**, respectively, within the duodenal lumen. Once enterokinase has activated some of the trypsin, trypsin then carries out the rest of the activation process.

Each of these proteolytic enzymes attacks different peptide linkages. The end products that result from this action are a mixture of small peptide chains and amino acids. Mucus secreted by the intestinal cells protects against digestion of the small-intestine wall by the activated proteolytic enzymes.

PANCREATIC AMYLASE

Like salivary amylase, pancreatic amylase contributes to carbohydrate digestion by converting polysaccharides into the disaccharide maltose. Pancreatic amylase hydrolyzes starches, glycogen, and most other carbohydrates, with the exception of cellulose. Amylase is secreted in

Why It Matters Pancreatic Insufficiency

When pancreatic enzymes are deficient, digestion of food is incomplete. Because the pancreas is the only significant source of lipase, pancreatic enzyme deficiency results in serious maldigestion of fats. The main clinical manifestation of pancreatic exocrine insufficiency is **steatorrhea**,

or excessive undigested fat in the feces. Up to 60 to 70 percent of the ingested fat may be excreted in the feces. Digestion of protein and carbohydrates is impaired to a lesser degree because salivary, gastric, and small-intestinal enzymes contribute to the digestion of these two foodstuffs.

saliva and gastric juice in humans.) Pancreatic lipase hydrolyzes dietary triglycerides into monoglycerides and free fatty acids, which are the absorbable units of fat. Like amylase, lipase is secreted in its active form because there is no risk of pancreatic self-digestion by lipase. Triglycerides are not a structural component of pancreatic cells.

PANCREATIC AQUEOUS ALKALINE SECRETION

Pancreatic enzymes function best in a neutral or slightly alkaline environment, yet the highly acidic gastric contents are emptied into the duodenal lumen in the vicinity of pancreatic enzyme entry into the duodenum. This acidic chyme must be neutralized quickly in the duodenal lumen, not only to allow optimal functioning of the pancreatic enzymes but also to prevent acid damage to the duodenal mucosa. The alkaline (NaHCO_3 -rich) fluid secreted by the pancreatic duct cells into the duodenal lumen serves the important function of neutralizing the acidic chyme as it empties into the duodenum from the stomach. This aqueous NaHCO_3 secretion is by far the largest component of pancreatic secretion. The volume of pancreatic secretion ranges between 1 and 2 L per day, depending on the type and degree of stimulation.

Pancreatic exocrine secretion

Pancreatic exocrine secretion is regulated primarily by hormonal mechanisms. A small amount of parasympathetically induced pancreatic secretion occurs during the cephalic phase of digestion, with a further token increase occurring during the gastric phase in response to gastrin. However, the predominant stimulation of pancreatic secretion occurs during the intestinal phase of digestion when chyme is in the small intestine. The release of the two major enterogastrones, secretin and cholecystokinin (CCK), in response to chyme in the duodenum plays the central role in controlling pancreatic secretion (► Figure 15-12).

ROLE OF SECRETIN IN PANCREATIC SECRETION

Of the factors that stimulate enterogastrone release (fat, acid, hypertonicity, and distension), the primary stimulus specifically for secretin release is acid in the duodenum. Secretin is secreted by the duodenal and jejunal mucosa in response to the release of acid. Secretin, in turn, is carried by the blood to the pancreas, where it stimulates the duct cells to markedly increase their secretion of a NaHCO_3 -rich aqueous fluid into the duodenum. Even though other stimuli may cause the release of secretin, it is appropriate that the most potent stimulus is acid, because secretin promotes the alkaline pancreatic secretion that neutralizes the acid. This mechanism provides a control system

for maintaining neutrality of the chyme in the intestine. The amount of secretin released is proportional to the amount of acid that enters the duodenum, so the amount of NaHCO_3 secreted parallels the duodenal acidity.

ROLE OF CCK IN PANCREATIC SECRETION

Cholecystokinin (CCK) is important in regulating pancreatic digestive enzyme secretion. The main stimulus for release of CCK from the duodenal mucosa is the presence of fat and, to a lesser extent, protein products. The circulatory system transports CCK to the pancreas, where it stimulates the pancreatic acinar cells to increase digestive enzyme secretion. Among these enzymes are lipase and the proteolytic enzymes, which further digest the fat and protein that initiated the response and also help digest carbohydrate. In contrast to fat and protein, carbohydrate does not have any direct influence on pancreatic digestive enzyme secretion.

All three types of pancreatic digestive enzymes are packaged together in the zymogen granules, so all the pancreatic enzymes are released together on exocytosis of the granules. Therefore, even though the *total amount* of enzymes released varies depending on the type of meal consumed (the most being secreted in response to fat), the *proportion* of enzymes released does not vary on a meal-to-meal basis. That is, a high-protein meal does not cause the release of a greater proportion of proteolytic enzymes. Evidence suggests, however, that long-term adjustments in the proportion of the types of enzymes produced may occur as an adaptive response to a prolonged change in diet.

► FIGURE 15-12 Hormonal control of pancreatic exocrine secretion

Ulcers: When Bugs Break the Barrier

PEPTIC ULCERS ARE EROSIONS that typically begin in the mucosal lining of the stomach and may penetrate into the deeper layers of the stomach wall. They occur when the gastric mucosal barrier is disrupted, and thus pepsin and hydrochloric acid act on the stomach wall instead of on food in the lumen. Frequent backflow of acidic gastric juices into the oesophagus or excess unneutralized acid from the stomach in the duodenum can lead to peptic ulcers in these sites as well.

Until recently, the exact cause of ulcers was unknown, but in a surprising discovery in the early 1990s, the bacterium *Helicobacter pylori* was pinpointed as the cause of more than 80 percent of all peptic ulcers. Thirty percent of the population harbours *H. pylori*. Those who have this slow bacterium have 3 to 12 times greater risk of developing an ulcer within 10 to 20 years of acquiring the infection than those without the bacterium. They are also at increased risk of developing stomach cancer.

For years, scientists had overlooked the possibility that ulcers could be triggered by an infectious agent, because bacteria typically cannot survive in a strongly acidic environment such as the stomach lumen. An exception, *H. pylori* exploits several strategies to survive in this hostile environment. First, these organisms are motile, being equipped with four to six flagella (whiplike appendages; see the accompanying photo), which enable them to tunnel through and take up residence under the stomach's thick layer of alkaline mucus. Here they are protected from the highly acidic gastric contents. Furthermore, *H. pylori* preferentially settles in the antrum, which has no acid-producing parietal cells, although HCl from the upper parts of the stomach does reach the antrum. Also, these bacteria produce *urease*, an enzyme that breaks down urea, an end product of protein metabolism, into ammonia (NH₃) and CO₂. Ammonia serves as a buffer (p. 631) that neutralizes stomach acid locally in the vicinity of the *H. pylori*.

H. pylori contributes to ulcer formation in part by secreting toxins that cause a persistent inflammation, or *chronic superficial gastritis*, at the site it colonizes. *H. pylori* further weakens the gastric mucosal barrier by disrupting the tight junctions between the gastric epithelial cells, thereby making the gastric mucosa leakier than normal.

Alone or in conjunction with this infectious culprit, other factors are known to contribute to ulcer formation. Frequent exposure to some chemicals can break the gastric mucosal barrier; the most important of these are ethyl alcohol and nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin, ibuprofen, or more potent medications for the treatment of arthritis or other chronic inflammatory processes. The barrier frequently breaks in patients with preexisting debilitating conditions, such as severe injuries or infections. Persistent stressful situations are frequently associated with ulcer formation, presumably because emotional response to stress can stimulate excessive gastric secretion.

© A.B. DOWSETT/Getty Images

Helicobacter Pylori. *Helicobacter pylori*, the bacterium responsible for most cases of peptic ulcers, has flagella that enable it to tunnel beneath the protective layer of mucus that coats the stomach lining.

When the gastric mucosal barrier is broken, acid and pepsin diffuse into the mucosa and underlying submucosa, with serious pathophysiological consequences. The surface erosion, or ulcer, progressively enlarges as increasing levels of acid and pepsin continue to damage the stomach wall. Two of the most serious consequences of ulcers are (1) haemorrhage, resulting from damage to submucosal capillaries, and (2) perforation, or complete erosion through the stomach wall, resulting in the escape of potent gastric contents into the abdominal cavity.

Treatment of ulcers includes antibiotics, H₂ histamine receptor blockers, and proton pump inhibitors. With the discovery of the infectious component of most ulcers, antibiotics are now a treatment of choice. The other drugs are also used alone or in combination with antibiotics.

Two decades before the discovery of *H. pylori*, researchers discovered an antihistamine (*cimetidine*) that specifically blocks H₂ receptors, the type of receptors that bind histamine released from the stomach. These receptors differ from H₁ receptors that bind the histamine involved in allergic respiratory disorders. Accordingly, traditional antihistamines used for respiratory allergies (such as hay fever and asthma) are not effective against ulcers, nor is cimetidine useful for respiratory problems.

Another recent class of drugs used in treating ulcers inhibits acid secretion by directly blocking the pump that transports H⁺ into the stomach lumen. These so-called proton-pump inhibitors (H⁺ is a naked proton without its electron) help reduce the corrosive effect of HCl on the exposed tissue.

For example, with a long-term switch to a high-protein diet, a greater proportion of proteolytic enzymes are produced. CCK may play a role in the adaptation of pancreatic digestive enzymes to changes in diet.

Just as gastrin is trophic to the stomach and small intestine, CCK and secretin exert trophic effects on the exocrine pancreas to maintain its integrity.

We now look at the contributions of the remaining accessory digestive unit: the liver and gallbladder.

The liver

Besides pancreatic juice, the other secretory product emptied into the duodenal lumen is **bile**. The **biliary system** includes the *liver*, the *gallbladder*, and associated ducts.

LIVER FUNCTIONS

The **liver** is the largest and most important metabolic organ in the body; it can be viewed as the body's major biochemical factory. Its importance to the digestive system is its secretion of *bile salts*, which aid fat digestion and absorption. The liver also performs a wide variety of functions not related to digestion, including the following:

1. Metabolic processing of the major categories of nutrients (carbohydrates, proteins, and lipids) after their absorption from the digestive tract
2. Detoxifying or degrading body wastes and hormones, as well as drugs and other foreign compounds
3. Synthesizing plasma proteins, including those needed for blood clotting and those that transport steroid and thyroid hormones and cholesterol in the blood
4. Storing glycogen, fats, iron, copper, and many vitamins
5. Activating vitamin D, which the liver does in conjunction with the kidneys
6. Removing bacteria and "worn-out" red blood cells, thanks to its resident macrophages (p. 447)
7. Excreting cholesterol and bilirubin, the latter being a breakdown product derived from the destruction of worn-out red blood cells

Given this wide range of complex functions, there is amazingly little specialization among cells within the liver. Each liver cell, or **hepatocyte**, performs the same wide variety of metabolic and secretory tasks (*hepato* means "liver"; *cyte* means "cell"). The specialization comes from the highly developed organelles within each hepatocyte. The only liver function not accomplished by the hepatocytes is the phagocytic activity carried out by the resident macrophages, which are known as **Kupffer cells**.

LIVER BLOOD FLOW

To carry out these wide-ranging tasks, the anatomic organization of the liver permits each hepatocyte to be in direct contact with blood from two sources: arterial blood coming from the aorta and venous blood coming directly from the digestive tract. Approximately 1 L of blood flows from the portal vein

into the liver each minute. Another 350 mL flow into the liver each minute from the hepatic artery. Like other cells, the hepatocytes receive fresh arterial blood via the hepatic artery, which supplies their oxygen and delivers blood-borne metabolites for hepatic processing. Venous blood also enters the liver by the **hepatic portal system**, a unique and complex vascular connection between the digestive tract and liver (► Figure 15-13). The

The liver receives blood from two sources:

1a Arterial blood, which provides the liver's O₂ supply and carries blood-borne metabolites for hepatic processing, is delivered by the **hepatic artery**.

1b Venous blood draining the digestive tract is carried by the **hepatic portal vein** to the liver for processing and storage of newly absorbed nutrients.

2 Blood leaves the liver via the **hepatic vein**.

► **FIGURE 15-13** Schematic representation of liver blood flow

veins draining the digestive tract do not directly join the inferior vena cava, the large vein that returns blood to the heart. Instead, the veins from the stomach and intestine enter the hepatic portal vein, which carries the products absorbed from the digestive tract directly to the liver for processing, storage, or detoxification before they gain access to the general circulation. Within the liver, the portal vein once again breaks up into a capillary network (the liver *sinusoids*) to permit exchange between the blood and hepatocytes before draining into the hepatic vein, which joins the inferior vena cava.

Liver lobules

The liver is organized into functional units known as **lobules**, which are hexagonal arrangements of tissue surrounding a central vein (► Figure 15-14a). At each of the six outer corners of the lobule are three vessels: a branch of the hepatic artery, a branch of the hepatic portal vein, and a bile duct. Blood from the branches of both the hepatic artery and the portal vein flows from the periphery of the lobule into large, expanded capillary spaces called **sinusoids**, which run between rows of liver cells to the central vein like spokes on a bicycle wheel (► Figure 15-14b). The Kupffer cells line the sinusoids and engulf and destroy old red blood cells and bacteria that pass through in the blood. The hepatocytes are arranged between the sinusoids in plates two cell layers thick, so that each lateral edge faces a sinusoidal pool of blood. The central veins of all the liver lobules converge to form the hepatic vein, which carries the blood away from the liver. The thin bile-carrying channel, a **bile canaliculus**, runs between the cells within each hepatic plate. Hepatocytes continuously secrete bile into these thin

channels, which carry the bile to a bile duct at the periphery of the lobule. The bile ducts from the various lobules converge to eventually form the *common bile duct*, which transports the bile from the liver to the duodenum. Each hepatocyte is in contact with a sinusoid on one side and a bile canaliculus on the other side.

Bile

The opening of the bile duct into the duodenum is guarded by the **sphincter of Oddi**, also called the hepatopancreatic sphincter, which prevents bile from entering the duodenum, except during digestion of meals (► Figure 15-15). When this sphincter is closed, most of the bile secreted by the liver is diverted back up into the **gallbladder**, a small, saclike structure tucked beneath but not directly connected to the liver. The bile is stored there until needed in the duodenum. The gallbladder can hold about 50 mL. Thus, bile is not transported directly from the liver to the gallbladder. The bile is subsequently stored and concentrated in the gallbladder between meals. After a meal, bile enters the duodenum as a result of the combined effects of gallbladder emptying and increased bile secretion by the liver. The amount of bile secreted per day ranges from 250 mL to 1 L, depending on the degree of stimulation.

Bile salts

Bile contains several organic constituents, namely *bile salts*, *cholesterol*, *lecithin*, and *bilirubin* (all derived from hepatocyte activity) in an *aqueous alkaline fluid* (added by the duct cells) similar to the pancreatic NaHCO_3 secretion. Even though bile does not

► FIGURE 15-14 Anatomy of the liver. (a) Hepatic lobule. (b) Wedge of a hepatic lobule

► **FIGURE 15-15 Enterohepatic circulation of bile salts.** The majority of bile salts are recycled between the liver and small intestine through the enterohepatic circulation (blue arrows). After participating in fat digestion and absorption, most bile salts are reabsorbed by active transport in the terminal ileum and returned through the hepatic portal vein to the liver, which resecreted them in the bile.

contain any digestive enzymes, it is important for the digestion and absorption of fats, primarily through the activity of bile salts.

Bile salts are derivatives of cholesterol. They are actively secreted into the bile and eventually enter the duodenum along with the other biliary constituents. Following their participation in fat digestion and absorption, most bile salts are reabsorbed into the blood by special active-transport mechanisms located in the terminal ileum. From here, bile salts are returned by the hepatic portal system to the liver, which resecreted them into the bile. This recycling of bile salts (and some of the other biliary constituents) between the small intestine and liver is called the **enterohepatic circulation** (*entero* means “intestine”; *hepatic* means “liver”) (► Figure 15-15).

The total amount of bile salts in the body averages about 3–4 g, yet 3–15 g of bile salts may be emptied into the duodenum in a single meal. Obviously, bile salts must be recycled many

times per day. Usually, only about 5 percent of the secreted bile escapes into the feces daily. These lost bile salts are replaced by new bile salts synthesized by the liver; in this way, the size of the pool of bile salts is kept constant.

Bile salts and fat digestion and absorption

Bile salts aid fat digestion through their detergent action (emulsification) and facilitate fat absorption by participating in the formation of micelles. Both functions are related to the structure of bile salts. Let’s see how.

DETERGENT ACTION OF BILE SALTS

The term **detergent action** refers to bile salts’ ability to convert large fat globules into a **lipid emulsion** consisting of many small fat droplets, each about 1 mm in diameter. Suspended in the aqueous chyme, the lipid emulsion increases the surface area of fat droplets that are available for attack by pancreatic lipase. Fat globules, no matter their size, are made up primarily of undigested triglyceride molecules. To digest fat, lipase must come into direct contact with the triglyceride molecule. Because triglycerides are not soluble in water, they tend to aggregate into large droplets in the watery environment of the small-intestine lumen. If bile salts did not emulsify these large droplets, lipase could act on the triglyceride molecules only at the surface of the large droplets, and fat digestion would be greatly prolonged.

Bile salts exert a detergent action similar to that of the detergent you use to break up grease when you wash dishes. A bile salt molecule contains a lipid-soluble part (a steroid derived from cholesterol) plus a negatively charged, water-soluble part. Bile salts *adsorb* on the surface of a fat droplet; that is, the lipid-soluble part of the bile salt dissolves in the fat droplet, leaving the charged water-soluble part

projecting from the surface of the droplet (► Figure 15-16a). This detergent-like action on the fat decreases the surface tension of the particle, increasing the ease of breakdown. Intestinal mixing movements break up large fat droplets into smaller ones. These small droplets would quickly recombine were it not for bile salts adsorbing on their surface and creating a shell of water-soluble negative charges on the surface of each little droplet. Because like charges repel, these negatively charged groups on the droplet surfaces cause the fat droplets to repel one another (► Figure 15-16b). This electrical repulsion prevents the small droplets from recombining into large fat droplets, and thus produces a lipid emulsion that increases the surface area available for lipase action.

Although bile salts increase the surface area available for attack by pancreatic lipase, lipase alone cannot penetrate the layer of bile salts adsorbed on the surface of the small emulsified fat droplets. Therefore, the pancreas secretes the polypeptide **colipase** along with lipase. Colipase binds both to lipase and to

(a) Structure of bile salts and their adsorption on the surface of a small lipid droplet

© 2016 Cengage

(b) Formation of a lipid emulsion through the action of bile salts

► **FIGURE 15-16 Schematic structure and function of bile salts.** (a) A bile salt consists of a lipid-soluble part that dissolves in the fat droplet and a negatively charged, water-soluble part that projects from the surface of the droplet. (b) When a large fat droplet is broken up into smaller fat droplets by intestinal contractions, bile salts adsorb on the surface of the small droplets, creating shells of negatively charged, water-soluble bile salt components that cause the fat droplets to repel one another. This emulsifying action holds the fat droplets apart and prevents them from recoalescing, thereby increasing the surface area of exposed fat available for digestion by pancreatic lipase.

has both a lipid-soluble and a water-soluble part, whereas cholesterol is almost totally insoluble in water. In a **micelle**, the bile salts and lecithin aggregate in small clusters with their fat-soluble parts huddled together in the middle to form a hydrophobic (water-fearing) core, while their water-soluble parts form an outer hydrophilic (water-loving) shell (► Figure 15-17). A micelle is 3–10 nm in diameter, about one-millionth the size of an emulsified lipid droplet. Micelles, being water soluble by virtue of their hydrophilic shells, can dissolve water-insoluble (and hence lipid-soluble) substances in their lipid-soluble cores. Micelles thus provide a handy vehicle for carrying water-insoluble substances through the watery luminal contents. The most important lipid-soluble substances carried within micelles are the products of fat digestion (monoglycerides and free fatty acids) as well as fat-soluble vitamins, which are all transported to their sites of absorption by this means. If they did not hitch a ride in the water-soluble micelles, these nutrients would float on the surface of the aqueous chyme (just as oil floats on top of water), never reaching the absorptive surfaces of the small intestine.

In addition, cholesterol, a highly water-insoluble substance, dissolves in the micelle's hydrophobic core. This mechanism is important in cholesterol homeostasis. The amount of cholesterol that can be carried in micellar formation depends on the relative amount of bile salts and lecithin in comparison to cholesterol.

Bilirubin

Bilirubin, the other major constituent of bile, does not play a role in digestion at all; instead it is a waste product excreted in the bile. Bilirubin is the primary bile pigment derived from the

breakdown of worn-out red blood cells. The typical lifespan of a red blood cell in the circulatory system is 120 days. Worn-out red blood cells are removed from the blood by the macrophages that line the liver sinusoids and reside in other areas in the body. Bilirubin is the end product from degradation of the heme (iron-containing) part of the haemoglobin contained within these old red blood cells (p. 437). This bilirubin

the bile salts at the surface of the fat droplets, thereby anchoring lipase to its site of action.

MICELLAR FORMATION

Bile salts—along with cholesterol and lecithin, which are also constituents of bile—play an important role in facilitating fat absorption through micellar formation. Like bile salts, lecithin

When cholesterol secretion by the liver is out of proportion to bile salt and lecithin secretion (either too much cholesterol or too little bile salts and lecithin), the excess cholesterol in the bile precipitates into microcrystals that can aggregate into **gallstones**. One treatment of cholesterol-containing gallstones involves ingestion of bile salts to increase

the bile salt pool in an attempt to dissolve the cholesterol stones. Only about 75 percent of gallstones are derived from cholesterol, however. The other 25 percent are made up of abnormal precipitates of another bile constituent, bilirubin.

is extracted from the blood by the hepatocytes and is actively excreted into the bile.

Bilirubin is a yellow pigment that gives bile its yellow colour. Within the intestinal tract, this pigment is modified by bacterial enzymes, giving rise to the characteristic brown colour of feces. When bile secretion does not occur, as when the bile duct is completely obstructed by a gallstone, the feces are greyish white. A small amount of bilirubin is normally reabsorbed by the intestine back into the blood, and when it is eventually excreted in the urine, it is largely responsible for the urine's yellow colour. The kidneys cannot excrete bilirubin until after it has been modified during its passage through the liver and intestine.

Clinical Note If bilirubin is formed more rapidly than it can be excreted, it accumulates in the body and causes **jaundice**. Patients with this condition appear yellowish, and this colour is

most readily seen in the whites of their eyes. Jaundice can be brought about in three different ways:

1. *Prehepatic* (the problem occurs “before the liver”), or *haemolytic, jaundice* is due to excessive breakdown (haemolysis) of red blood cells, which results in the liver being presented with more bilirubin than it is capable of excreting.
2. *Hepatic* (the problem is the liver) *jaundice* occurs when the liver is diseased and cannot deal with even the normal load of bilirubin.
3. *Posthepatic* (the problem occurs “after the liver”), or *obstructive, jaundice* occurs when the bile duct is obstructed, such as by a gallstone, so that bilirubin cannot be eliminated in the feces.

Secretion

Bile secretion may be increased by chemical, hormonal, and neural mechanisms:

- *Chemical mechanism (bile salts)*. Any substance that increases bile secretion by the liver is called a **choleretic**. The most potent choleretic is bile salts themselves. Between meals, bile is stored in the gallbladder, but during a meal, bile is emptied into the duodenum as the gallbladder contracts. After bile salts participate in fat digestion and absorption, they are reabsorbed and returned by the enterohepatic circulation to the liver, where they act as potent choleretics to stimulate further bile secretion. Therefore, during a meal, when bile salts are needed and being used, bile secretion by the liver is enhanced.
- *Hormonal mechanism (secretin)*. Besides increasing the aqueous NaHCO_3 secretion by the pancreas, secretin stimulates an aqueous alkaline bile secretion by the liver ducts without any corresponding increase in bile salts.
- *Neural mechanism (vagus nerve)*. Vagal stimulation of the liver plays a minor role in bile secretion during the cephalic phase of digestion, promoting an increase in liver bile flow before food ever reaches the stomach or intestine.

The gallbladder

Even though the factors just described increase bile secretion by the liver during and after a meal, bile secretion by the liver occurs continuously. Between meals, the secreted bile is shunted into

KEY

FIGURE 15-17 A micelle. Bile constituents (bile salts, lecithin, and cholesterol) aggregate to form micelles that consist of a hydrophilic (water-loving) shell and a hydrophobic (water-fearing) core. Because the outer shell of a micelle is water soluble, the products of fat digestion, which are not water soluble, can be carried through the watery luminal contents to the absorptive surface of the small intestine by dissolving in the micelle's lipid-soluble core. An emulsified fat droplet ranges in diameter from 200 to 5000 nm (average 1000 nm) compared to a micelle, which is 3 to 10 nm in diameter.

the gallbladder, where it is stored and concentrated. Active transport of salt out of the gallbladder, with water following osmotically, results in a 5 to 10 times concentration of the organic constituents.

Because the gallbladder stores this concentrated bile, it is the primary site for precipitation of concentrated bile constituents into gallstones. Fortunately, the gallbladder does not play an essential digestive role, so its removal as a treatment for gallstones or other gallbladder disease presents no particular problem. The bile secreted between meals is stored instead in the common bile duct, which becomes dilated.

During digestion of a meal, when chyme reaches the small intestine, the presence of food, especially fat products, in the duodenal lumen triggers the release of CCK. This hormone stimulates contraction of the gallbladder and relaxation of the sphincter of Oddi, so bile is discharged into the duodenum, where it appropriately aids in the digestion and absorption of the fat that initiated the release of CCK.

Hepatitis and cirrhosis

Hepatitis is an inflammatory disease of the liver that results from a variety of causes, including viral infection or exposure to toxic agents such as alcohol, carbon tetrachloride, and certain tranquilizers. Hepatitis ranges in severity from mild, reversible symptoms to acute, massive liver damage, with possible imminent death resulting from acute hepatic failure.

Repeated or prolonged hepatic inflammation, usually in association with chronic alcoholism, can lead to **cirrhosis**, a condition in which damaged hepatocytes are permanently replaced by connective tissue. Liver tissue has the ability to regenerate, normally undergoing a gradual turnover of cells. If part of the hepatic tissue is destroyed, the lost tissue can be replaced by an increase in the rate of cell division. There is a limit, however, to how rapidly hepatocytes can be replaced. In addition to hepatocytes, a small number of fibroblasts (connective tissue cells) are dispersed between the hepatic plates and form a supporting framework for the liver. If the liver is exposed to toxic substances, such as alcohol, so often that new hepatocytes cannot be generated rapidly enough to replace the damaged cells, the sturdier fibroblasts take advantage of the situation and overproduce. This extra connective tissue leaves little space for the hepatocytes' regrowth. Thus, as cirrhosis develops slowly over time, active liver tissue is gradually reduced, leading eventually to chronic liver failure.

This completes our discussion of the accessory digestive organs that empty their exocrine products into the small-intestine lumen. We now focus on the functions of the small intestine itself.

15.6 | Small Intestine

The **small intestine** is the site where most digestion and absorption take place. No further digestion is accomplished after the luminal contents pass beyond the small intestine, nor does further absorption of ingested nutrients occur, although the large intestine does absorb small amounts of salt and water. The small intestine lies coiled within the abdominal cavity, extending between the stomach and large intestine. It is roughly divided into three segments: the **duodenum**, the **jejunum**, and the **ileum**.

In this section we examine the small intestine in terms of motility, secretion, digestion, and absorption, as we have for the other digestive organs. Small-intestine motility includes *segmentation* and the *migrating motility complex*. Let's consider segmentation first.

Segmentation

Segmentation, the small intestine's primary method of motility during digestion of a meal, both mixes and slowly propels the chyme. When a portion of the small intestine becomes distended (stretched) with the chyme, the stretch of the intestine begins localized concentric contractions, which occur at regular intervals. This consists of oscillating, ringlike contractions of the circular smooth muscle along the small intestine's length; between the contracted segments are relaxed areas containing a small bolus of chyme. The contractile rings occur every few centimetres, dividing the small intestine into segments like a chain of sausages. These contractile rings do not sweep along the length of the intestine as peristaltic waves do. Rather, after a brief period of time, the contracted segments relax, and ringlike contractions appear in the previously relaxed areas (▶ Figure 15-18). The new contraction forces the chyme in a previously relaxed segment to move in both directions into the now relaxed adjacent segments. A newly relaxed segment therefore receives chyme from both the contracting segment immediately ahead of it and the one immediately behind it. Shortly thereafter, the areas of contraction and relaxation alternate again. In this way, the chyme is chopped, churned, and thoroughly mixed. These contractions can be compared to squeezing a pastry tube with your hands to mix the contents.

INITIATION AND CONTROL OF SEGMENTATION

Segmentation contractions are initiated by the small intestine's pacemaker cells, which produce a basic electrical rhythm (BER) similar to the gastric BER that governs peristalsis in the stomach. If the small-intestine BER brings the circular smooth muscle layer to threshold, segmentation contractions are induced, with the frequency of segmentation following the frequency of the BER. The frequency of contraction in the duodenum and jejunum is about 12 per minute, while in the terminal ileum the frequency drops to about 9 per minute.

The circular smooth muscle's degree of responsiveness and thus the intensity of segmentation contractions can be influenced by distension of the intestine, by the hormone gastrin, and by extrinsic nerve activity. All these factors influence the

► **FIGURE 15-18 Segmentation.** Segmentation consists of ringlike contractions along the length of the small intestine. Within a matter of seconds, the contracted segments relax, and the previously relaxed areas contract. These oscillating contractions thoroughly mix the chyme within the small-intestine lumen.

excitability of the small-intestine smooth muscle cells by moving the starting potential around which the BER oscillates closer to or farther from the threshold. Segmentation is slight or absent between meals but becomes very vigorous immediately after a meal. Both the duodenum and the ileum start to segment simultaneously when the meal first enters the small intestine. The duodenum starts to segment primarily in response to local distension caused by the presence of chyme. Segmentation of the empty ileum, in contrast, is brought about by gastrin secreted in response to the presence of chyme in the stomach, a mechanism known as the **gastroileal reflex**. Extrinsic nerves can modify the strength of these contractions. Parasympathetic stimulation enhances segmentation, whereas sympathetic stimulation depresses segmental activity.

FUNCTIONS OF SEGMENTATION

The mixing accomplished by segmentation serves the dual functions of mixing the chyme with the digestive juices secreted into the small-intestine lumen and exposing all the chyme to the absorptive surfaces of the small-intestine mucosa.

Segmentation not only accomplishes mixing but also slowly moves chyme through the small intestine. How can this be, when each segmental contraction propels chyme both forward and backward? The chyme slowly progresses forward because the frequency of segmentation declines along the length of the small intestine. The pacemaker cells in the duodenum spontaneously depolarize faster than those farther down the tract; segmentation contractions in the duodenum occur at a rate of 12 per minute, and in the terminal ileum they occur at a rate of only 9 per minute. Because segmentation occurs with greater frequency in the upper part of the small intestine than in the lower part, more chyme, on average, is pushed forward than is pushed backward. As a result, chyme is moved very slowly from the upper to the lower part of the

small intestine, being shuffled back and forth to accomplish thorough mixing and absorption in the process. This slow propulsive mechanism is advantageous because it allows ample time for the digestive and absorptive processes to take place. The contents usually take three to five hours to move through the small intestine.

The migrating motility complex

When most of the meal has been absorbed, segmentation contractions cease and are replaced between meals by the **migrating motility complex**—the “intestinal housekeeper.” This between-meal motility consists of weak, repetitive peristaltic waves that move a short distance down the intestine before dying out. The waves start at the stomach and migrate down the intestine; that is, each new peristaltic wave is initiated at a site a little farther down the small intestine. These short peristaltic waves take about 100 to 150 minutes to gradually migrate from the stomach to the end of the small intestine, with each contraction sweeping any remnants of the preceding meal plus mucosal debris and bacteria forward toward the colon, just like a good intestinal housekeeper. After the end of the small intestine is reached, the cycle begins again and continues to repeat itself until the next meal. The migrating motility complex is thought to be regulated between meals by the hormone **motilin**, which is secreted during the unfed state by endocrine cells of the small-intestine mucosa. When the next meal arrives, segmental activity is triggered again, and the migrating motility complex ceases. Motilin release is inhibited by feeding.

The ileocecal junction

At the junction between the small and large intestines, the last part of the ileum empties into the cecum (► Figure 15-19). Two factors contribute to this region’s ability to act as a barrier between the small and large intestines. First, the anatomic arrangement is such that valvelike folds of tissue protrude from the ileum into the lumen of the cecum. When the ileal contents are pushed forward, this **ileocecal valve** is easily pushed open, but the folds of tissue are forcibly closed when the cecal contents attempt to move backward. Second, the smooth muscle within the last several centimetres of the ileal wall is thickened, forming a sphincter that is under neural and hormonal control. Most of the time, this **ileocecal sphincter** remains at least mildly constricted. Pressure on the cecal side of the sphincter causes it to contract more forcibly; distension of the ileal side causes the sphincter to relax, a reaction mediated by the intrinsic plexuses in the area. In this way, the ileocecal junction prevents the bacteria-laden contents of the large intestine from contaminating the small intestine and at the same time lets the ileal contents pass into the colon. If the colonic bacteria gained access to the nutrient-rich small intestine, they would multiply rapidly. Relaxation of the sphincter is enhanced by the release of gastrin at the onset of a meal, when increased gastric activity is taking place. This relaxation allows the undigested fibres and unabsorbed solutes from the preceding meal to be moved forward as the new meal enters the tract.

► **FIGURE 15-19 Control of the ileocecal valve/sphincter.** The juncture between the ileum and large intestine is the ileocecal valve, which is surrounded by thickened smooth muscle, the ileocecal sphincter. Pressure on the cecal side pushes the valve closed and contracts the sphincter, preventing the bacteria-laden colonic contents from contaminating the nutrient-rich small intestine. The valve/sphincter opens and allows ileal contents to enter the large intestine in response to pressure on the ileal side of the valve and to the hormone gastrin that's secreted as a new meal enters the stomach.

Small-intestine secretions

Each day, the exocrine gland cells in the small-intestine mucosa secrete into the lumen about 1.5 L of an aqueous salt and mucous solution called **succus entericus** (juice of intestine). Secretion increases after a meal in response to local stimulation of the small-intestine mucosa by the presence of chyme.

The mucus in the secretion provides protection and lubrication. Furthermore, this aqueous secretion provides plenty of water to participate in the enzymatic digestion of food. Recall that digestion involves hydrolysis—bond breakage by reaction with water—which proceeds most efficiently when all the reactants are in solution.

No digestive enzymes are secreted into this intestinal juice. The small intestine does synthesize digestive enzymes, but they act within the brush-border membrane of the epithelial cells that line the lumen, instead of being secreted directly into the lumen.

SMALL-INTESTINE ENZYMES

Digestion within the small-intestine lumen is accomplished by the pancreatic enzymes, with fat digestion enhanced by bile secretion. As a result of pancreatic enzymatic activity, fats are completely reduced to their absorbable units of monoglycerides and free fatty acids, proteins are broken down into small peptide fragments and some amino acids, and carbohydrates are reduced to disaccharides and some monosaccharides. Fat digestion is therefore completed within the small-intestine lumen, but carbohydrate and protein digestion have not yet been brought to completion.

Special hairlike projections on the luminal surface of the small-intestine epithelial cells, the **microvilli**, form the **brush border**. The

brush-border plasma membrane contains three categories of membrane-bound enzymes:

1. **Enterokinase**, which activates the pancreatic enzyme trypsinogen
2. The **disaccharidases** (maltase, sucrase, and lactase), which complete carbohydrate digestion by hydrolyzing the remaining disaccharides (maltose, sucrose, and lactose, respectively) into their constituent monosaccharides
3. The **aminopeptidases**, which hydrolyze the small peptide fragments into their amino acid components, thereby completing protein digestion

Carbohydrate and protein digestion are therefore completed within the confines of the brush border. (Table 15-6 provides a summary of the digestive processes for the three major categories of nutrients.)

We are now ready to discuss absorption of nutrients. Up to this point, no food, water, or electrolytes have been absorbed.

Why It Matters Lactose Intolerance

A fairly common disorder, **lactose intolerance**, involves a deficiency of lactase, the disaccharidase specific for the digestion of lactose, or milk sugar. Most children under 4 years of age have adequate lactase, but this may be gradually lost so that in many adults, lactase activity is diminished or absent. When lactose-rich milk or dairy products are consumed by a person with lactase deficiency, the undigested lactose remains in the lumen and has several related consequences.

First, accumulation of undigested lactose creates an osmotic gradient that draws water into the intestinal lumen. Second, bacteria living in the large intestine have lactose-splitting ability, so they eagerly attack the lactose as an energy source, producing large quantities of carbon dioxide and methane gas in the process. Distension of the intestine by both fluid and gas produces pain (cramping) and diarrhoea. Infants with lactose intolerance may also suffer from malnutrition.

■ **TABLE 15-6** Digestive Processes for the Three Major Categories of Nutrients

Nutrients	Enzymes for Digesting Nutrient	Source of Enzymes	Site of Action of Enzymes	Action of Enzymes	Absorbable Units of Nutrients
Carbohydrate	Amylase	Salivary glands	Mouth and body of stomach	Hydrolyzes polysaccharides to disaccharides	
	Disaccharidases (maltase, sucrase, lactase)	Exocrine pancreas Small-intestine epithelial cells	Small-intestine lumen Small-intestine brush border	Hydrolyze disaccharides to monosaccharides	Monosaccharides, especially glucose
Protein	Pepsin	Stomach chief cells	Stomach antrum	Hydrolyzes protein to peptide fragments	
	Trypsin, chymotrypsin carboxypeptidase	Exocrine pancreas	Small-intestine lumen	Attack different peptide fragments	
	Aminopeptidases	Small-intestine epithelial cells	Small-intestine brush border	Hydrolyze peptide fragments to amino acids	Amino acids and a few small peptides
Fat	Lipase	Exocrine pancreas	Small-intestine lumen	Hydrolyzes triglycerides to fatty acids and monoglycerides	Fatty acids and monoglycerides
	Bile salts (not an enzyme)	Liver	Small-intestine lumen	Emulsify large fat globules for attack by pancreatic lipase

The small intestine and absorption

All products of carbohydrate, protein, and fat digestion, as well as most of the ingested electrolytes, vitamins, and water, are normally absorbed by the small intestine indiscriminately. The absorption from the small intestine each day consists of (depending on the diet) ≥ 200 g of carbohydrates, ≥ 100 g of fat, ≥ 50 g of amino acids, and 7–8 L of water. However, the capacity of the small intestine is much greater. Usually only the absorption of calcium and iron is adjusted to the body's needs. So the more food consumed, the more will be digested and absorbed—as people who are trying to control their weight are all too painfully aware.

Most absorption occurs in the duodenum and jejunum; very little occurs in the ileum, not because the ileum does not have absorptive capacity but because most absorption has already been accomplished before the intestinal contents reach the ileum. The small intestine has an abundant reserve of absorptive capacity. About 50 percent of the small intestine can be removed with little interference to absorption—with one exception. If the terminal ileum is removed, vitamin B₁₂ and bile salts are not properly absorbed, because the specialized transport mechanisms for these two substances are located only in this region. All other substances can be absorbed throughout the small intestine's length.

The mucous lining of the small intestine is remarkably well adapted for its special absorptive function for two reasons:

(1) it has a very large surface area, and (2) the epithelial cells in this lining have a variety of specialized transport mechanisms.

ADAPTATIONS THAT INCREASE THE SMALL INTESTINE'S SURFACE AREA

The following special modifications of the small-intestine mucosa greatly increase the surface area available for absorption (► Figure 15-20):

- The inner surface of the small intestine, which is thrown into permanent circular folds that are visible to the naked eye, increase the surface area threefold.
- Projecting from this folded surface are microscopic finger-like projections known as **villi**, which give the lining a velvety appearance and further increase the surface area (► Figure 15-21). The surface of each villus is covered by epithelial cells interspersed occasionally with mucous cells.
- Even smaller hairlike projections, the brush border or microvilli, arise from the luminal surface of these epithelial cells, again increasing the surface area. Each epithelial cell has as many as 3000 to 6000 of these microvilli, which are visible only with an electron microscope. The small-intestine enzymes perform their functions within the membrane of this brush border.

Altogether, the folds, villi, and microvilli provide the small intestine with a luminal surface area 600 times greater than if it

were a tube of the same length and diameter lined by a flat surface. In fact, if the surface area of the small intestine were spread out flat, it would cover an entire tennis court.

STRUCTURE OF A VILLUS

Absorption across the digestive tract wall involves transepithelial transport similar to movement of material across the kidney tubules (p. 574). Each villus has the following major components (see Figure 15-20c):

- *Epithelial cells that cover the surface of the villus.* The epithelial cells are joined at their lateral borders by tight junctions, which limit passage of luminal contents between the cells, although the tight junctions in the small intestine are leakier than those in the stomach. Within their luminal brush borders, these epithelial cells have carriers for absorption of specific nutrients and electrolytes from the lumen as well as membrane-bound digestive enzymes that complete carbohydrate and protein digestion.
- *A connective tissue core.* This core is formed by the lamina propria.
- *A capillary network.* Each villus is supplied by an arteriole that breaks up into a capillary network within the villus core. The capillaries rejoin to form a venule that drains away from the villus.
- *A terminal lymphatic vessel.* Each villus is supplied by a single blind-ended lymphatic vessel known as the **central lacteal**, which occupies the centre of the villus core.

During the process of absorption, digested substances enter the capillary network or the central lacteal. To be absorbed, a substance must pass completely through the epithelial cell, diffuse through the interstitial fluid within the connective tissue core of the villus, and then cross the wall of a capillary or lymph

Malabsorption (impairment of absorption) may be caused by damage to or reduction of the surface area of the small intestine. One of the most common causes is **gluten enteropathy**, also known as **celiac disease**. In this condition, the person's small intestine is abnormally sensitive to *gluten*, a protein constituent of wheat, barley, and rye. These grain products are widely prevalent in processed foods. This condition is a complex immunological disorder

in which exposure to gluten erroneously activates a T-cell response that damages the intestinal villi: the normally luxuriant array of villi is reduced, the mucosa becomes flattened, and the brush border becomes short and stubby (▶ Figure 15-22). Because this loss of villi decreases the surface area available for absorption, absorption of all nutrients is impaired. The condition is treated by eliminating gluten from the diet.

▶ **FIGURE 15-22 Reduction in the brush border with gluten enteropathy.** (a) Electron micrograph of the brush border of a small-intestine epithelial cell in a normal individual. (b) Electron micrograph of the short, stubby brush border of a small-intestine epithelial cell in a patient with gluten enteropathy

vessel. Like renal transport, intestinal absorption may be active or passive; active absorption involves energy expenditure during at least one of the transepithelial transport steps.

The mucosal lining

Dipping down into the mucosal surface between the villi are shallow invaginations known as the **crypts of Lieberkühn** (see ▶ Figure 15-20c). Unlike the gastric pits, these intestinal crypts do not secrete digestive enzymes, but they do secrete water and electrolytes, which, along with the mucus secreted by the cells on the villus surface, constitute the succus entericus.

Furthermore, the crypts function as nurseries. The epithelial cells lining the small intestine slough off and are replaced at a rapid rate as a result of the high mitotic activity of *stem cells* in the crypts. New cells that are continually produced in the crypts migrate up the villi and, in the process, push off the older cells at the tips of the villi into the lumen. In this manner, more than 100 million intestinal cells are shed per minute. The entire trip from crypt to tip averages about three

days, so the epithelial lining of the small intestine is replaced approximately every three days. Because of this high rate of cell division, the crypt stem cells are very sensitive to damage by radiation and anticancer drugs, both of which may inhibit cell division.

The new cells undergo several changes as they migrate up the villus. The concentration of brush-border enzymes increases, and the capacity for absorption improves, so the cells at the tip of the villus have the greatest digestive and absorptive capability. Just at their peak, these cells are pushed off by the newly migrating cells. Thus, the luminal contents are constantly exposed to cells that are optimally equipped to complete the digestive and absorptive functions efficiently. Furthermore, just as in the stomach, the rapid turnover of cells in the small intestine is essential because of the harsh luminal conditions. Cells exposed to the abrasive and corrosive luminal contents are easily damaged and cannot live for long, so they must be continually replaced by a fresh supply of newborn cells.

The old cells sloughed off into the lumen are not entirely lost to the body. These cells are digested, with the cell constituents

absorbed into the blood and reclaimed for synthesis of new cells, among other things.

In addition to the stem cells, Paneth cells are also found in the crypts. **Paneth cells** serve a defensive function, safeguarding the stem cells. They produce two chemicals that thwart bacteria: (1) *lysozyme*, the bacterial-lysing enzyme also found in saliva; and (2) *defensins*, small proteins with antimicrobial powers.

We now examine how the epithelial lining of the small intestine is specialized to accomplish absorption of luminal contents and also the mechanisms by which the specific dietary constituents are normally absorbed.

Sodium absorption and water absorption

Sodium may be absorbed both passively and actively. When the electrochemical gradient favours movement of Na^+ from the lumen to the blood, passive diffusion of Na^+ can occur *between* the intestinal epithelial cells—through what's referred to as leaky tight junctions—and into the interstitial fluid within the villus. Movement of Na^+ *through* the cells is energy dependent and involves two different carriers; the process is similar to Na^+ reabsorption across the kidney tubules (pp. 575) (Sodium passively enters the epithelial cells across the luminal border either by itself through Na^+ channels or in the company of glucose or amino acid by means of a cotransport carrier. Sodium is actively pumped out of the cell at the basolateral border into the interstitial fluid in the lateral spaces between the cells where they are not joined by tight junctions. From the interstitial fluid, Na^+ diffuses into the capillaries.

As with the renal tubules in the early part of the nephron, the absorption of Cl^- , H_2O , glucose, and amino acids from the small intestine is linked to this energy-dependent Na^+ absorption. Chloride passively follows down the electrical gradient created by Na^+ absorption and can be actively absorbed as well if needed. Most H_2O absorption in the digestive tract depends on the active carrier that pumps Na^+ into the lateral spaces, resulting in a concentrated area of high osmotic pressure in that localized region between the cells, similar to the situation in the kidneys (p. 581). This localized high osmotic pressure induces H_2O to move from the lumen through the cell (and possibly from the lumen through the leaky tight junction) into the lateral space. Water entering the space reduces the osmotic pressure but raises the hydrostatic (fluid) pressure. As a result, H_2O is flushed out of the lateral space into the interior of the villus, where it is picked up by the capillary network. Meanwhile, more Na^+ is pumped into the lateral space to encourage more H_2O absorption.

Carbohydrate and protein

Absorption of the digestion end products of both carbohydrates and proteins involves special carrier-mediated transport systems that require energy expenditure and Na^+ cotransport, and both categories of end products are absorbed into the blood.

CARBOHYDRATE ABSORPTION

Dietary carbohydrates are generally complex and must be broken down prior to absorption. The actions of salivary amylase break down these polysaccharides into disaccharides, which are further

broken down into monosaccharides by disaccharidases located in the brush borders of the small-intestine epithelial cells. All carbohydrates are absorbed as monosaccharides (▶ Figure 15-23).

Very little carbohydrate is absorbed by way of basic diffusion, and instead is absorbed by active transport. The transporters that mediate the absorption of monosaccharides are (1) Na^+ monosaccharide cotransport and (2) Na^+ -independent facilitated diffusion. Recall that the pores of the mucosa used for diffusion are impermeable to water-soluble solutes with larger molecular weights, including carbohydrates. As well, the active transport process is selective, with certain monosaccharides being preferentially transported before others. For example, galactose is transported before glucose, and glucose is transported before fructose.

Glucose and galactose are both absorbed by secondary active transport, in which cotransport carriers on the luminal border transport both the monosaccharide and Na^+ from the lumen into the interior of the intestinal cell. The operation of these cotransport carriers, which do not directly use energy themselves, depends on the Na^+ concentration gradient established by the energy-consuming basolateral $\text{Na}^+ - \text{K}^+$ pump (p. 44). Glucose (or galactose), having been concentrated in the cell by the cotransport carriers, leaves the cell down its concentration gradient by means of a passive carrier in the basolateral border and enters the blood within the villus. In addition to glucose absorption through the cells by means of the cotransport carrier, recent evidence suggests that a significant amount of glucose crosses the epithelial barrier through the leaky tight junctions between the epithelial cells. Fructose is absorbed into the blood solely by facilitated diffusion (passive carrier-mediated transport; p. 43).

PROTEIN ABSORPTION

Both ingested proteins and endogenous (within the body) proteins that have entered the digestive tract lumen from the three following sources are digested and absorbed:

1. Digestive enzymes—all of which are proteins—that have been secreted into the lumen
2. Proteins within the cells that are pushed off from the villi into the lumen during the process of mucosal turnover
3. Small amounts of plasma proteins that normally leak from the capillaries into the digestive tract lumen

About 20–40 g of endogenous protein enter the lumen each day from these three sources. This quantity can amount to more than the quantity of protein in ingested food. All endogenous proteins must be digested and absorbed along with the dietary proteins to prevent depletion of the body's protein stores. The amino acids absorbed from both food and endogenous protein are used primarily to synthesize new protein in the body. As the building of muscle tissue is important to athletes, amino acids are important to their diet. Just how much protein to consume and when to consume it is something that many athletes and coaches consider for optimal performance.

The protein presented to the small intestine for absorption is primarily in the form of amino acids and a few small peptide

- 1 The dietary polysaccharides starch and glycogen are converted into the disaccharide maltose through the action of salivary and pancreatic amylase.
- 2 Maltose and the dietary disaccharides lactose and sucrose are converted to their respective monosaccharides by the disaccharidases (maltase, lactase, and sucrase) located in the brush borders of the small-intestine epithelial cells.
- 3 The monosaccharides glucose and galactose are absorbed into the interior of the cell and eventually enter the blood by means of Na⁺ and energy-dependent secondary active transport.
- 4 The monosaccharide fructose is absorbed into the blood by passive facilitated diffusion.

fragments (➤ Figure 15-24). Amino acids are absorbed across the intestinal cells by secondary active transport, similar to glucose and galactose absorption. Thus, glucose, galactose, and amino acids all get a “free ride” in on the energy expended for Na⁺ transport. Small peptides gain entry by means of a different carrier and are broken down into their constituent amino acids by the aminopeptidases in the brush-border membrane or by intracellular peptidases. Like monosaccharides, amino acids enter the capillary network within the villus.

Digested fat

Fat absorption is quite different from carbohydrate and protein absorption, because the insolubility of fat in water presents a special problem. Fat must be transferred from the watery chyme through the watery body fluids, even though fat is not water soluble. Therefore, fat must undergo a series of physical and chemical transformations to circumvent this problem during its digestion and absorption (➤ Figure 15-25).

- 1 Dietary and endogenous proteins are hydrolyzed to their constituent amino acids and a few small peptide fragments by gastric pepsin and pancreatic proteolytic enzymes.
- 2 Amino acids are absorbed into the small-intestine epithelial cells and eventually enter the blood by means of Na⁺ and energy-dependent secondary active transport. Various amino acids are transported by carriers specific for them.
- 3 The small peptides, which are absorbed by a different type of carrier, are broken down into their amino acids by aminopeptidases in the brush borders of epithelial cells or by intracellular peptidases.

► FIGURE 15-24 Protein digestion and absorption

A REVIEW OF FAT EMULSIFICATION AND DIGESTION

When the stomach contents are emptied into the duodenum, the ingested fat is aggregated into large, oily triglyceride droplets that float in the chyme. Recall that through the bile salts' detergent action in the small-intestine lumen, the large droplets are dispersed into a lipid emulsification of small droplets, exposing a much greater surface area of fat for digestion by pancreatic lipase. The products of lipase digestion (monoglycerides and free fatty acids) are also not very water soluble, so very little of these end products of fat digestion can diffuse

through the aqueous chyme to reach the absorptive lining. However, biliary components facilitate absorption of these fatty end products by forming micelles.

FAT ABSORPTION

As already discussed, micelles are water-soluble particles that can carry the end products of fat digestion within their lipid-soluble interiors. Once these micelles reach the luminal membranes of the epithelial cells, the monoglycerides and free fatty acids passively diffuse from the micelles through the lipid component of the epithelial cell membranes to enter the interior of these cells. As these fat products leave the micelles and are absorbed across the epithelial cell membranes, the micelles can pick up more monoglycerides and free fatty acids, which have been produced from digestion of other triglyceride molecules in the fat emulsion.

Bile salts continuously repeat their fat-solubilizing function down the length of the small intestine until all fat is absorbed. Then the bile salts themselves are reabsorbed in the terminal ileum by special active transport. This is an efficient process, because relatively small amounts of bile salts can facilitate digestion and absorption of large amounts of fat, with each bile salt performing its ferrying function repeatedly before it is reabsorbed. When bile salts are present, about 96–98 percent of the fat is absorbed, but in the absence of bile salts only about 49–51 percent of the fat is absorbed.

Once within the interior of the epithelial cells, the monoglycerides and free fatty acids are resynthesized into triglycerides. These triglycerides conglomerate into droplets and are coated with a layer of lipoprotein (synthesized by the endoplasmic reticulum of the epithelial cell), which makes the fat droplets water soluble. The large, coated fat droplets, known as **chylomicrons**, are extruded by exocytosis from the epithelial cells into the interstitial fluid within the villus. The chylomicrons subsequently enter the central lacteals rather than the capillaries because of the structural differences between these two vessels. Capillaries have a basement membrane (an outer layer of polysaccharides) that prevents chylomicrons from entering, but the lymph vessels do not have this barrier. Therefore, fat can be absorbed into the lymphatics, but not directly into the blood.

The actual absorption or transfer of monoglycerides and free fatty acids from the chyme across the luminal membranes of the intestinal epithelial cells is a passive process, because the lipid-soluble fatty end products merely dissolve in and pass through the lipid part of the membrane. However, the overall sequence of events needed for fat absorption does require energy. For example, bile salts are actively secreted by the liver, and the resynthesis of triglycerides and formation of chylomicrons within the epithelial cells are active processes.

Vitamin absorption

Water-soluble vitamins are primarily absorbed passively with water, whereas fat-soluble vitamins are carried in the micelles and absorbed passively with the end products of fat digestion. Some of the vitamins can also be absorbed by carriers, if necessary. Vitamin B₁₂ is unique in that it must be in combination with gastric intrinsic factor for absorption by receptor-mediated endocytosis in the terminal ileum.

FIGURE 15-25 Fat digestion and absorption

Iron and calcium absorption

In contrast to the almost complete, unregulated absorption of other ingested electrolytes, dietary iron and calcium may not be absorbed completely because their absorption is subject to regulation, depending on the body's needs for these electrolytes.

IRON ABSORPTION

Iron is essential for haemoglobin production. The normal iron intake is typically 15–20 mg/day, yet a man usually absorbs about 0.5–1 mg/day into the blood, and a woman takes up slightly more, at 1.0–1.5 mg/day (women need more

Because fat is not soluble in water, it must undergo a series of transformations in order to be digested and absorbed.

- 1 Dietary fat in the form of large fat globules composed of triglycerides is emulsified by the detergent action of bile salts into a suspension of smaller fat droplets. This lipid emulsion prevents the fat droplets from coalescing and thereby increases the surface area available for attack by pancreatic lipase.
- 2 Lipase hydrolyzes triglycerides into monoglycerides and free fatty acids.
- 3 These water-insoluble products are carried in the interior of water-soluble micelles, which are formed by bile salts and other bile constituents, to the luminal surface of the small-intestine epithelial cells.
- 4 When a micelle approaches the absorptive epithelial surface, the monoglycerides and fatty acids leave the micelle and passively diffuse through the lipid bilayer of the luminal membranes.
- 5 The monoglycerides and free fatty acids are resynthesized into triglycerides inside the epithelial cells.

- 6 These triglycerides aggregate and are coated with a layer of lipoprotein to form water-soluble chylomicrons, which are extruded through the basal membrane of the cells by exocytosis.
- 7 Chylomicrons are unable to cross the basement membrane of blood capillaries, so instead they enter the lymphatic vessels, the central lacteals.

FIGURE 15-26 Iron absorption

iron because they periodically lose iron in menstrual blood flow).

Two main steps are involved in absorption of iron into blood: (1) absorption of iron from the lumen into small-intestinal epithelial cells, and (2) absorption of iron from the epithelial cells into the blood (Figure 15-26).

Iron is actively transported from the lumen into the epithelial cells, with women having about four times as many active-transport sites for iron as men. The extent to which ingested iron is taken up by the epithelial cells depends on the type of iron consumed (ferrous iron, Fe^{2+} , is absorbed more easily than ferric iron, Fe^{3+}). Also, the presence of other substances in the lumen can either promote or reduce iron absorption. For example, vitamin C increases iron absorption, primarily by reducing ferric to ferrous iron. Phosphate and oxalate, in contrast, combine with ingested iron to form insoluble iron salts that cannot be absorbed.

After active absorption into the small-intestine epithelial cells, iron has two possible fates:

1. Iron needed immediately for production of red blood cells is absorbed into the blood for delivery to the bone marrow, the site of red blood cell production. Iron is transported in the blood by a plasma protein carrier known as **transferrin**. The hormone responsible for stimulating red blood cell production, erythropoietin

- 1 Only a portion of ingested iron is in a form that can be absorbed.
- 2 Dietary iron that is absorbed into the small intestine epithelial cells and is immediately needed for red blood cell production is transferred into the blood.
- 3 In the blood, absorbed iron is carried to the bone marrow bound to transferrin, a plasma protein carrier.
- 4 Absorbed dietary iron that is not immediately needed is stored in the epithelial cells as ferritin, which cannot be transferred into the blood.
- 5 Excess iron in the blood can be dumped into the ferritin pool.
- 6 This unused iron is lost in the feces as the ferritin-containing epithelial cells are sloughed.
- 7 Dietary iron that was not absorbed is also lost in the feces.

(p. 438), is believed to also enhance iron absorption from the intestinal cells into the blood. The absorbed iron is then used in the synthesis of haemoglobin for the newly produced red blood cells.

2. Iron not immediately needed remains stored within the epithelial cells in a granular form called **ferritin**, which cannot be absorbed into the blood. If the blood level of iron is too high, excess iron may be dumped from the blood into this unabsorbable pool of ferritin in the intestinal epithelial cells. Iron stored as ferritin is lost in the feces within three days because the epithelial cells containing these granules are sloughed off during mucosal regeneration. Large amounts of iron in the feces give them a dark, almost black colour.

CALCIUM ABSORPTION

The amount of calcium (Ca^{2+}) ions absorbed is controlled in relation to the need of the body for calcium. Calcium has to be actively absorbed, but a small amount of Ca^{2+} is absorbed passively. Vitamin D greatly stimulates this active transport. Vitamin D can exert this effect only after it has been activated in the liver and kidneys—a process enhanced by parathyroid hormone. Appropriately, secretion of parathyroid hormone increases in response to a fall in Ca^{2+} concentration in the blood.

Normally, of the average 1000 mg of Ca^{2+} taken in daily, only about two-thirds is absorbed in the small intestine, with the rest passing out in the feces.

Absorbed nutrients and the liver

The venules that leave the small-intestine villi, along with those from the rest of the digestive tract, empty into the hepatic portal vein, which carries the blood to the liver. Consequently, anything absorbed into the digestive capillaries first must pass through the hepatic biochemical factory before entering the general circulation. Thus, the products of carbohydrate and protein digestion are channelled into the liver, where many of these energy-rich products are subjected to immediate metabolic processing. Furthermore, harmful substances that may have been absorbed are detoxified by the liver before gaining access to the general circulation. After passing through the portal circulation, the venous blood from the digestive system empties into the vena cava and returns to the heart to be distributed throughout the body, carrying glucose and amino acids for use by the tissues.

Fat, which cannot penetrate the intestinal capillaries, is picked up by the central lacteal and enters the lymphatic system instead, bypassing the hepatic portal system. Contractions of the villi, accomplished by the muscularis mucosa, periodically compress the central lacteal and squeeze the lymph out of this vessel. The lymph vessels eventually converge to form the *thoracic duct*, a large lymph vessel that empties into the venous system within the chest. In this way, fat ultimately gains access to the blood. The absorbed fat is carried by the systemic circulation to the liver and to other tissues of the body. Therefore, the liver does have a chance to act on the digested fat, but not until the fat has been diluted by the blood in the general circulatory system. This dilution of fat protects the liver from being inundated with more fat than it can handle at one time.

Extensive absorption and secretion

The small intestine normally absorbs about 9 L of fluid per day in the form of water and solutes, including the absorbable units of nutrients, vitamins, and electrolytes. How can that be, when humans normally ingest only about 1250 mL of fluid and consume 1250 g of solid food (80% of which is H_2O) per day? ■ Table 15-7 illustrates the tremendous daily absorption performed by the small intestine. Each day about 9500 mL of water and solutes enter the small intestine. Note that of this 9500 mL, only 2500 mL are ingested from the external environment. The remaining 7000 mL (7 L) of fluid are digestive juices derived from the plasma. Recall that plasma is the ultimate source of digestive secretions, because the secretory cells extract from the plasma the necessary raw materials for their secretory product. Considering that the entire plasma volume is only about 2.75 L, absorption must closely parallel secretion to keep the plasma volume from falling sharply.

Of the 9500 mL of fluid entering the small-intestine lumen per day, about 95 percent, or 9000 mL of fluid, is normally absorbed by the small intestine back into the plasma, with only 500 mL of the small-intestine contents passing on into the colon. Thus, the body does not lose the digestive juices. After

■ **TABLE 15-7** Volumes Absorbed by the Small and Large Intestine per Day

Volume entering the small intestine per day

Source	Ingested	Food eaten	1250 g*
		Fluid drunk	1250 mL
	Secreted from the plasma	Saliva	1500 mL
		Gastric juice	2000 mL
		Pancreatic juice	1500 mL
		Bile	500 mL
		Intestinal juice	1500 mL
Volume absorbed by the small intestine per day			9000 mL
Volume entering the colon from the small intestine per day			500 mL
Volume absorbed by the colon per day			350 mL
Volume of feces eliminated from the colon per day			150 g*

* 1 mL of H_2O weighs 1 g. Therefore, because of a high percentage of food and feces is H_2O , we can roughly equate grams of food or feces with millilitres of fluid.

© 2016 Cengage

the constituents of the juices are secreted into the digestive tract lumen and perform their function, they are returned to the plasma. The only secretory product that escapes from the body is bilirubin, a waste product that must be eliminated.

Biochemical balance

Because the secreted juices are normally absorbed back into the plasma, the acid-base balance of the body is not altered by digestive processes. When secretion and absorption do not parallel each other, however, acid-base abnormalities can result. ▶ Figure 15-27 provides a summary of the biochemical balance that normally exists among the stomach, pancreas, and small intestine. The arterial blood entering the stomach contains Cl^- , CO_2 , H_2O , and Na^+ , among other things. During HCl secretion, the gastric parietal cells extract Cl^- , CO_2 , and H_2O from the plasma (the CO_2 and H_2O are essential for H^+ secretion) and add to it (the HCO_3^- is formed in the process of generating H^+). The HCO_3^- is transported into the plasma in exchange for the secreted Cl^- . Plasma Na^+ levels are not altered by gastric secretory processes. Because HCO_3^- is an alkaline ion, venous blood leaving the stomach is more alkaline than arterial blood delivered to it.

The overall acid-base balance of the body is not altered, however, because the pancreatic duct cells extract a comparable amount of HCO_3^- (along with Na^+) from the plasma to neutralize the acidic gastric chyme as it empties into the small intestine. Within the intestinal lumen, the alkaline pancreatic NaHCO_3 secretion neutralizes the gastric HCl secretion, yielding NaCl and H_2CO_3 . The latter molecules form Na^+ and Cl^- plus CO_2 and H_2O , respectively. All four of these constituents (Na^+ , Cl^- , CO_2 , and H_2O) are absorbed by the intestinal epithelium into the plasma. Note that these are exactly the same constituents present in the arterial blood entering the stomach. Through

► **FIGURE 15-27 Biochemical balance among the stomach, pancreas, and small intestine.** When digestion and absorption proceed normally, no net loss or gain of acid or base or other chemicals from the body fluids occurs as a consequence of digestive secretions. The parietal cells of the stomach extract Cl^- , CO_2 , and H_2O from and add to the blood during HCl secretion. The pancreatic duct cells extract the HCO_3^- as well as Na^+ from the blood during NaHCO_3 secretion. Within the small-intestine lumen, pancreatic NaHCO_3 neutralizes gastric HCl to form NaCl and H_2CO_3 , which decomposes into CO_2 and H_2O . Subsequently, the intestinal cells absorb Na^+ , Cl^- , CO_2 , and H_2O into the blood, thereby replacing the constituents that were extracted from the blood during gastric and pancreatic secretion.

these interactions, the body normally does not experience a net gain or loss of acid or base during digestion.

15

Diarrhoea

When vomiting or diarrhoea occur, these normal neutralization processes cannot take place. We have already described vomiting in the section on gastric motility. The other common digestive tract disturbance that can lead to a loss of fluid and an acid-base imbalance is **diarrhoea**. This condition

is characterized by passage of a highly fluid fecal matter, often with increased frequency of defecation. Just as with vomiting, the effects of diarrhoea can be either beneficial or harmful. Diarrhoea is beneficial when rapid emptying of the intestine hastens elimination of harmful material from the body. However, not only are some of the ingested materials lost but some of the secreted materials that normally would have been reabsorbed are lost as well. Excessive loss of intestinal contents causes dehydration, loss of nutrient material, and metabolic acidosis resulting from loss of HCO_3^- (p. 635). The abnormal fluidity of the feces usually occurs because the small intestine is unable to absorb fluid as extensively as normal. This extra unabsorbed fluid passes out in the feces.

The causes of diarrhoea are as follows:

1. The most common cause of diarrhoea is excessive small-intestinal motility, which arises either from local irritation of the gut wall by bacterial or viral infection of the small intestine or from emotional stress. Rapid transit of the small-intestine contents does not allow enough time for adequate absorption of fluid to occur.
2. Diarrhoea also occurs when excess osmotically active particles, such as those found in lactase deficiency, are present in the digestive tract lumen. These particles cause excessive fluid to enter and be retained in the lumen, thus increasing the fluidity of the feces.
3. Toxins of the bacterium *Vibrio cholerae* (the causative agent of cholera) and certain other microorganisms promote the secretion of excessive amounts of fluid by the small-intestine mucosa, resulting in profuse diarrhoea. Diarrhoea produced in response to toxins from infectious agents is the leading cause of death of small children in developing nations. Fortunately, a low-cost, effective *oral rehydration therapy* that takes advantage of the intestine's glucose cotransport carrier is saving the lives of millions of children. (For details about oral rehydration therapy, see ► Concepts, Challenges, and Controversies, p. 690.)

Check Your Understanding 15.6

1. Describe the structural features that increase the surface area of the small intestine, and explain the significance of increasing the surface area.
2. Discuss how the $\text{Na}^+ - \text{K}^+$ pump of mucosal epithelial cells facilitates nutrient absorption.

15.7 | Large Intestine

The **large intestine** consists of the colon, cecum, appendix, and rectum (► Figure 15-28). The **cecum** forms a blind-ended pouch below the junction of the small and large intestines at the ileocecal valve. The small, finger-like projection at the bottom of the cecum is the **appendix**, a lymphoid tissue that houses lymphocytes (p. 464). The **colon**, which makes up most of the large intestine, is not coiled like the small intestine but consists of

► FIGURE 15-28 Anatomy of the large intestine

three relatively straight parts: the *ascending colon*, the *transverse colon*, and the *descending colon*. The end part of the descending colon becomes S-shaped, forming the *sigmoid colon* (*sigmoid* means “S-shaped”), then straightens out to form the **rectum** (*rectum* means “straight”).

A drying and storage organ

The colon normally receives about 500–1500 mL of chyme from the small intestine each day. Because most digestion and absorption have been accomplished in the small intestine, the contents delivered to the colon consist of indigestible food residues (such as cellulose), unabsorbed biliary components, and the remaining fluid. The colon extracts more water and salt from the contents. Most of the absorption occurs in the upper half of the colon, while the distal half is used as more of a storage area. What remains to be eliminated is known as **feces**. The primary function of the large intestine is to store feces before defecation. Cellulose and other indigestible substances in the diet provide bulk and help maintain regular bowel movements by contributing to the volume of the colonic contents.

Haustral contractions

The outer longitudinal smooth muscle layer does not completely surround the large intestine. Instead, it consists only of three separate, conspicuous, longitudinal bands of muscle, the **taeniae coli**, which run the length of the large intestine. These

taeniae coli are shorter than the underlying circular smooth muscle and mucosal layers would be if these layers were stretched out flat. Because of this, the underlying layers are gathered into pouches or sacs called **haustra**, much as the material of a full skirt is gathered at the narrower waistband. The haustra are not merely passive, permanent gathers, however; they actively change location as a result of contraction of the circular smooth muscle layer.

Most of the time, movements of the large intestine are slow and nonpropulsive, which is appropriate for its absorptive and storage functions. The colon’s main motility is **haustral contractions** initiated by the autonomous rhythmicity of colonic smooth muscle cells. These contractions, which throw the large intestine into haustra, are similar to small-intestine segmentations, but they occur much less frequently. Thirty minutes may elapse between haustral contractions, whereas segmentation contractions in the small intestine occur at rates of between 9 and 12 per minute. The location of the haustral sacs gradually changes as a relaxed segment that has formed a sac slowly contracts, while a previously contracted area simultaneously relaxes to form a new sac. These movements

are nonpropulsive; they slowly shuffle the contents in a back-and-forth mixing movement that exposes the colonic contents to the absorptive mucosa. Haustral contractions are largely controlled by locally mediated reflexes involving the intrinsic plexuses.

Mass movements

Three to four times a day, generally after meals, a marked increase in motility takes place during which large segments of the ascending and transverse colon contract simultaneously, driving the feces one-third to three-fourths of the length of the colon in a few seconds. These massive contractions, appropriately called **mass movements**, drive the colonic contents into the distal part of the large intestine, where material is stored until defecation occurs.

When food enters the stomach, mass movements are triggered in the colon primarily by the **gastrocolic reflex**, which is mediated from the stomach to the colon by gastrin and by the extrinsic autonomic nerves. In many people, this reflex is most evident after the first meal of the day and is often followed by the urge to defecate. Thus, when a new meal enters the digestive tract, reflexes are initiated to move the existing contents farther along down the tract to make way for the incoming food. The gastroileal reflex moves the remaining small-intestine contents into the large intestine, and the gastrocolic reflex pushes the colonic contents into the rectum, triggering the defecation reflex.

Oral Rehydration Therapy: Sipping a Simple Solution Saves Lives

DIARRHOEA-INDUCING MICROORGANISMS SUCH AS *Vibrio CHOLERA*, which causes cholera, are the leading cause of death in children younger than age 5 worldwide. The problem is especially pronounced in developing countries, refugee camps, and elsewhere where poor sanitary conditions encourage the spread of the microorganisms, and medical supplies and healthcare personnel are scarce. Fortunately, a low-cost, easily obtainable, uncomplicated remedy—**oral rehydration therapy (ORT)**—has been developed to combat potentially fatal diarrhoea. This treatment exploits the membrane transporters located at the luminal border of the villus epithelial cells.

Let's examine the pathophysiology of life-threatening diarrhoea and then see how simple ORT can save lives. During digestion of a meal, the crypt cells of the small intestine normally secrete succus entericus—a solution of salt and mucus—into the lumen. These cells actively transport Cl^- into the lumen, promoting the parallel passive transport of Na^+ and H_2O from the blood into the lumen. The fluid provides the watery environment needed for enzymatic breakdown of ingested nutrients into absorbable units. Glucose and amino acids, the absorbable units of dietary carbohydrates and proteins, respectively, are absorbed by secondary active transport. This absorption mechanism uses the Na^+ –glucose (or amino acid) cotransport carriers (SGLT) located at the luminal membrane of the villus epithelial cells. In addition, separate active Na^+ carriers not linked with nutrient absorption transfer Na^+ , passively accompanied by Cl^- and H_2O , from the lumen into the blood.

The net result of these various carrier activities is absorption of the secreted salt and H_2O along with the digested nutrients. Normally, absorption of salt and H_2O exceeds their secretion, so not only are the secreted fluids salvaged but also additional ingested salt and H_2O are absorbed.

Cholera and most diarrhoea-inducing microbes cause diarrhoea by stimulating the secretion of Cl^- or impairing the absorption of Na^+ . As a result, more fluid is secreted from the blood into the lumen than is subsequently transferred back into the blood. The excess fluid is lost in the feces, producing the watery stool characteristic of diarrhoea. More important, the loss of fluids and electrolytes that came from the blood leads to dehydration. The subsequent reduction in effective circulating

plasma volume can cause death in a matter of days or even hours, depending on the severity of the fluid loss.

In the middle of the last century, physicians learned that replacing the lost fluids and electrolytes intravenously saves the lives of most patients with diarrhoea. In many parts of the world, however, adequate facilities, equipment, and personnel are not available to administer intravenous rehydration therapy. Consequently, millions of children still succumbed to diarrhoea annually.

In 1966 researchers learned that SGLT is not affected by diarrhoea-causing microbes. This discovery led to the development of ORT. When both Na^+ and glucose are present in the lumen, they are cotransported from the lumen into the villus epithelial cells, from which they enter the blood. Because H_2O osmotically follows the absorbed Na^+ , ingestion of a glucose and salt solution promotes the uptake of fluid into the blood from the intestinal tract without the need for intravenous replacement of fluids.

The first proof of ORT's life-saving ability in the field came in 1971 when several million refugees poured into India from war-ravaged Bangladesh. Of the thousands of refugees who fell victim to cholera and other diarrhoeal diseases, more than 30 percent died because of the scarcity of sterile fluids and needles for intravenous therapy. In one refugee camp, however, under the supervision of a group of scientists who had been experimenting with ORT, families were taught to administer ORT to people with diarrhoea, most of whom were small children. The scarce intravenous solutions were reserved for those unable to drink. Death from diarrhoea was reduced to 3 percent in this camp, compared with a tenfold higher mortality among refugees elsewhere.

Based on this evidence, the World Health Organization (WHO) started aggressively promoting ORT. Packets of dry ingredients for ORT are now manufactured locally in more than 60 countries. The WHO estimates that about 30 percent of the world's children who contract diarrhoea are treated with the prepackaged mixture or home-prepared versions. In the United States, commercially prepared oral solutions are widely available at pharmacies and supermarkets. An estimated 1 million children worldwide are saved annually as a result of ORT.

The defecation reflex

When mass movements of the colon move feces into the rectum, the resultant distension of the rectum stimulates stretch receptors in the rectal wall, initiating the **defecation reflex**. When fecal matter fills the rectum, sensory impulses initiated by stretch receptors due to the distension are sent to the sacral portion of the spinal cord, and a reflex signal is sent via the parasympathetics to the distal colon. This reflex causes the **internal anal sphincter** (which is smooth muscle) to relax and the rectum

and sigmoid colon to contract more vigorously. If the **external anal sphincter** (which is skeletal muscle) is also relaxed, defecation occurs. Being skeletal muscle, the external anal sphincter is under voluntary control. The initial distension of the rectal wall is accompanied by the conscious urge to defecate. If circumstances are unfavourable for defecation, voluntary tightening of the external anal sphincter can prevent defecation despite the defecation reflex. If defecation is delayed, the distended rectal wall gradually relaxes, and the urge to defecate subsides until

the next mass movement propels more feces into the rectum, once again distending the rectum and triggering the defecation reflex. During periods of inactivity, both anal sphincters remain contracted to ensure fecal continence.

When defecation does occur, it is usually assisted by voluntary straining movements that involve simultaneous contraction of the abdominal muscles and a forcible expiration against a closed glottis. This is another instance where the valsalva manoeuvre is used, with the purpose of greatly increasing intra-abdominal pressure, which helps expel the feces.

Constipation

If defecation is delayed too long, **constipation** may result. When colonic contents are retained for longer periods of time than normal, more than the usual amount of water is absorbed from the feces, so they become hard and dry. Normal variations in frequency of defecation among individuals range from after every meal to up to once a week. When the frequency is delayed beyond what is normal for a particular person, constipation and its attendant symptoms may occur. These symptoms include abdominal discomfort, dull headache, loss of appetite sometimes accompanied by nausea, and mental depression.

Contrary to popular belief, these symptoms are not caused by toxins absorbed from the retained fecal material. Although bacterial metabolism produces some potentially toxic substances in the colon, these substances normally pass through the portal system and are removed by the liver before they can reach the systemic circulation. Instead, the symptoms associated with constipation are caused by prolonged distension of the large intestine, particularly the rectum; the symptoms promptly disappear after relief from distension.

Possible causes for delayed defecation that might lead to constipation include (1) ignoring the urge to defecate; (2) decreased colon motility accompanying aging, emotion, or a low-bulk diet; (3) obstruction of fecal movement in the large bowel caused by a local tumour or colonic spasm; and (4) impairment of the defecation reflex, such as through injury of the nerve pathways involved.

 **Clinical Note** If hardened fecal material becomes lodged in the appendix, it may obstruct normal circulation and mucous secretion in this narrow, blind-ended appendage. This blockage leads to inflammation of the appendix, that is, **appendicitis**. The inflamed appendix often becomes swollen and filled with pus, and the tissue may die as a result of local circulatory interference. If not surgically removed, the diseased appendix may rupture, spewing its infectious contents into the abdominal cavity.

Large-intestine secretion

The large intestine does not secrete any digestive enzymes. None are needed, because digestion is completed before chyme ever reaches the colon. Colonic secretion consists of an alkaline (NaHCO_3) mucous solution, whose function is to protect the large-intestine mucosa from mechanical and chemical injury. The mucus provides lubrication to facilitate passage of the feces, whereas the NaHCO_3 neutralizes irritating acids produced by local bacterial fermentation. Secretion increases in response to

mechanical and chemical stimulation of the colonic mucosa mediated by short reflexes and parasympathetic innervation.

No digestion takes place within the large intestine because there are no digestive enzymes. However, the colonic bacteria do digest some of the cellulose for their use.

THE COLON

Because of slow colonic movement, bacteria have time to grow and accumulate in the large intestine. In contrast, in the small intestine the contents are normally moved through too rapidly for bacterial growth to occur. Furthermore, the mouth, stomach, and small intestine secrete antibacterial agents, but the colon does not. Not all ingested bacteria are destroyed by lysozyme and HCl, however. The surviving bacteria continue to thrive in the large intestine. The number of bacteria living in the human colon is about 10 times the number of cells in the human body. Collectively, this mass of bacteria amounts to about 1000 g. An estimated 500 to 1000 different species of bacteria typically live in the colon. These colonic microorganisms are typically harmless and, in fact, provide beneficial functions. For example, indigenous bacteria (1) enhance intestinal immunity by competing with potentially pathogenic microbes for nutrients and space (p. 463), (2) promote colonic motility, (3) help maintain colonic mucosal integrity, and (4) make nutritional contributions. For example, bacteria synthesize absorbable vitamin K and raise colonic acidity, thereby promoting the absorption of calcium, magnesium, and zinc. Furthermore, contrary to earlier assumptions, some of the glucose released during bacterial processing of dietary fibre is absorbed by the colonic mucosa.

SALT AND WATER

Some absorption takes place within the colon, but not to the same extent as in the small intestine. Because the luminal surface of the colon is fairly smooth, it has considerably less absorptive surface area than the small intestine. Furthermore, the colon does not have the extensive, specialized transport mechanisms that the small intestine has. When excessive small-intestine motility delivers the contents to the colon before the absorption of nutrients has been completed, the colon cannot absorb most of these materials, and they are lost in diarrhoea.

The colon normally absorbs salt and water. Sodium is actively absorbed, chloride follows passively down the electrical gradient, and water follows osmotically. The colon absorbs token amounts of other electrolytes, as well as vitamin K synthesized by colonic bacteria.

Through absorption of salt and water, a firm fecal mass is formed. Of the 500 mL of material entering the colon per day from the small intestine, the colon normally absorbs about 350 mL, leaving 150 g of feces to be eliminated from the body each day (see ■ Table 15-7). This fecal material normally consists of 100 g of water and 50 g of solid, including undigested cellulose, bilirubin, bacteria, and small amounts of salt. Thus, contrary to popular thinking, the digestive tract is not a major excretory passageway for eliminating wastes from the body. The main waste product excreted in the feces is bilirubin. The other fecal constituents are unabsorbed food residues and bacteria, which were never actually a part of the body.

INTESTINAL GASES

Occasionally, instead of feces passing from the anus, intestinal gas, or **flatus**, passes out. This gas is derived primarily from two sources: (1) swallowed air (as much as 500 mL of air may be swallowed during a meal), and (2) gas produced by bacterial fermentation in the colon. The flatus is typically a mixture of nitrogen and carbon dioxide, and small amounts of hydrogen, methane, and hydrogen sulphide. The presence of gas percolating through the luminal contents gives rise to gurgling sounds known as **borborygmi**. Eructation (burping) removes most of the swallowed air from the stomach, but some passes on into the intestine. Usually, very little gas is present in the small intestine, because the gas is either quickly absorbed or passes into the colon. Most gas in the colon is due to bacterial activity, with the quantity and nature of the gas dependent on the type of food eaten and the characteristics of the colonic bacteria. Some foods, such as beans, contain types of carbohydrates that humans cannot digest but that can be attacked by gas-producing bacteria. Much of the gas is absorbed through the intestinal mucosa. The rest is expelled through the anus.

To selectively expel gas when feces are also present in the rectum, the person voluntarily contracts the abdominal muscles and the external anal sphincter at the same time. When abdominal contraction raises the pressure against the contracted anal sphincter sufficiently, the pressure gradient forces air out at a high velocity through a slitlike anal opening that is too narrow for solid feces to escape through. This passage of air at high velocity causes the edges of the anal opening to vibrate, giving rise to the characteristic low-pitched sound accompanying passage of gas.

Check Your Understanding 15.7

1. Compare haustral contractions of the large intestine to segmentation contractions of the small intestine.
2. Describe the role of NaHCO_3 secretions by the large intestine mucosa. Compare the function of this secretion with that of pancreatic NaHCO_3 secretion.

15.8 | Overview of the Gastrointestinal Hormones

Throughout our discussion of digestion, we have mentioned different functions of the three major gastrointestinal hormones: gastrin, secretin, and CCK. In this section we fit all these functions together so you can appreciate the overall adaptive importance of these interactions. Also, we introduce a more recently identified gastrointestinal hormone, GIP, as well as a hormone that connects nutrient consumption with glucose metabolism, GLP-1.

Gastrin

Protein in the stomach stimulates the release of gastrin, which performs the following functions:

1. It acts in multiple ways to increase secretion of HCl and pepsinogen. These two substances, in turn, are of primary importance in initiating digestion of the protein that promoted their secretion.
2. It enhances gastric motility, stimulates ileal motility, relaxes the ileocecal sphincter, and induces mass movements in the colon—functions that are all aimed at keeping the contents moving through the digestive tract on the arrival of a new meal.
3. It also is trophic not only to the stomach mucosa but also to the small-intestine mucosa, which helps maintain a well-developed, functionally viable digestive tract lining.

Predictably, gastrin secretion is inhibited by an accumulation of acid in the stomach and by the presence in the duodenal lumen of acid and other constituents that necessitate a delay in gastric secretion.

Secretin

As the stomach empties into the duodenum, the presence of acid in the duodenum stimulates the release of secretin, which performs the following interrelated functions:

1. It inhibits gastric emptying to prevent further acid from entering the duodenum until the acid already present is neutralized.
2. It inhibits gastric secretion to reduce the amount of acid being produced.
3. It stimulates the pancreatic duct cells to produce a large volume of aqueous NaHCO_3 secretion, which is emptied into the duodenum to neutralize the acid.
4. It stimulates secretion by the liver of a NaHCO_3 -rich bile, which likewise is emptied into the duodenum to assist in the neutralization process. Neutralization of the acidic chyme in the duodenum helps prevent damage to the duodenal walls and provides a suitable environment for the optimal functioning of the pancreatic digestive enzymes, which are inhibited by acid.
5. Along with CCK, secretin is trophic to the exocrine pancreas.

CCK

As chyme empties from the stomach, fat and other nutrients enter the duodenum. These nutrients, especially fat and, to a lesser extent, protein products, cause the release of CCK, which performs the following interrelated functions:

1. It inhibits gastric motility and secretion, thereby allowing adequate time for the nutrients already in the duodenum to be digested and absorbed.
2. It stimulates the pancreatic acinar cells to increase secretion of pancreatic enzymes, which continue the digestion

of these nutrients in the duodenum (this action is especially important for fat digestion, because pancreatic lipase is the only enzyme that digests fat).

3. It causes contraction of the gallbladder and relaxation of the sphincter of Oddi so that bile empties into the duodenum to aid fat digestion and absorption. Bile salts' detergent action is particularly important in enabling pancreatic lipase to perform its digestive task. Once again, the multiple effects of CCK are remarkably well adapted to dealing with the fat and other nutrients whose presence in the duodenum triggered the release of this hormone.
4. Furthermore, it is appropriate that both secretin and CCK, which have profound stimulatory effects on the exocrine pancreas, are trophic to this tissue.
5. CCK has also been implicated in long-term adaptive changes in the proportion of pancreatic enzymes produced in response to prolonged changes in diet.
6. Besides facilitating the digestion of ingested nutrients, CCK is an important regulator of food intake. It plays a key role in satiety, the sensation of having had enough to eat (p. 705).

GIP

A more recently recognized hormone released by the K cells in the duodenum, **glucose-dependent insulinotropic peptide (GIP)**, helps promote metabolic processing of the nutrients once they are absorbed. This hormone was originally named *gastric inhibitory peptide (GIP)* for its presumed role as an enterogastrome. It was believed to inhibit gastric motility and secretion, similar to secretin and CCK. GIP's contribution in this regard is now considered minimal. Instead, this hormone stimulates insulin release by the pancreas. To a lesser extent, GIP inhibits water and electrolyte absorption in the small intestine and the secretion of acids and pepsin. Again, this is remarkably adaptive. As soon as the meal is absorbed, the body has to shift its metabolic gears to use and store the newly arriving nutrients. The metabolic activities of this absorptive phase are largely under the control of insulin (pp. 272). Stimulated by the presence of a meal in the digestive tract, GIP initiates the release of insulin in anticipation of absorption of the meal, in a feedforward fashion. Insulin is especially important in promoting the uptake and storage of glucose. Appropriately, glucose in the duodenum increases GIP secretion.

GLP-1

The major source of the hormone **glucagon-like peptide-1 (GLP-1)** in the body is the intestinal L cell. Secretion of GLP-1 by L cells is dependent on the presence of nutrients in the lumen of the small intestine. The nutrients that initiate secretion (secretagogues) include major nutrients such as carbohydrate, protein, and lipid. The major physiological role of GLP-1 is to connect the consumption of nutrients with glucose metabolism. In circulation, GLP-1 has a short half-life (<2 minutes) and is rapidly catabolized. It is a potent glucose-dependent stimulator

(antihyperglycaemic) of insulin secretion, while suppressing glucagon secretion. The effectiveness of GLP-1 in post-meal (post-prandial) insulin secretion is easy to demonstrate, because an oral dose of glucose triggers a much greater plasma insulin response than does an intravenous glucose dose; the intravenous dose bypasses the digestive tract. When plasma glucose concentration is in the normal fasting range (~4 mmol/L) GLP-1 no longer stimulates insulin. GLP-1 appears to restore the glucose sensitivity of pancreatic β -cells, which may involve increased expression of GLUT2 receptor and glucokinase. GLP-1 inhibits gastric secretion and motility, which delays carbohydrate absorption and contributes to satiety.

Both GLP-1 and GIP use feedforward mechanisms to increase the amount of insulin released from the β -cells of the pancreas; hence, these two hormones are termed *incretin hormones*. A substantial volume of research on both of these incretins has been conducted by Canadian researchers, many associated with UBC—S.J. Kim, C.H. McIntosh, S. Widenmaier, and T.J. Kieffer to name a few. The specific effects of GLP-1 are as follows:

- Promotes insulin sensitivity (potential for diabetes treatment)
- Increases insulin secretion from the pancreas
- Decreases glucagon secretion from the pancreas
- Increases insulin sensitivity in both α -cells and β -cells
- Increases the mass β -cells and their insulin gene expression
- Inhibits gastric secretion and gastric emptying in the stomach
- Increases satiety, thereby reducing food intake

This overview of the multiple, integrated, adaptive functions of the gastrointestinal hormones provides an excellent example of the remarkable efficiency of the human body.

Check Your Understanding 15.8

1. Explain the significance of some GI hormones being trophic.
2. Name the targets of secretin and of CCK.

Chapter in Perspective: Focus on Homeostasis

To maintain constancy in the internal environment, materials that are used up in the body (such as energy-rich nutrients and O_2) or uncontrollably lost from the body (such as evaporative H_2O loss from the airways or salt loss in sweat) must constantly be replaced by new supplies of these materials from the external environment. All these replacement supplies, except oxygen, are acquired through the digestive system. Fresh supplies of oxygen are transferred to the internal environment by the respiratory system, but all the nutrients, water, and various electrolytes needed to maintain homeostasis are acquired through the digestive system. The large, complex, ingested food is broken down by the digestive system into

small absorbable units. These small energy-rich nutrient molecules are transferred across the small-intestine epithelium into the blood for delivery to the cells to replace the nutrients constantly used for ATP production and for repair and growth of body tissues. Likewise, ingested water, salt, and other electrolytes are absorbed by the intestine into the blood.

Unlike regulation in most body systems, regulation of digestive system activities is not aimed at maintaining homeostasis. The quantity of nutrients and water ingested is subject to control, but the quantity of ingested materials absorbed by the digestive tract is not subject to control, with few exceptions. The hunger mechanism governs food intake to help maintain energy balance (Chapter 16), and the thirst mechanism controls water intake to help maintain water balance (Chapter 14). However, we do not always need these control mechanisms, and we often eat and drink when we are not hungry or thirsty.

Once these materials are in the digestive tract, the digestive system does not vary its rate of nutrient, water, or electrolyte uptake according to body needs (with the exception of iron and calcium); rather, it optimizes conditions for digesting and absorbing what is ingested. Truly, what you eat is what you get. The digestive system is subject to many regulatory processes, but these are not influenced by the nutritional or hydration state of the body. Instead, these control mechanisms are governed by the composition and volume of digestive tract contents so that the rate of motility and secretion of digestive juices are optimal for digestion and absorption of the ingested food.

If excess energy-rich nutrients are ingested and absorbed, the extra is placed in storage, such as in adipose tissue (fat), so that the blood level of nutrient molecules remains at a constant level. Excess ingested water and electrolytes are eliminated in the urine to homeostatically maintain the blood levels of these constituents.

REVIEW EXERCISES

Objective Questions (Answers on p. A-52)

- The extent of nutrient uptake from the digestive tract depends on the body's needs. (*True or false?*)
- The stomach is relaxed during vomiting. (*True or false?*)
- Acid cannot normally penetrate into or between the cells that line the stomach, and this enables the stomach to contain acid without injuring itself. (*True or false?*)
- Protein is continually lost from the body through digestive secretions and sloughed epithelial cells, which pass out in the feces. (*True or false?*)
- Foodstuffs not absorbed by the small intestine are absorbed by the large intestine. (*True or false?*)
- The endocrine pancreas secretes secretin and CCK. (*True or false?*)
- A digestive reflex involving the autonomic nerves is known as a _____ reflex, whereas a reflex in which all elements of the reflex arc are located within the gut wall is known as a _____ reflex.
- When food is mechanically broken down and mixed with gastric secretions, the resultant thick, liquid mixture is known as _____.
- The entire lining of the small intestine is replaced approximately every _____ days.
- The two substances absorbed by specialized transport mechanisms located only in the terminal ileum are _____ and _____.
- The most potent choleric is _____.
- Which of the following is NOT a function of saliva?
 - begins digestion of carbohydrate
 - facilitates absorption of glucose across the oral mucosa
 - facilitates speech
 - exerts an antibacterial effect
 - plays an important role in oral hygiene

13. Match the following:

- | | |
|--|---|
| _____ 1. prevents reentry of food into the mouth during swallowing | (a) closure of the pharyngoesophageal sphincter |
| _____ 2. triggers the swallowing reflex | (b) elevation of the uvula |
| _____ 3. seals off the nasal passages during swallowing | (c) position of the tongue against the hard palate |
| _____ 4. prevents air from entering the oesophagus during breathing | (d) closure of the gastroesophageal sphincter |
| _____ 5. closes off the respiratory airways during swallowing | (e) bolus pushed to the rear of the mouth by the tongue |
| _____ 6. prevents gastric contents from backing up into the oesophagus | (f) tight apposition of the vocal folds |

14. Use the answer code on the right to identify the characteristics of the listed substances:

- | | |
|--|----------------------|
| _____ 1. activates pepsinogen | (a) pepsin |
| _____ 2. inhibits amylase | (b) mucus |
| _____ 3. is essential for vitamin B ₁₂ absorption | (c) HCl |
| _____ 4. can act autocatalytically | (d) intrinsic factor |
| _____ 5. is a potent stimulant for acid secretion | (e) histamine |
| _____ 6. breaks down connective tissue and muscle fibres | |
| _____ 7. begins protein digestion | |
| _____ 8. serves as a lubricant | |
| _____ 9. kills ingested bacteria | |
| _____ 10. is alkaline | |
| _____ 11. coats the gastric mucosa | |

Written Questions

- Describe the four basic digestive processes.
- List the three categories of energy-rich foodstuffs and the absorbable units of each.

- List the components of the digestive system. Describe the cross-sectional anatomy of the digestive tract.
- What four general factors are involved in regulating digestive system function? What is the role of each?
- Describe the types of motility in each component of the digestive tract. What factors control each type of motility?
- State the composition of the digestive juice secreted by each component of the digestive system. Describe the factors that control each digestive secretion.
- List the enzymes involved in digesting each category of foodstuff. Indicate the source and control of secretion of each of the enzymes.
- Why are some digestive enzymes secreted in inactive form? How are they activated?
- What absorption processes take place within each component of the digestive tract? What special adaptations of the small intestine enhance its absorptive capacity?
- Describe the absorptive mechanisms for salt, water, carbohydrate, protein, and fat.
- What are the contributions of the accessory digestive organs? What are the nondigestive functions of the liver?
- Summarize the functions of each of the three major gastrointestinal hormones.
- What waste product is excreted in the feces?
- How is vomiting accomplished? What are the causes and consequences of vomiting, diarrhoea, and constipation?
- Describe the process of mucosal turnover in the stomach and small intestine.

Quantitative Exercise (Solution on p. A-52)

- Suppose a lipid droplet in the gut is essentially a sphere with a diameter of 1 cm.
 - What is the surface area-to-volume ratio of the droplet? (*Hint: The area of a sphere is $4\pi r^2$, and the volume is $4/3\pi r^3$.*)
 - Now, suppose that this sphere were emulsified into 100 essentially equal-sized droplets. What is the average surface area-to-volume ratio of each droplet?
 - How much greater is the total surface area of these 100 droplets compared with the original single droplet?
 - How much did the total volume change as a result of emulsification?

(Explanations on p. A-53)

- Why do patients who have had a large part of their stomach removed for treatment of stomach cancer or severe peptic ulcer disease have to eat small quantities of food frequently instead of consuming three meals a day?
- The number of immune cells in the *gut-associated lymphoid tissue (GALT)* housed in the mucosa is estimated to be equal to the total number of these defence cells in the rest of the body. Speculate on the adaptive significance of this extensive defence capability of the digestive system.

3. How would defecation be accomplished in a patient paralyzed from the waist down by a lower spinal cord injury?
4. After bilirubin is extracted from the blood by the liver, it is conjugated (combined) with glucuronic acid by the enzyme glucuronyl transferase within the liver. Only when conjugated can bilirubin be actively excreted into the bile. For the first few days of life, the liver does not make adequate quantities of glucuronyl transferase. Explain how this transient enzyme deficiency leads to the common condition of jaundice in newborns.
5. Explain why removal of either the stomach or the terminal ileum leads to pernicious anaemia.

CLINICAL CONSIDERATION

(Explanation on p. A-53)

Thomas W. experiences a sharp pain in his upper-right abdomen after eating a high-fat meal. Also, he has noted that his feces are greyish white instead of brown. What is the most likely cause of his symptoms? Explain why each of these symptoms occurs with this condition.

Energy Balance and Temperature Regulation

Body systems maintain homeostasis

Homeostasis

Among the factors that are homeostatically maintained are the availability of energy-rich nutrients to the cells and the temperature of the internal environment. The hypothalamus helps regulate food intake, which is of primary importance in energy balance. The hypothalamus also helps maintain body temperature. It can vary heat production by the skeletal muscles and can adjust heat loss from the skin surface by varying the amount of warmed blood flowing through the skin vessels and by controlling sweat production.

Scanning electron micrograph of fat (adipose) tissue

Food intake is essential to power cell activities. For body weight to remain constant, the caloric value of food must equal total energy needs. Energy balance and thus body weight are maintained primarily by controlling food intake. Energy expenditure generates heat, which is important in temperature regulation. Humans, usually in environments cooler than their bodies, must constantly generate heat to maintain their body

temperature. Also, they must have mechanisms to cool the body if it gains too much heat from heat-generating skeletal muscle activity or from a hot external environment. Body temperature must be regulated because the rate of cellular chemical reactions depends on temperature, and overheating damages cell proteins. The hypothalamus is the major integrating centre for maintaining both energy balance and body temperature.

Energy Balance and Temperature Regulation

CONTENTS AT A GLANCE

16.1 Energy balance

16.2 Temperature regulation

Clinical Connections

Joanne, a 42-year-old female, has been morbidly obese her entire life. Two years ago she weighed 161 kg and was 165 cm tall. This calculates to a BMI of 59.1, which is class 3 obesity. Five years earlier she was diagnosed with type 2 diabetes, likely associated with her obesity. She was also hypertensive and suffered from sleep apnea. Despite a lifetime of attempting to lose weight through diet and exercise, she was unsuccessful. At age 40, due to morbid obesity and underlying medical conditions, her physician recommended bariatric surgery, and she underwent a Roux-en-Y gastric bypass procedure.

During her recovery over the past two years she lost 56 kg and now weighs 106 kg. Although she still has type 2 diabetes mellitus, she now controls it by diet and exercise. As well, there has been a decrease in the degree of her hypertension, and she no longer requires treatment for sleep apnea. She now feels much better about herself and is able to maintain her weight through regular exercise and by eating many healthy, small meals throughout the day.

16.1 | Energy Balance

Each cell in the body, whether it is operating aerobically or anaerobically, needs energy to perform the functions essential for the cell's own survival (such as active transport and cellular repair) and also to carry out its specialized contributions toward maintaining homeostasis (such as gland secretion or muscle contraction). All energy used by cells is ultimately provided by food intake of carbohydrates, fats, and proteins.

In biological terms, **energy balance** can be represented in the following equation:

$$\begin{aligned} \text{Energy Intake} = & \text{internal heat produced} \\ & + \text{external work} + \text{internal work} \\ & + \text{energy storage} \end{aligned}$$

In this section we discuss the different elements that make up this energy balance equation.

Thermodynamics

According to the **first law of thermodynamics**, energy can be neither created nor destroyed. Therefore, energy is subject to the same kind of input–output balance as are the chemical components of the body, such as water and salt (p. 608).

ENERGY INPUT AND OUTPUT

The energy within ingested food, primarily carbohydrates, fats, and proteins, constitutes *energy input* to the body. Chemical energy locked in the bonds that hold the atoms together in nutrient molecules is released when these molecules are broken down in the body. Cells capture a portion of this nutrient energy by means of the high-energy phosphate bonds of ATP (pp. 24 and Appendix B, p. A-17). Energy harvested from biochemical processing of ingested nutrients is either used immediately to perform biological work or stored in the body (e.g., glycogen, lipids) for later use as needed during periods when food is not being digested and absorbed.

Energy output, or *expenditure*, by the body falls into two categories (► Figure 16-1): external work and internal work. **External work** is the energy expended when skeletal muscles contract to move external objects or to move the body in relation to the environment. **Internal work** constitutes all other forms of biological energy expenditure that do not accomplish mechanical work outside the body. Internal work encompasses two types of energy-dependent activities: (1) skeletal muscle activity used for purposes other than external work (e.g., muscle contractions for postural maintenance and shivering), and (2) all the energy-expending activities that must go on all the time just to sustain life. The latter include the work of pumping blood and breathing; the energy required for active transport of critical materials across plasma membranes; and the energy used during synthetic reactions for the maintenance, repair, and growth of cellular structures—in short, the “metabolic cost of living.”

CONVERSION OF NUTRIENT ENERGY TO HEAT

Not all energy in nutrient molecules can be harnessed to perform biological work. Energy cannot be created or destroyed, but it can be converted from one form to another. The energy in nutrient molecules not used to energize work is transformed into **thermal energy**, otherwise known as **heat**. During biochemical processing, only about 50–60 percent of the energy in nutrient molecules is transferred to ATP; the other 40–50 percent of nutrient energy is lost as heat. During ATP expenditure by the cells, another 25 percent of the energy derived from ingested food becomes heat. Therefore, only about 25–35 percent of nutrient energy is available for internal and external work. The remaining about 75 percent is lost as heat during the transfer of energy from nutrient → ATP → cellular use.

Moreover, of the energy actually captured for use by the body, almost all eventually becomes heat. For example, energy used by the heart to pump blood is gradually changed into heat by friction as blood flows through the vessels. Even in performing external work, skeletal muscles convert chemical energy (ATP) into mechanical energy inefficiently; about 75 percent of the energy is lost as heat. In this way, all energy liberated from ingested food that is not directly used for moving external objects or stored in fat (adipose tissue) deposits (or, in the case of growth, as protein) eventually becomes body heat. However, much of the heat is used to maintain body temperature.

Metabolic rate

The rate at which energy is expended by the body during both external and internal work is known as the **metabolic rate**:

$$\text{Metabolic rate} = \text{energy expenditure/unit of time}$$

Because most of the body’s energy expenditure eventually appears as heat, the metabolic rate is normally expressed as the rate of heat production in kilocalories per hour. The basic unit of heat energy is the **calorie**, which is the amount of heat needed to raise the temperature of 1 g of H₂O by 1°C. This unit is too small when discussing the human body because of the amount of heat produced, so the term **kilocalorie (kcal) or Calorie (C)** is used, which is equivalent to 1000 calories. Thus, 1 kcal = 1C = 1000 calories. When nutritionists speak of calories in quantifying the energy content of various foods, they are referring to a kcal or Calorie. There are 4 kcal and 9 kcal of heat energy released when 1 g of glucose and 1 g of fat are burned (oxidized), respectively. It does not matter whether the oxidation takes place inside or outside the body.

CONDITIONS FOR MEASURING THE BASAL METABOLIC RATE

Metabolic rate and, consequently, the amount of heat produced change in relation to a variety of factors, such as exercise, daily activities, age, anxiety, body composition and size, thyroid hormone, sympathetic stimulation (release of epinephrine and norepinephrine), growth

► Figure 16-1 Energy input and output

hormone, shivering, climate, sleep, and food intake. Increased skeletal muscle activity through exercise or other daily activities is the factor that can increase metabolic rate to the greatest extent (Table 16-1). Even slight increases in muscle tone notably elevate the metabolic rate, and therefore heat production. For this reason, a person's metabolic rate is determined under standardized conditions that have been established to control factors that alter metabolic rate. In this way, the metabolic activity necessary to maintain basic body function can be determined. **Basal metabolic rate (BMR)** refers to the rate of energy use in the body during absolute rest, but while awake; it is the minimum energy (kcal) needed to maintain basic physiological function. The BMR is measured under the following conditions:

1. Physical rest is required—no exercise for at least 30 minutes prior to test to eliminate excess muscular heat production.
2. Mental rest is also needed to minimize skeletal muscle tone (sympathetic stimulation, epinephrine) associated with stress.
3. The room environment should be comfortable (20–24°C, low lights, and person laying down).
4. The person should not have eaten any food for at least 12 hours to avoid **diet-induced thermogenesis** (*thermo*

TABLE 16-1 Rate of Energy Expenditure for a 70 kg Person during Different Types of Activity*

Form of Activity	Energy Expenditure (kcal/h)
Sleeping	65
Awake, lying still	77
Sitting at rest	100
Standing relaxed	105
Getting dressed	118
Keyboarding	140
Walking slowly on level (4 km/h)	200
Carpentry, painting a house	240
Sexual intercourse	280
Bicycling on level (8.8 km/h)	304
Shovelling snow, sawing wood	480
Swimming	500
Jogging (8.5 km/h)	570
Rowing (20 strokes/min)	828
Walking up stairs	1100

*To provide some perspective when viewing this table, keep in mind that two regular Oreo cookies contain approximately 107 Calories, which translates into 107 kcals. Thus, one hour of TV watching does not expend the kilocalorie equivalent of two Oreo cookies.

means “heat”; *genesis* means “production”) or the obligatory increase in metabolic rate that occurs from food intake. This short-lived (≤ 12 hour) rise in metabolic rate is due not to digestive activities but to the increased metabolic activity associated with the processing and storage of ingested nutrients (e.g., in the liver).

METHODS OF MEASURING THE BASAL METABOLIC RATE

The rate of heat produced can be measured directly or indirectly. With **direct calorimetry**, the person sits in an insulated chamber with water circulating through the walls. The difference in the temperature of the water entering and leaving the chamber reflects the amount of heat liberated from the person (metabolic heat) and picked up by the water as it passes through the chamber. This provides an accurate measurement of heat production, but due to the size and cost of the chamber is not practical. A more convenient and common method of BMR measurement is **indirect calorimetry**. This method simply requires the measurement of a person's oxygen uptake per unit, which is easy and more cost effective. Recall that

Accordingly, a direct relationship exists between the volume of oxygen used and the quantity of heat produced. This relationship also depends on the type of food that is oxidized. Carbohydrates (4 kcals/g), proteins (4 kcals/g), and fats (9 kcals/g) need different amounts of oxygen for their oxidation, yielding different amounts of kilocalories when oxidized. However, when averaged, we can estimate the quantity of heat produced per litre of oxygen consumed on a typical, mixed, Canadian diet. This approximate value, known as the **energy equivalent of O₂**, is 5 kcals/L of oxygen consumed. Thus, the metabolic rate of a person consuming 15 L/h of oxygen can be estimated as follows:

$$\begin{aligned} 15 \text{ L/h} &= \text{O}_2 \text{ consumption} \\ \times 5 \text{ kcals/L} &= \text{energy equivalent of O}_2 \\ 75 \text{ kcals/h} &= \text{estimated metabolic rate} \end{aligned}$$

In this way, a simple measurement of oxygen consumption can be used to reasonably estimate body heat production to determine metabolic rate.

Once the rate of heat production is determined under the prescribed basal conditions, it must be compared to norms for people of the same sex, age, height, weight, and body composition, because these factors all affect the basal rate of energy expenditure. For example, a large man actually has a higher rate of heat production than a smaller man, but expressed in terms of total surface area (which reflects height and weight), the output in kilocalories per hour per square metre of body surface area is normally similar.

FACTORS INFLUENCING THE BASAL METABOLIC RATE

Many factors influence metabolic rate, including the following key factors:

- **Thyroid hormone.** Thyroxine is a very important determinant of BMR due to its whole-body metabolic effect. When

maximal quantities of thyroxine are secreted, metabolic rate increases 50–100 times. As thyroid hormone increases, the BMR increases correspondingly.

- *Sympathetic stimulation.* Often in concert with the release of epinephrine and norepinephrine, stimulation of the SNS increases metabolic rate by increasing cellular metabolism (e.g., skeletal smooth muscle tone). This neural-hormonal milieu also influences the rate of glycogenolysis. In addition, sympathetic stimulation is associated with the release of heat from brown fat stores. Contrary to the belief that only neonates have brown fat stores, adults have brown fat stores as well, and those who work outdoors frequently have greater brown fat stores than those who work inside. The heat released from **brown fat** results from the high number of mitochondria in the fat stores. When stimulated by the sympathetic nervous system, the oxidation of fat droplets results in large amounts of heat production. Why is all the heat produced? Because oxidative phosphorylation within the brown fat stores is uncoupled, so no ATP is generated, just heat.
- *Exercise.* By far, this is the factor that causes the greatest increase in BMR rate, due to the size and metabolic potential of the muscle tissue (45–70% of total body weight). A few seconds of maximal muscular exercise can increase overall heat production by about 50 times for a few minutes.
- *Daily activities.* Similar to exercise, the more vigorous the daily activity (e.g., moving furniture) and the larger the percentage of muscle mass involved in completing the activity, the larger the increase in metabolism.
- *Sex.* Men often have more muscle mass than women; thus, they have a greater amount of metabolically active tissue, which gives them a greater overall metabolism.
- *Age.* As we age our metabolic rate declines. From birth to about 18 years, there is a rapid decline, and from 18 to 70, there is a more gradual decline. The high metabolic rate in the early years of life results from the body's need to rapidly synthesize cellular material for growth. Obviously, this declines with age. As we age, the maintenance of muscle mass through physical activity (e.g., resistance training) is important.

Surprisingly, the BMR is not the body's lowest metabolic rate. The rate of energy expenditure during sleep is 10–15 percent lower than the BMR, presumably because of the more complete muscle relaxation that occurs during the paradoxical stage of sleep (p. 134).

Energy input and energy output

Because energy cannot be created or destroyed, energy input must equal energy output, as follows:

$$\begin{array}{l} \text{Energy input} = \text{energy output} \\ \text{Energy in food} = \text{external} + \text{internal heat} \pm \text{stored} \\ \text{consumed} \quad \text{work} \quad \text{production} \quad \text{energy} \end{array}$$

There are three possible states of energy balance:

1. *Neutral energy balance.* If the amount of energy in food intake equals the amount of energy expended during external and internal work, plus the basal internal energy expenditure (appearing as body heat), then energy input and output are balanced, and body weight should remain constant.
2. *Positive energy balance.* If the amount of energy in food intake is greater than the amount of energy expended during external and internal work, the extra energy consumed but not used is stored in the body (e.g., fat, glycogen), and body weight increases.
3. *Negative energy balance.* Conversely, if the energy from food intake is less than the body's immediate energy needs, the body must use stored energy (fats and glycogen) to meet energy needs, and body weight decreases accordingly.

For a person to maintain a constant body weight (with the exception of minor fluctuations caused by changes in H₂O content), energy acquired through food intake must equal energy expenditure by the body. Because the average adult maintains a fairly constant weight over long periods of time, this implies that precise homeostatic mechanisms exist to maintain a long-term balance between energy intake and energy expenditure. Theoretically, total body energy content could be maintained at a constant level by regulating the magnitude of food intake, physical activity, internal work, and heat production. Control of food intake to match changing metabolic expenditures is the major means of maintaining a neutral energy balance. The level of physical activity is principally under voluntary control, and mechanisms that alter the degree of internal work and heat production are aimed primarily at regulating body temperature rather than total energy balance.

However, after several weeks of eating less or more than desired, small counteracting changes in metabolism may occur. For example, a compensatory increase in the body's efficiency of energy use in response to underfeeding partially explains why some dieters become stuck at a plateau after having lost the first five or so kilograms of weight fairly easily. Similarly, a compensatory reduction in the efficiency of energy use in response to overfeeding accounts in part for the difficulty experienced by very thin people who are deliberately trying to gain weight. Despite these modest compensatory changes in metabolism, regulation of food intake is the most important factor in the long-term maintenance of energy balance and body weight.

Food intake

Even though food intake is adjusted to balance changing energy needs over a period of time, there are no calorie receptors per se to monitor energy input and output, or total body energy content. Instead, blood-borne chemicals that signal the body's nutritional state, such as levels of stored fat or feeding status, are important factors regulating food intake. Control of food intake relies on more than a single signal; it is established by the integration of multiple signals that provide overall information about the body's energy status. Various molecular signals (discussed in this

section) ensure that feeding behaviour is synchronized with the body's short- and long-term energy needs. Some of this information is used for short-term regulation of food intake, that is, controlling meal size and frequency. Interestingly, over a 24-hour period, the energy ingested rarely matches the energy expenditure for that time. However, over the long-term (i.e., months), the correlation between total caloric intake and total energy output is good. If the relationship is undisturbed (e.g., by illness), total energy content of the body—and thus body weight—remains relatively stable. *In saying this, maintaining a healthy body weight is more complex than simply calculating total calories consumed versus total calories expended; the type of food (e.g., sugars) consumed and genetics (epigenetics) also play an important role.*

Before we focus on other factors that influence energy balance, we first turn our attention to the body's long- and short-term signals (hormones) for monitoring caloric need and energy content.

Clinical Connections

The purpose of bariatric surgery to treat morbid obesity is to reduce food intake.

Although there are many different types of procedures, Joanne underwent a Roux-en-Y gastric bypass procedure. The surgery involves creating a small pouch with a volume of around 30 mL by dividing the upper end of the stomach. The small intestine is then severed and attached to the pouch. The section of small intestine still attached to the stomach is then reattached further down the small intestine to allow drainage. With the entire stomach being replaced by the small volume of the pouch, food intake is severely restricted.

ROLE OF THE ARCUATE NUCLEUS: NEUROPEPTIDE Y AND MELANOCORTINS

Control of energy balance and food intake is primarily a function of the hypothalamus. The **arcuate nucleus** of the hypothalamus plays a central role in both the long-term control of energy balance and body weight and the short-term control of food intake on a meal-to-meal basis. The arcuate nucleus is an arch-shaped collection of neurons located adjacent to the floor of the third ventricle. Multiple, highly integrated, redundant pathways criss-cross into and out of the arcuate nucleus—indicative of this structure's complex involvement in feeding and satiety. **Feeding (appetite) signals** give rise to the sensation of **hunger**, driving us to eat. By contrast, **satiety** is the feeling of being full, telling us when we have had enough, and suppressing the desire to eat.

The arcuate nucleus has two subsets of neurons that function in an opposing manner. One subset releases *neuropeptide Y*, and the other releases *melanocortins*.¹ **Neuropeptide Y (NPY)**, a potent

appetite stimulator, leads to increased food intake, thus promoting weight gain. **Melanocortins**, a group of hormones typically associated with skin colour, have been shown to exert an unexpected role in energy homeostasis. Melanocortins, most notably a *melanocyte-stimulating hormone* (p. 226), suppress appetite, leading to reduced food intake and weight loss (loss of fat stores). Melanocortins do not play a direct role in determining human skin colouration; rather, this is determined by the activation of the melanocortin 1 receptor and by the particular form of melanin that's produced in melanocytes following stimulation by melanocortins.

But NPY and melanocortins are not the final effectors in appetite control. These arcuate-nucleus chemical messengers, in turn, influence the release of neuropeptides in other parts of the brain that exert more direct control over food intake. Scientists are currently trying to unravel the other factors that act upstream and downstream from NPY and melanocortins to regulate appetite. The following regulatory inputs to the arcuate nucleus and beyond are important in the long-term maintenance of energy balance and the short-term control of food intake at meals (► Figure 16-2).

LONG-TERM MAINTENANCE OF ENERGY BALANCE: LEPTIN AND INSULIN

The notion that fat cells (**adipocytes**) in adipose tissue (subcutaneous or visceral) are merely a storage site for triglycerides has undergone a shift with the discovery of their active role in energy homeostasis. Adipose tissue is an intricate, vital, and active metabolic and endocrine organ that has both local (autocrine/paracrine) and systemic (endocrine) effects. Adipose tissue contains connective and nervous tissues and immune cells, and together functions as an integrated unit. Not only does adipose tissue respond to afferent signals from hormones and the central nervous system, but also adipocytes secrete their own hormones (bioactive peptides), collectively termed **adipokines** (► Table 16-2). These factors include cytokines, adiponectin, plasminogen, FFA, adipsin, angiotensinogens, and resistin. We now take a closer look at the important hormone *leptin*.

Leptin was discovered in the mid-1990s by Dr. Friedman, and was the first blood-borne molecular satiety signal identified. Leptin is one of the most important adipokines, a hormone important in the regulation of food intake and body weight (*leptin* means “thin”). The amount of leptin in the blood is an excellent indicator of the total triglycerides stored in adipose tissue: the larger the volume of fat stores, the more leptin released into the blood. Many of the effects of leptin related to energy intake and expenditure are mediated via the arcuate nucleus of the hypothalamus, whereas other effects are mediated directly on peripheral tissues (e.g., muscle and pancreatic cells). However, leptin's primary role is to serve as a metabolic signal of energy sufficiency. It acts via negative feedback, because increased leptin from growing fat stores serves to turn off the hunger signal, thus decreasing food consumption and promoting weight loss. Its inhibitory action works by suppressing hypothalamic output of appetite-stimulating NPY and by stimulating output of appetite-suppressing melanocortins.

In contrast, a decline in leptin is linked with the adaptive physiological response to starvation, which increases appetite and decreases energy expenditure (conservation of fuel).

¹The two subsets of neurons in the arcuate nucleus are the NPY/AgRP population and the POMC/CART population. AgRP stands for *agouti-related protein*. Both NPY and AgRP stimulate appetite. POMC stands for *pro-opiomelanocortin*, the precursor molecule that gives rise to melanocortins. CART stands for *cocaine- and amphetamine-related transcript*. Melanocortins and CART peptide both suppress appetite. For simplicity, we discuss the role of NPY and melanocortins only but recognize that other chemical signals released from the arcuate nucleus exert similar functions.

Figure 16-2 Factors that influence food intake

The starvation response can be staved off with the administration of low-dose leptin (increasing circulating leptin) replacement. This starvation response is even found in states of obesity, and interestingly, naturally high levels of leptin (endogenous) or treatment with low-dose leptin (exogenous) is effective in satiating obese persons. This is consistent with the theory of leptin resistance (discussed in the section Obesity: Kcals Required and Other Factors).

Another blood-borne signal that plays an important role in long-term control of body weight is **insulin**. This hormone is secreted by the pancreas in response to an increase in glucose concentration and other nutrients in the blood post-meal. Insulin stimulates the

cellular uptake and storage of the nutrient glucose. In this way, the increase in insulin secretion that accompanies nutrient abundance, use, and storage appropriately inhibits the NPY-secreting cells of the arcuate nucleus, thereby suppressing further food intake.

In addition to the importance of leptin, insulin, and perhaps other so-called **adiposity signals** (fat-related) in the long-term control of body weight, other factors play a role in controlling the timing and size of meals. Several blood-borne messengers from the digestive tract and pancreas are important in regulating how often and how much we eat in a given day. We now look at how these messengers function.

■ **TABLE 16-2 Major Adipokines**

Adipokine	Function
Leptin	Released from stored fat; suppresses appetite; dominant long-term regulator of energy balance and body weight
Adiponectin	Secretion from adipocytes suppressed in obesity; promotes fatty acid oxidation by muscle; increases sensitivity to insulin; decreases body weight by increasing energy expenditure; has anti-inflammatory actions
Resistin	Released primarily in obesity; leads to insulin resistance
Visfatin	Released primarily from visceral fat; stimulates glucose uptake; binds with insulin receptor at a site distinct from the insulin-binding site
Tumour Necrosis Factor α (TNF-α) and Interleukin 6 (IL-6)	Promote low-level inflammation in fat and throughout body

SHORT-TERM EATING BEHAVIOUR: GHRELIN AND PYY₃₋₃₆ SECRETION

Two peptides important in the short-term control of food intake have recently been identified: *ghrelin* and *peptide YY₃₋₃₆* (PYY₃₋₃₆), which signify hunger and fullness, respectively. Both are secreted by the digestive tract. **Ghrelin**, the so-called hunger hormone, is a fast-acting appetite stimulator produced by the stomach and regulated by the feeding status (*ghrelin* is the Hindu word for “growth”). Secretion of this mealtime stimulator peaks before meals and makes people feel like eating, then falls once food is eaten. Ghrelin stimulates appetite by activating the hypothalamic NPY-secreting neurons.

Peptide YY₃₋₃₆ (PYY₃₋₃₆) is a counterpart of ghrelin. The secretion of (PYY₃₋₃₆), which is produced by the small and large intestines, is at its lowest level before a meal but rises during meals and signals satiety. This peptide acts by inhibiting the appetite-stimulating NPY-secreting neurons in the arcuate nucleus. By thwarting appetite, PYY₃₋₃₆ is believed to be an important mealtime terminator.

We now examine several additional factors involved in signalling the body’s condition on the hunger–satiety continuum.

BEYOND THE ARCULATE NUCLEUS: OREXINS AND OTHERS

Two hypothalamic areas are richly supplied by axons from the NPY- and melanocortin-secreting neurons of the arcuate nucleus. These second-order neuronal areas involved in energy balance and food intake are the **lateral hypothalamic area (LHA)** and **paraventricular hypothalamic nucleus (PVN)**. In a recently proposed model, the LHA and PVN release chemical messengers in response to input from the arcuate nucleus neurons. These messengers act

downstream from the NPY and melanocortin signals to regulate appetite. The LHA produces two closely related neuropeptides known as **orexins**, which are potent stimulators of food intake (*orexis* means “appetite”). Moreover, orexin may also stimulate wakefulness and energy expenditure. Orexin dysregulation was linked with narcolepsy, and recent animal studies indicate that a potential chief role of orexin might be to integrate metabolism, circadian rhythm, and sleep to determine periods of sleep and alertness. NPY stimulates the release of orexins, leading to an increase in appetite and greater food intake, whereas melanocortins inhibit the secretion of orexins. By contrast, the PVN releases chemical messengers—for example, **corticotropin-releasing hormone**—that decrease appetite and food intake. (As its name implies, corticotropin-releasing hormone is better known for its role as a hormone; see Chapter 6.) Melanocortins stimulate and NPY inhibits the release of these appetite-suppressing neuropeptides.

In contrast to the key role of the hypothalamus in maintaining energy balance and long-term control of body weight, there is a region in the brain stem known as the **nucleus tractus solitarius (NTS)** that processes signals important in the feeling of being full. This region is considered the *satiety centre*. Not only does the NTS receive input from the higher hypothalamic neurons involved in energy homeostasis, but it also receives afferent inputs from the digestive tract and elsewhere that signal satiety (e.g., afferent neural input indicating the extent of stomach distension). We now turn our attention to cholecystokinin, the most important of these satiety signals.

CHOLECYSTOKININ AS A SATIETY SIGNAL

Cholecystokinin (CCK), one of the gastrointestinal hormones released from the duodenal mucosa during digestion of a meal, is an important satiety signal for regulating the size of meals. CCK is secreted in response to the presence of nutrients in the small intestine. Through multiple effects on the digestive system, CCK facilitates digestion and absorption of these nutrients (p. 692). It is appropriate that this blood-borne signal, whose rate of secretion is correlated with the amount of nutrients ingested, also contributes to the sense of being full after a meal has been consumed but before it has actually been digested and absorbed. We feel satisfied when enough food to replenish our body’s energy store is in the digestive tract—even though the energy store is still low. This explains why we stop eating before the ingested food is digested and therefore available to meet the body’s energy needs.

■ Clinical Connections

Gastric bypass surgery influences food intake not only because it physically restricts food intake. Due to the very small pouch size after the surgery, gastric distension is rapid, which activates mechanoreceptors that tell the brain that the stomach is full and to stop eating. The small stomach volume also results in food entering the small intestine faster, which activates chemical satiety signal pathways such as CCK and PYY earlier. It has been suggested that these later effects have a greater effect on post-bariatric surgery weight loss than the reduction of food volume itself.

PSYCHOSOCIAL AND ENVIRONMENTAL INFLUENCES

We have described the automatic, involuntary signals that control food intake. In addition, as with water intake, there are psychological, social, and environmental factors that shape people's eating habits. Often our decision to eat or stop eating is not determined merely by whether we are hungry or full, respectively. Frequently, we eat out of habit (eating three meals a day on schedule no matter what our status on the hunger-satiety continuum) or because of social custom (food often plays a prime role in entertainment, leisure, and business activities). Even well-intentioned family pressure—"Clean your plate before you leave the table"—can have an impact on the amount consumed.

Furthermore, the amount of pleasure derived from eating can reinforce feeding behaviour. Eating foods with an enjoyable taste, smell, and texture can increase appetite and food intake. This has been demonstrated in an experiment in which rats were offered their choice of highly palatable human foods. They overate by as much as 70–80 percent and became obese. When the rats returned to eating their regular monotonous but nutritionally balanced rat chow, their obesity was rapidly reversed.

Stress, anxiety, depression, and boredom have also been shown to alter feeding behaviour in ways that are unrelated to energy needs in both experimental animals and humans. University students often eat when studying to reduce stress, or because they are tired of studying; in this instance, food satisfies a psychological need, not hunger. Thus, any comprehensive explanation of how food intake is controlled must take into account these voluntary eating acts that can reinforce or override the internal signals governing feeding behaviour.

The gut microbiome and energy homeostasis

What foods we choose to consume and the amount of exercise we do are important factors in energy homeostasis. However, an important element often overlooked is the intestinal microbiome. Gut bacteria represent 1–3 percent of our total body mass. It is a highly active population that, because of constantly growing and dividing, likely contributes significantly to our body's total energy usage. The gut bacteria also play a significant role in regulating digestion efficiency, in that the microbiome processes certain ingested foods and molecules to make them available to us, their host. Gut bacteria are also considered a virtual endocrine organ because they secrete compounds that affect other cells within the body and may even play a role in the hypothalamic-pituitary-adrenal axis as part of the body's integrated response to stress. Such secretions potentially can affect total body energy balance and energy stores to modulate weight gain and loss. While there has been extensive research on how the microbiome can influence weight in rodent models, the direct connection in humans is still unclear.

Obesity: kcals required and other factors

Obesity is defined as excessive fat content in the adipose tissue stores; being 20 percent overweight compared with normal standards is considered the arbitrary boundary for obesity. In 2014, Statistics Canada reported that 20.2 percent

of Canadian adults were categorized as obese, using body mass index (BMI). This is up from 2003, when about 15 percent of the adult population was obese. These trends are the same for both males and females. If we take overweight and obese classifications together, approximately 53.6 percent of adult Canadians were in this category. (For more information on the obesity epidemic in Canada, see Concepts, Challenges, and Controversies, pp. 708–709.) Much of the world is following the same trend, recently leading the World Health Organization to coin the new word *globesity* to describe the worldwide situation.

Obesity occurs when, over a period of time, more kilocalories are ingested in food than are used to support the body's energy needs, and the excess energy is stored as triglycerides in adipose tissue. Early in the development of obesity, existing fat cells get larger (hypertrophy). An average adult has between 40 billion and 50 billion adipocytes. Each fat cell can store the maximum of about 1.2 µg of triglycerides. Once the existing fat cells are full, if people continue to consume more calories than they expend, they make more adipocytes (hyperplasia).

Although it is clear that a sedentary lifestyle is one primary reason for obesity, and that increasing physical activity levels may help maintain a normal healthy body weight, control of food intake is very important. The causes of obesity are many, and some remain obscure. However, some factors that may be involved include the following:

- *Disturbances in leptin (and potentially ghrelin) signalling.* The discovery of the hormone leptin was an important milestone linking the regulation of metabolism (i.e., hypothalamus) with the levels of energy storage (adipocytes). Research in this area has been aided by the use of genetically altered mice, including db/db (i.e., diabetic) and ob/ob (i.e., obese) mice. The primary genetic defect in these mice relates to either diminished leptin production (ob/ob) or impaired leptin receptors (db/db). Ob/ob mice, for example, can display many abnormalities seen in starving animals (even though they are obese), such as hyperphagia and decreased immune function, which can be reversed with a regular injection of leptin (leptin replacement). Thus, even though the ob/ob mouse's body weight and energy balance have not changed, increased leptin levels correct these abnormalities. Similar examples of obesity in humans have been linked with an alteration of leptin or the leptin receptor. Some cases of obesity have been linked to leptin resistance, meaning the brain does not detect leptin as a signal to turn down appetite until a higher set point (fat storage point) is achieved.

Nevertheless, the mechanism for leptin resistance is unknown, but may be related to defects in leptin signalling or transport across the blood-brain barrier. In both rodent (db/db mice) and human obesity studies, plasma leptin concentrations are elevated in proportion to the degree of adiposity (volume of fat cells), supporting the concept of leptin resistance in obesity. One goal of obesity research is to find the mechanism for leptin resistance and develop drugs that bypass the resistance by targeting neural processing steps, which are downstream from leptin (e.g., release of melanocortins).

Interestingly, just as circulating leptin levels are increased in the obese person, the level of the appetite-stimulating hormone ghrelin is decreased. It is certain that ghrelin has a hunger-stimulating effect, as well as an adipogenic effect (fat-storing effect). However, the mechanism through which ghrelin contributes to the development or maintenance of obesity is not yet clear. However, it is suggested that from an overall functional perspective, ghrelin and leptin might be complementary peptides in the regulatory system that informs the central nervous system about short-term and long-term energy balance.

- *Lack of exercise.* Numerous studies have shown that, on average, overweight people do not eat any more than those of normal body weight. One possible explanation is that overweight persons do not overeat but “underexercise”—the “couch potato” syndrome. Very low levels of physical activity are typically not accompanied by comparable reductions in food intake.

Moreover, moderate- to high-intensity physical activity (e.g., exercise) has three important effects that influence caloric expenditure and body weight: (1) during exercise more kilocalories are burned compared to sitting on the couch, so extra kilocalories are not stored but expended; (2) exercise improves insulin sensitivity, which reduces insulin levels and assists the satiety signal; (3) exercise makes the TCA cycle (p. 25) run faster, decreasing the amount of citrate leaving the mitochondria, which reduces the availability of the acetyl group for the production of fat; and (4) exercise reduces stress, which reduces cortisol and appetite associated with stress.

- *Differences in the “fidget factor.”* **Nonexercise activity thermogenesis (NEAT)**, or the fidget factor, might explain some variation in fat storage among people. NEAT refers to energy expended by physical activities other than planned exercise. Those who engage in toe tapping or other types of repetitive, spontaneous physical activity expend a substantial number of kilocalories throughout the day without a conscious effort.
- *Differences in extracting energy from food.* Another reason why lean people and obese people may have dramatically different body weights despite consuming the same number of kilocalories may lie in the efficiency with which each extracts energy from food. Studies suggest that lean individuals tend to derive less energy from the food they consume, because they convert more of the food’s energy into heat than into energy for immediate use or for storage. For example, slim individuals have more **uncoupling proteins**, which allow their cells to convert more of the nutrient calories into heat instead of fat; these people can eat a lot without gaining weight. By contrast, obese people may have more efficient metabolic systems for extracting energy from food; this is a useful trait in times of food shortage, but a hardship when trying to maintain a desirable weight when food is plentiful.
- *Development of an excessive number of fat cells as a result of overfeeding.* One of the problems in fighting obesity is that once fat cells are created, they do not disappear with dieting and weight loss. Even if a dieter loses a large portion of the

triglyceride fat stored in these cells, the depleted cells remain, ready to refill. Therefore, rebound weight gain after losing weight is difficult to avoid and discouraging for the person.

- *The existence of certain endocrine disorders, such as hypothyroidism* (p. 252). Hypothyroidism involves a deficiency of thyroid hormone, the main factor that bumps up the BMR so that the body burns more kilocalories in its resting state.
- An abundance of convenient, highly palatable, energy-dense, relatively inexpensive foods.
- The presence of brown fat stores may protect against obesity as we age. A relationship between BMI and brown fat stores has been detected. The trend indicates that a high level of brown fat stores typically correlate with a low BMI. Rodent studies have indicated that brown fat has profound effects on body weight and energy balance, and brown fat stores are found in adult humans (p. 702). Recall that one grouping of neurons in the arcuate nucleus is the NPY (potent appetite stimulator) neurons. Injection of NPY into this brain area reduces sympathetic stimulation of brown adipose tissue and, in doing so, simultaneously decreases energy expenditure and increases the expression of enzymes involved in lipogenesis in white fat (Billington, C.J., et al. [1991]. Effects of intracerebroventricular injection of neuropeptide Y on energy metabolism. *Am J Physiol Integr Comp Physiol*, 260: R321–27; G. Bray. [1992]. Peptides affect the intake of specific nutrients and the sympathetic nervous system. *Am J Clin Nutr*, 55: 265S–71S).
- The consumption of the sugar fructose may be associated with the obesity epidemic. Fructose, the sugar typically found in fruit, is also found in table sugar (sucrose) and many other foods (e.g., fast foods). Fructose is processed by the body in a different way than glucose. For example, glucose is an immediate energy source, whereas fructose must be converted in the liver to energy, fat, or glucose before it can be used by tissues. Additionally, the pathway for glucose breakdown is turned off when there is an accumulation of energy and fat, thereby preventing excess production. However, fructose breakdown does not have a feedback mechanism. Therefore, a massive ingestion of fructose would result in an overwhelming production of energy and fat. Some suggest that eating a high sugar diet—that is, a diet high in sucrose (because it is half fructose) or high-fructose corn syrup—is similar to eating a high fat diet, which results in weight gain and high cholesterol. So not all sugars are created equal!
- Genetics and inheritable traits. As discussed, the root of obesity is multifaceted, involving interactions among neuroendocrine status, environmental factors, sedentarism or poor dietary habits, and also genetics. Genetics play a large role in our lives, and thus it is no surprise that they can influence energy balance. For example, certain genetic diseases (e.g., Prader–Willi syndrome, PWS) have metabolic consequences. Prader–Willi syndrome is a genetic disorder present at birth in which seven genes on chromosome 15 are deleted or unexpressed. Those with PWS may have physical, mental, and behavioural problems—for example, the insistent feeling of hunger, which causes high levels of food consumption and thus energy balance.

What Is Obesity?

Obesity means having an excessive amount of body fat. Fat is contained under the skin (subcutaneous), within the muscle (intramuscularly), and around the organs (visceral). Fat is an energy reserve, and when we consume too many kilocalories, the extra energy is stored as body fat.

The distribution (location) of body fat is also a concern. Obese people often have a significant amount of abdominal subcutaneous fat, intramuscular fat, and visceral fat deposits, all of which are associated with the development of numerous cardiovascular diseases and insulin resistance.

Two commonly used determinants of obesity are percentage of body fat and body mass index (BMI). Most healthcare professionals agree that men who have more than 25 percent body fat and women who have more than 30 percent body fat are obese. Women generally store more fat than men. Alternatively, the body weight classification of BMI (body weight in kilograms/height in metres squared) indicates that a value greater than 30 is classified as obese. Much time, energy, and money have been directed into the study of obesity, with the hope of reducing its prevalence in today's society and the prevalence of associated diseases.

Measurement Techniques

Techniques used to measure body composition include hydrostatic weighing (underwater weighing), the Bod Pod (air displacement), and Dual Energy X-ray Absorptiometry (DEXA, an X-ray test). These methods are used primarily in research.

The most common method of indirectly determining the percentage body fat is skin-fold thickness—the measurement of the thickness of a layer of skin and subcutaneous fat in several parts of the body. Another method is bioelectrical impedance (BIA), which involves sending a low-voltage electrical current through the body. However, the results from these two methods are less accurate than hydrostatic weighing, the Bod Pod method, or DEXA.

One of the simplest and most accurate measures of whole-body composition is BMI. Canadian healthcare professionals often rely on BMI to diagnose obesity. BMI measurement is supported by the World Health Organization, the American College of Sports Medicine, Health Canada, and the Canadian Society for Exercise Physiology as a valid body-composition classification system and representation of total body fat. It is simple to perform because it requires only height and weight to calculate, and it is inexpensive to use.

If the waist circumference (WC, in centimetres) is included with BMI, a more comprehensive assessment of body composition or weight distribution can be achieved, and it provides a more complete assessment of the health risks. (Body mass index is considered an indicator of whole body composition, whereas WC is an indicator of central adiposity [abdominal subcutaneous and visceral fat]). Taken together, a better picture of fat weight distribution can be gathered.

The importance of WC has also been demonstrated in scientific research. Those who have a greater amount of abdominal fat

(subcutaneous and visceral) are predisposed to numerous diseases (e.g., heart disease). Waist circumference measurement allows the fine-tuning of the assessment of body composition. For example, a man can have a normal BMI (e.g., 24) but have a large amount of abdominal adiposity (e.g., ≥ 102); he would thus be at an increased risk for various diseases, whereas someone of normal BMI (e.g., 24) and lower WC (e.g., 95) is at lower risk for certain diseases.

BMI can vary greatly from person to person, and thus the classification of obesity varies. It is generally divided into the following subcategories: Class I (BMI 30.0–34.9), with a high risk of developing health problems; Class II (BMI 35.0–39.9), with a very high risk of health problems; and Class III (BMI 40 or more), with an extremely high risk of health issues. (See table Percentage Distribution of BMI.)

The diseases associated with being overweight or obese include type 2 diabetes (insulin resistance), dyslipidaemia (high amount of blood lipids), hypertension (high blood pressure), coronary heart disease (blockage of coronary artery), gallbladder disease (gallstones), obstructive sleep apnea (disruption of breathing), and certain cancers (such as colon cancer). These are generally classified as cardiovascular diseases, and the mortality rates associated with these diseases increase with weight gain. Obviously, a person who is in the obese category has an increased risk for these diseases, compared to a person in the overweight category.

Obesity occurs when individuals consume more calories from food than they expend as energy. The human body needs calories to sustain life—to supply energy for physical activity. It is important for a person of normal BMI and WC to consume adequate calories to maintain body weight and energy balance. However, when individuals eat more calories than they burn, the energy balance is tipped toward weight gain. This imbalance between calories in and calories out may differ from one person to another, since such factors as genetics and environment also play a role.

Genetic Factors

Obesity tends to run in families, which suggests a genetic association. However, families also tend to have the same or a similar diet and lifestyle habits that might contribute to obesity. Fettering out a genetic influence from other potential influences (environmental) on obesity is usually very difficult. Nonetheless, research does show a link between obesity and heredity.

The relationship between ZFP36 gene expression levels, obesity-related phenotypes, and adipokines is an example of genetics influencing obesity. (Dr. David Dyck at the University of Guelph has studied the role of adipokines in skeletal muscle insulin sensitivity.) The findings indicate that ZFP36 gene expression in omental adipose tissue (visceral adipose tissue around the liver) may offer partial protection against the development of insulin resistance and diabetes normally associated with obesity. There are also genetic disorders that predispose a person to obesity. An example of this is Prader–Willi syndrome, a rare disorder in which genes are missing on chromosome 15, resulting in hyperphagia (excessive hunger), leading to overeating and thus obesity.

Environmental and Social Factors

Environment strongly influences obesity. The number of obese adult persons in Canada has risen significantly in the last 20 years. Thus, the adult population is gaining weight and changing their body composition in a negative fashion. Since the 1980s, the genetic makeup has not changed, but the environment has.

Environmental factors typically include physical activity (recreational pastimes, access to facilities, transportation), nutrition (portion size, restaurant selection, food selection), and social factors (poverty, education). We often eat out too frequently, consume too much fat, and are too physically inactive. Also, our environment does not always support healthy choices and habits. For example, work weeks are longer, and often both parents are working, which makes day-to-day activity more hectic and planning for nutritious meals more difficult.

In Canada, a 2015 Canadian Health Measures Survey (CMHS) indicates that 28.1 percent of adults 18 years or older had a BMI ≥ 30 , and 36 percent were overweight.

The 2015 CMHS shows that the number of persons in Canada considered obese has increased dramatically since the late 1970s. Using height and weight data collected in the late 1970s during the Canada Health Survey, the age-adjusted obesity rate was 13.8 percent, which is below the 2015 figure of 28.1 percent. The increase is evident in each of the three obesity categories, particularly in Classes II and III.

Percentage Distribution of BMI, by Sex and Household Population Aged 18 and Older, Canada (Excluding Territories), 2015

	BOTH SEXES	MEN	WOMEN
	Percent	Percent	Percent
Underweight	1.7	0.8	2.6
Normal Weight	34.2	30.8	37.5
Overweight (not obese)	36.0	39.9	32.1
Obese Class I	16.7	18.1	15.4
Obese Class II	7.4	7.8	6.9
Obese Class III	4.0	2.6	5.5
Overweight and Obese (BMI ≥ 25)	64.1	68.4	59.9
Obese (BMI ≥ 30)	28.1	28.5	27.8

Source: Statistics Canada, CANSIM Table 117-0005, Distribution of the household population by adult body mass index (BMI) - Health Canada (HC) classification, by sex and age group. <http://www5.statcan.gc.ca/cansim/a26?lang=eng&id=1170005&p2=33>

Obesity in Canadian children has also increased. Between 1981 and 1996, the rate of obesity in children (7 to 13 years old) tripled. The rate of overweight and obesity combined among children also increased by more than 250 percent between 1981 and 2001. In 2015, for children ages 3 to 17, 14.2 percent were overweight, and 9.0 percent were obese.

Obesity rates are also different for various populations (cultures) and geographical locations within Canada. A population that has recently been investigated and potentially found to have a high prevalence of obesity is Indigenous children. A study completed by Dr. Noreen Willows from the University of Alberta examined the prevalence of overweight and obesity in Quebec Cree children (aged 9 to 12 years). It revealed that 33 percent of the children were overweight, and 38 percent were obese.

To fight this trend, health needs to be promoted in a variety of school subject areas, and social inequities need to be addressed, including the unequal access to physical activity facilities. The financial cost of obesity and physical inactivity varies depending on the types of costs included, but the cost is estimated to have been about \$5.3 billion in 2001. This is a large economic burden on Canada's healthcare system and a particular burden on individual Canadians.

The **Canadian Obesity Network (CON)**—which consists of researchers, physicians, teachers, hospitals, industries, and others—facilitates access to information, people, funding, and the collective experience of a wide range of partners and individuals. CON is now one of Canada's leading obesity research, prevention, and management communities. It assists with the dissemination of information via news, resources, forums, and workshops, which makes possible a better understanding and management of obesity. Further information can be found on the CON website: <http://www.obesitynetwork.ca>.

Other Factors

Other factors that are or may be associated with obesity are specific diseases, such as hypothyroidism (reduced thyroid hormone), which can lower metabolic rate and energy levels. As well, some medical drugs have been associated with obesity: for example, antidepressants, steroids, and psychiatric medications.

Additionally, differences in the regulatory pathways for energy balance—either those governing food intake or those of energy expenditure—arise from genetic variations. Specifically, *epigenetics* are those inheritable changes in genetic expression that occur without changes in the sequencing of DNA. Individuals who demonstrate changes in DNA methylation (i.e., the addition of a methyl group) or other epigenetically related processes (e.g., covalent modifications to histones) could have greater susceptibility to changes in energy storage. Understanding epigenetics may eventually assist nutritionists and exercise specialists in devising the most appropriate diet and exercise plan based on the prediction of body-weight homeostasis (energy balance).

Despite this rather lengthy list, our knowledge about the causes and control of obesity is still limited, as evidenced by the number of people who are constantly trying to stabilize their weight at a more desirable level. This is important from more than an aesthetic viewpoint. It is known that obesity can predispose an individual to disease and premature death.

Anorexia nervosa: An issue of control

The converse of obesity is generalized nutritional deficiency. The obvious causes for reduction of food intake below energy needs are lack of availability of food, interference with swallowing or digestion, and impairment of appetite.

One poorly understood disorder in which lack of appetite is a prominent feature is **anorexia nervosa**. Anorexia (anorexia nervosa) is an eating disorder focused on weight loss. However, the weight loss eventually becomes a form of control over one's body, and the desire to become thinner and more aesthetically pleasing becomes secondary. This means the pattern of dieting or eating restriction does not change, but the psychology of the condition changes to one of control.

People with anorexia persist with the endless cycle of eating restriction, frequently to the point of starvation, in an attempt to feel a sense of control over their body. This cycle is akin to any type of drug or substance addiction. Anorexia afflicts primarily females: Canadian statistics suggest that more than 95 percent of anorexics are female, but males are also at risk.

Anorexia typically becomes apparent near preadolescence or adolescence. In Canada, since 1987, hospitalizations for eating disorders have increased by approximately 35 percent among young women under the age of 15 years. Men represent only about 5 percent of those with anorexia. An Ontario study found that about 0.3 percent of men aged 15 to 64 years and about 2.1 percent of women had anorexia nervosa or bulimia (<http://www.phac-aspc.gc.ca/publicat/human-humain06/10-eng.php>). Closely related to anorexia nervosa is bulimia nervosa, an eating disorder whose root cause is also psychological. There are two forms or types of bulimia: purging and nonpurging. The purging type is the most common and involves self-induced vomiting, laxatives, and diuretics as a means of rapidly reducing the contents of the stomach. Nonpurging bulimia is less common but typically involves binge eating followed by excessive exercise or fasting to counter the calories.

Research suggests that people for whom thinness is highly important or a professional requirement (e.g., athletes, models) tend to be at risk for eating disorders in general. There is no research that outlines why some people develop anorexia and others do not. Societal demands and expectations may play a role, but are not thought to be the root of the disease. The disease likely begins with the basic and common pressure to be thin and attractive, as portrayed in magazines and on television, but it is accelerated by a poor self-image.

Research also suggests that genetics may play a role in determining a person's susceptibility to anorexia, and so attempts have been made to identify the gene(s) that might affect a person's tendency to develop this disorder. Additionally, some researchers suggest that anorexia may be related to dysfunction in the hypothalamus, which is responsible for regulating certain metabolic processes. Still others have suggested that imbalances in neurotransmitter levels in the brain may occur in people suffering from anorexia.

Treatment typically takes the form of a multidisciplinary or team-oriented approach. The team may consist of a physician (initial diagnosis), nutritionist (treatment protocol), and psychologist (cognitive behavioural therapy). The goal is often to improve body functioning (e.g., strength and immune system functioning) and treat the psychology of the condition.

Check Your Understanding 16.1

1. Define external work, internal work, metabolic rate, appetite signals, satiety signals, adiposity signals, adipokines, visceral fat, and subcutaneous fat.
2. Explain how the basal metabolic rate can be determined indirectly.
3. Make a chart listing the involuntary regulatory signals on appetite, and indicate the source and effect of each (i.e., whether it increases or decreases appetite).

16.2 | Temperature Regulation

Humans are usually in environments cooler than their bodies, but we constantly generate heat internally, which helps maintain body temperature. Heat production ultimately depends on the oxidation of metabolic fuel derived from food.

Changes in body temperature in either direction alter cell activity; an increase in temperature speeds up cellular chemical reactions, whereas a fall in temperature slows down these reactions. Because cell function is sensitive to fluctuations in internal temperature, **temperature regulation** is important, and we homeostatically maintain body temperature at a level optimal for cellular metabolism to proceed in a stable fashion. Overheating is more serious than cooling. Even moderate elevations of body temperature begin to cause nerve malfunction and irreversible protein denaturation. Most people suffer convulsions when the

internal body temperature reaches about 41°C ; 43.3°C is considered the upper limit compatible with life.

By contrast, most of the body's tissues can transiently withstand substantial cooling. This characteristic is useful during cardiac surgery when the heart must be stopped. The patient's body temperature is deliberately lowered. The cooled tissues need less nourishment than they do at normal body temperature because of their reduced metabolic activity. However, a pronounced, prolonged fall in body temperature slows metabolism to a fatal level.

Internal core temperature

The normal body temperature, taken orally (by mouth), has traditionally been considered 37°C . However, a recent study indicates that normal body temperature varies among individuals and varies throughout the day, ranging from 35.5°C in the morning to 37.7°C in the evening, with an overall average of 36.7°C .

Furthermore, there is no single body temperature, because the temperature varies from organ to organ. From a thermoregulatory viewpoint, the body may conveniently be viewed as a *central core* surrounded by an *outer shell*. The temperature within the inner core, which consists of the abdominal and thoracic organs, the central nervous system, and the skeletal muscles, generally remains fairly constant. This internal **core temperature** is subject to precise regulation to maintain its homeostatic constancy. The core tissues function best at a relatively constant temperature of around 37.8°C .

The skin and subcutaneous fat constitute the outer shell. In contrast to the constant high temperature in the core, the temperature within the shell is generally cooler and may vary substantially. For example, skin temperature may fluctuate between 20°C and 40°C without damage. In fact, the temperature of the skin is deliberately varied as a control measure to help maintain the core's thermal constancy.

SITES FOR MONITORING BODY TEMPERATURE

Several easily accessible sites are used for monitoring body temperature. The oral and axillary (under the armpit) temperatures are comparable, whereas rectal temperature averages about 0.56°C higher. Also recently available is a temperature-monitoring instrument that scans the heat generated by the eardrum and converts this temperature into an oral equivalent. However, none of these measurements is an absolute indication of the internal core temperature, which is a bit higher, at 37.8°C , than the monitored sites.

NORMAL VARIATIONS IN CORE TEMPERATURE

Even though the core temperature is held relatively constant, several factors cause it to vary slightly:

1. Most people's core temperature normally varies about 1°C during the day, with the lowest level occurring early in the morning before rising (6–7 a.m.) and the highest point occurring in late afternoon (5–7 p.m.). This variation is due to an innate biological rhythm, or biological clock (p. 240).

2. Women also experience a monthly rhythm in core temperature in connection with their menstrual cycle. The core temperature averages 0.5°C higher during the last half of the cycle, from the time of ovulation to menstruation. This mild sustained elevation in temperature during this period was once thought to be caused by the increased secretion of progesterone, one of the ovarian hormones, but this is no longer believed to be the case. The actual cause is still undetermined.
3. The core temperature increases during exercise because of the tremendous increase in heat production by the contracting muscles. During hard exercise, the core temperature may increase to as much as 40°C . In a resting person, this temperature would be considered a fever, but it is normal during strenuous exercise.
4. Because the temperature-regulating mechanisms are not 100 percent effective, the core temperature may vary slightly with exposure to extremes of temperature. For example, the core temperature may fall several degrees in cold weather or rise a degree or so in hot weather.

In these ways, the core temperature can vary at the extremes between about 35.6°C and 40°C , but it usually deviates less than a few degrees. This relative constancy is made possible by multiple thermoregulatory mechanisms coordinated by the hypothalamus.

Heat input and heat output

The core temperature is a reflection of the body's total heat content. Heat input to the body must balance heat output to maintain a constant total heat content and thus a stable core temperature (► Figure 16-3). *Heat input* occurs by way of heat gain from the external environment and from internal heat production, the latter being the most important source of heat for the body. Recall that most of the body's energy expenditure ultimately appears as heat. This heat is important in maintaining core temperature. In fact, usually more heat is generated than required to maintain body temperature at a normal level, so the excess heat must be eliminated from the body. *Heat output* occurs by way of heat loss from exposed body surfaces to the external environment.

► Figure 16-3 Heat input and output

Balance between heat input and output is frequently disturbed by (1) changes in internal heat production for purposes unrelated to regulation of body temperature, most notably by exercise, which markedly increases heat production; and (2) changes in the external environmental temperature that influence the degree of heat gain or heat loss that occurs between the body and its surroundings. Compensatory adjustments must take place in heat-loss and heat-gain mechanisms to maintain body temperature within narrow limits despite changes in metabolic heat production and changes in environmental temperature. If the core temperature starts to fall, heat production is increased and heat loss is minimized so that normal temperature can be restored. Conversely, if the temperature starts to rise above normal, core temperature can be corrected by increasing heat loss while simultaneously reducing heat production.

We now elaborate on the means by which heat gains and losses can be adjusted to maintain body temperature.

Heat exchange: Radiation, conduction, convection, and evaporation

All heat loss or heat gain between the body and external environment must take place between the body surface and its surroundings. The same physical laws of nature that govern heat transfer between inanimate objects also control the transfer of heat between the body surface and environment. The temperature of an object may be thought of as a measure of the concentration of heat within the object. Accordingly, heat always moves down its concentration gradient, that is, down a **thermal gradient** from a warmer to a cooler region (*thermo* means “heat”).

The body uses four mechanisms of heat transfer: *radiation*, *conduction*, *convection*, and *evaporation*.

RADIATION

Radiation is the emission of heat energy from the surface of a warm body in the form of **electromagnetic waves (heat waves)**, which travel through space (▶ Figure 16-4a). When radiant energy strikes an object and is absorbed, the energy of the wave motion is transformed into heat within the object. The human body both emits (source of heat loss) and absorbs (source of heat gain) radiant energy. Whether the body loses or gains heat by radiation depends on the difference in temperature between the skin surface and the surfaces of other objects in the body’s environment. Because net transfer of heat by radiation is always from warmer objects to cooler ones, the body gains heat by radiation from objects warmer than the skin surface, such as the sun, a radiator, or burning logs. By contrast, the body loses heat by radiation to objects in its environment whose surfaces are cooler than the surface of the skin, such as building walls, furniture, or trees. On average, humans lose close to half of their heat energy through radiation.

CONDUCTION

Conduction is the transfer of heat between objects of differing temperatures that are in direct contact with each other, with heat moving down its thermal gradient from the warmer to the

cooler object by being transferred from molecule to molecule. All molecules are constantly in vibratory motion, with warmer molecules moving faster than cooler ones. When molecules of differing heat content touch each other, the faster-moving, warmer molecule agitates the cooler molecule into more rapid motion, thereby warming up the cooler molecule. During this process, the original warmer molecule loses some of its thermal energy as it slows down and cools off a bit. Given enough time, therefore, the temperature of the two touching objects eventually equalizes.

The rate of heat transfer by conduction depends on the *temperature difference* between the touching objects and the *thermal conductivity* of the substances involved (i.e., how easily heat is conducted by the molecules of the substances). Heat can be lost or gained by conduction when the skin is in contact with a good conductor (▶ Figure 16-4b). When you hold a snowball, for example, your hand becomes cold because heat moves by conduction from your hand to the snowball. Conversely, when you apply a heating pad to a body part, the part is warmed up as heat is transferred directly from the pad to the body.

Similarly, you either lose or gain heat by conduction to the layer of air in direct contact with your body. The direction of heat transfer depends on whether the air is cooler or warmer, respectively, than your skin. Only a small percentage of total heat exchange between the skin and environment takes place by conduction alone, however, because air is not a very good conductor of heat. (For this reason, swimming pool water at 26.7°C feels cooler than air at the same temperature; heat is conducted more rapidly from the body surface into the water, which is a good conductor, than into the air, which is a poor conductor.)

CONVECTION

The term *convection* refers to the transfer of heat energy by *air* (or H_2O) *currents*. As the body loses heat by conduction to the surrounding cooler air, the air in immediate contact with the skin is warmed. Because warm air is lighter (less dense) than cool air, the warmed air rises while cooler air moves in next to the skin to replace the vacating warm air. The process is then repeated (▶ Figure 16-4c). These air movements, known as *convection currents*, help carry heat away from the body. If it were not for convection currents, no further heat could be dissipated from the skin by conduction once the temperature of the layer of air immediately around the body equilibrated with skin temperature.

The combined conduction–convection process of dissipating heat from the body is enhanced by forced movement of air across the body surface, either by external air movements, such as those caused by the wind or a fan, or by movement of the body through the air, as during bicycle riding. Because forced air movement sweeps away the air warmed by conduction and replaces it with cooler air more rapidly, a greater total amount of heat can be carried away from the body over a given time period. Thus, wind makes us feel cooler on hot days, and windy days in the winter are more chilling than calm days at the same cold temperature. For this reason, weather forecasters have developed the concept of *wind chill factor*.

(a) **Radiation**—the transfer of heat energy from a warmer object to a cooler object in the form of electromagnetic waves (“heat waves”), which travel through space.

(b) **Conduction**—the transfer of heat from a warmer to a cooler object that is in direct contact with the warmer one. The heat is transferred through the movement of thermal energy from molecule to adjacent molecule.

(c) **Convection**—the transfer of heat energy by air currents. Cool air warmed by the body through conduction rises and is replaced by more cool air. This process is enhanced by the forced movement of air across the body surface.

(d) **Evaporation**—conversion of a liquid such as sweat into a gaseous vapour, a process that requires heat (the heat of vaporization), which is absorbed from the skin.

© 2016 Cengage

► Figure 16-4 Mechanisms of heat transfer

EVAPORATION

Evaporation is the final method of heat transfer used by the body. When water evaporates from the skin surface, the heat required to transform water from a liquid to a gaseous state is absorbed from the skin, thereby cooling the body (► Figure 16-4d). Evaporative heat loss is what makes you feel cooler when your bathing suit is wet than when it is dry. Evaporative heat loss occurs continually from the linings of the respiratory airways and from the surface of the skin. Heat is continuously lost through the H_2O vapour in the expired air as a result of the air’s humidification during its passage through the respiratory system. Similarly, because the skin is not completely waterproof, H_2O molecules constantly diffuse through the skin and evaporate. This ongoing evaporation from the skin is completely unrelated to the sweat glands. These passive evaporative heat-loss processes are not subject to physiological control and go on even in very cold weather, when the problem is one of conserving body heat.

Sweating is an active evaporative heat-loss process under sympathetic nervous control. The rate of evaporative heat loss

can be deliberately adjusted by varying the extent of sweating, which is an important homeostatic mechanism to eliminate excess heat as needed. For example, see Why It Matters, which illustrates the importance of sweating. In fact, when the environmental temperature exceeds the skin temperature, sweating is the only avenue for heat loss, because the body is gaining heat by radiation and conduction under these circumstances.

Sweat is a dilute salt solution actively extruded to the surface of the skin by sweat glands dispersed all over the body. The sweat glands can produce up to 4 L of sweat per hour. Sweat must be evaporated from the skin for heat loss to occur. If sweat merely drips from the surface of the skin or is wiped away, no heat loss is accomplished. The most important factor determining the extent of evaporation of sweat is the *relative humidity* of the surrounding air (the percentage of H_2O vapour actually present in the air compared with the greatest amount that the air can possibly hold at that temperature; e.g., a relative humidity of 70 percent means the air contains 70 percent of the H_2O vapour it is capable of holding). When the relative humidity is high, the

One of the most effective heat-loss mechanisms for the purpose of thermoregulation in a warm to hot environment is evaporation from sweating. For the sweating mechanism to work effectively, you must acclimate to the new warmer environment. This takes a little time. For example, the average sweat rate for a nonacclimated person in a warmer environment is about 1.5 L/h. Following 10 days of acclimation, the person's sweat rate increases to approximately 3 L/h, and in the following six weeks may achieve a sweat rate of 3.75 L/h. The change in sweat rate associated with acclimation is one reason why it is a good idea to arrive early when you travel to a warmer environment—your physiological systems need the time to adjust. This would be good advice for Canadians travelling to warm countries during our winter months,

or for Canadian athletes travelling to warmer countries to compete in outdoor events. Note that if you decide to travel early to a warm environment for the purpose of acclimation, the next step you must take is to properly hydrate so that the sweating mechanism can work effectively. Without sufficient water intake, the sweating mechanism does not function efficiently, and your body will begin to gain and store unneeded heat; this impairs normal physiological functions. The general rule of thumb during moderate intensity work (e.g., labourer) or exercise (e.g., golfing) in a warm to hot environment is 150–350 mL of water every 15–20 minutes, and following the work or exercise about 450–675 mL for every 0.5 kg decrease in body weight. So those heading south for a winter getaway golfing trip need to acclimate and hydrate.

air is already almost fully saturated with H_2O , so it has limited ability to take up additional moisture from the skin. Thus, little evaporative heat loss can occur on hot, humid days. The sweat glands continue to secrete, but the sweat simply remains on the skin or drips off instead of evaporating and producing a cooling effect. As a measure of the discomfort associated with combined heat and high humidity, meteorologists have devised the *temperature–humidity index*.

The hypothalamus and thermosensory inputs

The hypothalamus serves as the body's thermostat. The home thermostat keeps track of the temperature in a room and triggers a heating mechanism (the furnace) or a cooling mechanism (the air conditioner) as necessary to maintain the room temperature at the indicated setting. Similarly, the hypothalamus, as the body's thermoregulatory integrating centre, receives afferent information about the temperature in various regions of the body and initiates extremely complex, coordinated adjustments in heat-gain and heat-loss mechanisms as necessary to correct any deviations in core temperature from the normal setting. The hypothalamus is far more sensitive than the home thermostat, however, because it can respond to changes in blood temperature as small as 0.01°C . The degree of response to deviations in body temperature is finely matched so that precisely enough heat is lost or generated to restore the temperature to normal.

To appropriately adjust the delicate balance between the heat-loss mechanisms and the opposing heat-producing and heat-conserving mechanisms, the hypothalamus must be continuously informed of both the core and the skin temperature. This is accomplished by specialized temperature-sensitive receptors called thermoreceptors. The core temperature is monitored by *central thermoreceptors*, which are located within the hypothalamus and elsewhere in the central nervous system and the abdominal organs. *Peripheral thermoreceptors* monitor skin

temperature throughout the body and transmit information about changes in surface temperature to the hypothalamus.

Two centres for temperature regulation have been identified in the hypothalamus. The *posterior region* is activated by cold and subsequently triggers reflexes that mediate heat production and heat conservation. The *anterior region*, which is activated by warmth, initiates reflexes that mediate heat loss. Let's examine the means by which the hypothalamus fulfills its thermoregulatory functions.

Shivering

The body can gain heat as a result of internal heat production generated by metabolic activity or from the external environment if the latter is warmer than body temperature. Because body temperature usually is higher than environmental temperature, metabolic heat production is the primary source of body heat. In a resting person, most body heat is produced by the thoracic and abdominal organs as a result of ongoing, homeostatic metabolic activities. Beyond this basal level, the rate of metabolic heat production can be variably increased primarily by changes in skeletal muscle activity or, to a lesser extent, by certain hormonal actions. Therefore, changes in skeletal muscle activity constitute the primary method of heat gain to assist temperature regulation.

ADJUSTMENTS IN HEAT PRODUCTION BY SKELETAL MUSCLES

In response to a fall in core temperature caused by exposure to cold, the hypothalamus takes advantage of the fact that an increase in skeletal muscle activity generates additional heat. Acting through descending pathways that terminate on the motor neurons controlling the skeletal muscles, the hypothalamus first gradually increases skeletal muscle tone (tension within the muscle). Soon shivering begins. **Shivering** consists of rhythmic, oscillating skeletal muscle contractions and

relaxations at a rate of 10–20 per second. This mechanism is very effective in increasing heat production; all the energy liberated during these muscle tremors is converted to heat because no external work is accomplished. Within a matter of seconds to minutes, internal heat production may increase two- to fivefold as a result of shivering.

Frequently, these reflex changes in skeletal muscle activity are augmented by increased voluntary, heat-producing actions, such as bouncing up and down or hand clapping. Such behavioural responses appear to share neural systems in common with the involuntary physiological responses. The hypothalamus and limbic system are extensively involved with controlling motivated behaviour (p. 113).

In the opposite situation—a rise in core temperature caused by heat exposure—two mechanisms reduce heat-producing skeletal muscle activity: muscle tone is reflexly reduced, and voluntary movement is curtailed. When the air becomes very warm, people often complain it is “too hot to even move.” These responses are not as effective at reducing heat production during heat exposure as are the muscular responses that increase heat production during cold exposure, for two reasons. First, because muscle tone is normally quite low, the capacity to reduce it further is limited. Second, the elevated body temperature tends to increase the rate of metabolic heat production because the temperature has a direct effect on the rate of chemical reactions.

NONSHIVERING THERMOGENESIS

Although reflex and voluntary changes in muscle activity are the major means of increasing the rate of heat production, **nonshivering (chemical) thermogenesis** also plays a role in thermoregulation. In most experimental animals, chronic cold exposure brings about an increase in metabolic heat production that is independent of muscle contraction—that is, the increase is brought about by changes in heat-generating chemical activity. In humans, nonshivering thermogenesis is most important in newborns, because they lack the ability to shiver. Nonshivering thermogenesis is mediated by the hormones epinephrine and thyroid hormone, both of which increase heat production by stimulating fat metabolism. Newborns have deposits of a special type of adipose tissue known as *brown fat*, which is especially capable of converting chemical energy into heat. The role of nonshivering thermogenesis in adults remains controversial.

Having examined the mechanisms for adjusting heat production, we now turn to the other side of the equation—adjustments in heat loss.

Heat loss

Heat-loss mechanisms are also subject to control, again largely by the hypothalamus. When we are hot, we want to increase heat loss to the environment; when we are cold, we want to decrease heat loss. The amount of heat lost to the environment by radiation and conduction–convection is largely determined by the temperature gradient between the skin and external environment. The body’s central core is a heat-generating

chamber in which the temperature must be maintained at approximately 37.8°C. Surrounding the core is an insulating shell through which heat exchanges between the body and external environment take place. To maintain a constant core temperature, the insulative capacity and temperature of the shell can be adjusted to vary the temperature gradient between the skin and external environment, thereby influencing the extent of heat loss.

The insulative capacity of the shell can be varied by controlling the amount of blood flowing through the skin. Skin blood flow serves two functions. First, it provides a nutritive blood supply to the skin. Second, as blood is pumped to the skin from the heart, it has been heated in the central core and carries this heat to the skin. Most skin blood flow is for the function of temperature regulation; at normal room temperature, 20–30 times more blood flows through the skin than is needed to meet the skin’s nutritional needs.

In the process of thermoregulation, skin blood flow can vary tremendously, from 400 mL/min up to 2500 mL/min. The more blood that reaches the skin from the warm core, the closer the skin’s temperature is to the core temperature. The skin’s blood vessels diminish the effectiveness of the skin as an insulator by carrying heat to the surface, where it can be lost from the body by radiation and conduction–convection. Accordingly, vasodilation of the skin vessels (specifically, the arterioles), which permits increased flow of heated blood through the skin, increases heat loss. Conversely, vasoconstriction of the skin vessels, which reduces skin blood flow, decreases heat loss by keeping the warm blood in the central core, where it is insulated from the external environment. Cold, relatively bloodless skin provides excellent insulation between the core and the environment. However, the skin is not a perfect insulator, even with maximum vasoconstriction. Despite minimal blood flow to the skin, some heat can still be transferred by conduction from the deeper organs to the skin surface and then can be lost from the skin to the environment.

These skin vasomotor responses are coordinated by the hypothalamus by means of sympathetic nervous system output. Increased sympathetic activity to the skin vessels produces heat-conserving vasoconstriction in response to cold exposure, whereas decreased sympathetic activity produces heat-losing vasodilation of the skin vessels in response to heat exposure.

Recall that the cardiovascular control centre in the medulla oblongata also exerts control over the skin arterioles (as well as arterioles throughout the body) by means of adjusting sympathetic activity to these vessels for the purpose of blood pressure regulation (p. 400). Hypothalamic control over the skin arterioles for the purpose of temperature regulation takes precedence over the cardiovascular control centre’s control of these same vessels (p. 402). Thus, changes in blood pressure can result from pronounced thermoregulatory skin vasomotor responses. For example, blood pressure can fall on exposure to a very hot environment, because the skin vasodilator response set in motion by the hypothalamic thermoregulatory centre overrides the skin vasoconstrictor response called forth by the medullary cardiovascular control centre.

The hypothalamus, heat production, and heat loss

Let’s now pull together the coordinated adjustments in heat production and heat loss in response to exposure to either a cold or a hot environment (Table 16-3).

COORDINATED RESPONSES TO COLD EXPOSURE

In response to cold exposure, the posterior region of the hypothalamus directs the increase in heat production, such as by shivering and, simultaneously, the decrease in heat loss (i.e., conserving heat) by skin vasoconstriction and other measures.

Because there is a limit to the body’s ability to reduce skin temperature through vasoconstriction, even maximum vasoconstriction is insufficient to prevent excessive heat loss when the external temperature falls extremely low. Accordingly, other measures are needed to further reduce heat loss. In animals with dense fur or feathers, the hypothalamus, acting through the sympathetic nervous system, brings about contraction of the tiny muscles at the base of the hair or feather shafts to lift the hair or feathers off the skin surface. This puffing up traps a layer of poorly conductive air between the skin surface and the environment, which increases the insulating barrier between the core and the cold air, thereby reducing heat loss. Even though the hair-shaft muscles contract in humans in response to cold exposure, this heat-retention mechanism is ineffective because of the low density and fine texture of most human body hair. The result, instead, is *goosebumps*.

After maximum skin vasoconstriction has been achieved as a result of exposure to cold, further heat dissipation in humans can be prevented only by behavioural adaptations, such as postural changes that reduce as much as possible the exposed surface area from which heat can escape. These postural changes include manoeuvres such as hunching over, clasping the arms in front of the chest, or curling up in a ball.

Putting on warmer clothing further insulates the body from too much heat loss. Clothing entraps layers of poorly conductive air between the skin surface and the environment, thereby diminishing loss of heat by conduction from the skin

to the cold external air and curtailing the flow of convection currents.

COORDINATED RESPONSES TO HEAT EXPOSURE

Under the opposite circumstance—heat exposure—the anterior part of the hypothalamus reduces heat production by decreasing skeletal muscle activity and promotes increased heat loss by inducing skin vasodilation. When even maximal skin vasodilation is inadequate to rid the body of excess heat, sweating is brought into play to accomplish further heat loss through evaporation. In fact, if the air temperature rises above the temperature of maximally vasodilated skin, the temperature gradient reverses itself so that heat is gained from the environment. Sweating is the only means of heat loss under these conditions.

We also employ voluntary measures, such as using fans, wetting the body, drinking cold beverages, and wearing cool clothing, to further enhance heat loss. Contrary to popular belief, wearing light-coloured, loose clothing is cooler than being nude. Naked skin absorbs almost all the radiant energy that strikes it, whereas light-coloured clothing reflects almost all the radiant energy that falls on it. So it is actually cooler to wear light-coloured clothing that is loose and thin enough to permit convection currents and evaporative heat loss to occur, rather than wearing no clothes.

THERMONEUTRAL ZONE

Skin vasomotor activity is highly effective in controlling heat loss in environmental temperatures between 20°C and 29°C. Within this range—known as the **thermoneutral zone**—the core temperature can be kept constant by vasomotor responses, without the need for supplementary heat-production or heat-loss mechanisms to come into play. When external air temperature falls below the lower limits of the ability of skin vasoconstriction to reduce heat loss further, the major burden of maintaining core temperature is borne by increased heat production, especially shivering. At the other extreme, when external air temperature exceeds the upper limits of the ability of skin vasodilation to increase heat loss further, sweating becomes the dominant factor in maintaining core temperature.

TABLE 16-3 Coordinated Adjustments in Response to Cold or Heat Exposure

IN RESPONSE TO COLD EXPOSURE (COORDINATED BY THE POSTERIOR HYPOTHALAMUS)		IN RESPONSE TO HEAT EXPOSURE (COORDINATED BY THE ANTERIOR HYPOTHALAMUS)	
Increased Heat Production	Decreased Heat Loss (heat conservation)	Decreased Heat Production	Increased Heat Loss
Increased muscle tone	Skin vasoconstriction	Decreased muscle tone	Skin vasodilation
Shivering Increased voluntary exercise*	Postural changes to reduce exposed surface area (hunching shoulders, etc.)*	Decreased voluntary exercise*	Sweating Cool clothing*
Nonshivering thermogenesis	Warm clothing*		

*Behavioural adaptations

FEVER

The term **fever** refers to an elevation in body temperature as a result of infection or inflammation. In response to microbial invasion, certain phagocytic cells (macrophages) release a chemical known as endogenous pyrogen, which, among its many infection-fighting effects (p. 470), acts on the hypothalamic thermoregulatory centre to raise the setting of the body's thermostat (► Figure 16-5). The hypothalamus now maintains the temperature at the new set level, instead of maintaining normal body temperature. If, for example, endogenous pyrogen raises the set point to 38.9°C, the hypothalamus senses that the normal prefever temperature is too cold, so it initiates the cold-response mechanisms to raise the temperature to 38.9°C. Specifically, the hypothalamus initiates shivering to rapidly increase heat production, and promotes skin vasoconstriction to rapidly reduce heat loss, both of which drive the temperature upward. These events account for the sudden cold chills often experienced at the onset of a fever. Feeling cold, the person may put on more blankets as a voluntary mechanism that helps raise body temperature by conserving body heat. Once the new temperature is achieved, body temperature is regulated as normal in response to cold and heat but at a higher setting. Fever production in response to an infection is therefore a deliberate outcome and is not due to a breakdown of thermoregulatory mechanisms. Although the physiological significance of a fever is still unclear, many medical experts believe a rise in body temperature has a beneficial role in fighting infection. A fever

► Figure 16-5 Fever production

augments the inflammatory response and may interfere with bacterial multiplication.

During fever production, endogenous pyrogen raises the set point of the hypothalamic thermostat by triggering the local release of *prostaglandins*, which are local chemical mediators that act directly on the hypothalamus. Aspirin reduces a fever by inhibiting the synthesis of prostaglandins. Aspirin does not lower the temperature in a person without a fever, because in the absence of endogenous pyrogen, prostaglandins are not present in the hypothalamus in appreciable quantities.

The exact molecular cause of a fever “breaking” naturally is unknown, although it presumably results from reduced pyrogen release or decreased prostaglandin synthesis. When the hypothalamic set point is restored to normal, the temperature at 38.9°C (in this example) is too high. The heat-response mechanisms cool down the body. Skin vasodilation occurs, and sweating commences. The person feels hot and throws off extra covers. The gearing up of these heat-loss mechanisms by the hypothalamus reduces the temperature to normal.

Hyperthermia

Hyperthermia denotes any elevation in body temperature above the normally accepted range. The term *fever* is usually reserved for an elevation in temperature caused by the release of endogenous pyrogen, which resets the hypothalamic set point during infection or inflammation; *hyperthermia* refers to all other imbalances between heat gain and heat loss that increase body temperature. Hyperthermia has a variety of causes, some of which are normal and harmless, others pathological and fatal.

EXERCISE-INDUCED HYPERTHERMIA

The most common cause of hyperthermia is sustained exercise. As a physical consequence of the tremendous heat load generated by exercising muscles, body temperature rises during the initial stage of exercise because heat gain exceeds heat loss (► Figure 16-6). The elevation in core temperature reflexly triggers heat-loss mechanisms (skin vasodilation and sweating), which eliminate the discrepancy between heat production and

1 At the onset of exercise, the rate of heat production initially exceeds the rate of heat loss, so the core temperature rises.

2 When heat loss mechanisms are reflexly increased sufficiently to equalize the elevated heat production, the core temperature stabilizes slightly above the resting point for the duration of the exercise.

► Figure 16-6 Hyperthermia in sustained exercise

The Extremes of Heat and Cold Can Be Fatal

PROLONGED EXPOSURE TO TEMPERATURE EXTREMES in either direction can overtax the body's thermoregulatory mechanisms, leading to disorders and even death.

Heat-Related Disorders

Heat exhaustion, a state of collapse usually manifested by fainting, is caused by reduced blood pressure due to overtaxing the heat-loss mechanisms. Extensive sweating reduces cardiac output by depleting the plasma volume, and pronounced skin vasodilation causes a drop in total peripheral resistance. Because blood pressure is determined by cardiac output multiplied by total peripheral resistance, the following occurs: blood pressure falls, an insufficient amount of blood is delivered to the brain, and fainting takes place. Heat exhaustion is a consequence of overactivity of the heat-loss mechanisms rather than a breakdown of these mechanisms. Because the heat-loss mechanisms have been very active, body temperature is only mildly elevated in heat exhaustion. By forcing the cessation of activity when the heat-loss mechanisms are no longer able to cope with heat gain through exercise or a hot environment, heat exhaustion serves as a safety valve to help prevent the more serious consequences of heatstroke.

Heatstroke is an extremely dangerous situation that arises from the complete breakdown of the hypothalamic thermoregulatory systems. Heat exhaustion may progress into heatstroke if the heat-loss mechanisms continue to be overtaxed. Heatstroke is more likely to occur on overexertion during a prolonged exposure to a hot, humid environment. The elderly—in whom thermoregulatory responses are generally slower and less efficient—are particularly vulnerable to heatstroke during prolonged, stifling heat waves. So too are individuals who are taking certain common tranquilizers, such as Valium, because these drugs interfere with the hypothalamic thermoregulatory centres' neurotransmitter activity.

The most striking feature of heatstroke is a lack of compensatory heat-loss measures, such as sweating, in the face of a rapidly rising body temperature. No sweating occurs, despite a markedly elevated body temperature, because the hypothalamic thermoregulatory control centres are not functioning properly and cannot initiate heat-loss mechanisms. During the development of heatstroke, body

temperature starts to climb because the heat-loss mechanisms are eventually overwhelmed by prolonged, excessive heat gain. Once the core temperature reaches the point at which the hypothalamic temperature-control centres are damaged by the heat, the body temperature rapidly rises even higher due to the complete shutdown of heat-loss mechanisms. Furthermore, as body temperature increases, the rate of metabolism increases correspondingly. This is because higher temperatures speed up the rate of all chemical reactions, resulting in even greater heat production. This positive-feedback state sends the temperature spiralling upward. Heatstroke is a very dangerous situation that is rapidly fatal if untreated. Even with treatment to halt and reverse the rampant rise in body temperature, the mortality rate is still high. The rate of permanent disability in survivors is also high because of irreversible protein denaturation caused by the high internal heat.

Cold-Related Disorders

At the other extreme, the body can be harmed by cold exposure in two ways: frostbite and generalized hypothermia. **Frostbite** involves excessive cooling of a particular part of the body to the point where tissue in that area is damaged. When exposed tissues actually freeze, the tissue damage results from cell disruption caused by the formation of ice crystals or by a lack of liquid water.

Hypothermia, a fall in body temperature, occurs when generalized cooling of the body exceeds the ability of the normal heat-producing and heat-conserving regulatory mechanisms to match the excessive heat loss. As hypothermia sets in, the rate of all metabolic processes slows down due to the declining temperature. Higher cerebral functions are the first affected by body cooling, leading to loss of judgment, apathy, disorientation, and tiredness, all of which diminish the cold victim's ability to initiate voluntary mechanisms to reverse the falling body temperature. As body temperature continues to plummet, depression of the respiratory centre occurs, reducing the ventilatory drive so that breathing becomes slow and weak. Activity of the cardiovascular system is also gradually reduced. The heart is slowed and cardiac output decreased. Cardiac rhythm is disturbed, eventually leading to ventricular fibrillation and death.

heat loss. As soon as the heat-loss mechanisms have stepped up sufficiently to equalize heat production, the core temperature stabilizes at a level slightly above the set point, despite continued heat-producing exercise. Thus, during sustained exercise, body temperature initially rises and then is maintained at the higher level as long as the exercise continues.

PATHOLOGICAL HYPERTHERMIA

Hypertemia can also be brought about in a completely different way: excessive heat production in connection with abnormally high circulating levels of thyroid

hormone or epinephrine that result from dysfunctions of the thyroid gland or adrenal medulla, respectively. Both these hormones elevate the core temperature by increasing the overall rate of metabolic activity and heat production.

Hyperthermia can also result from malfunction of the hypothalamic control centres. Certain brain lesions, for example, destroy the normal regulatory capacity of the hypothalamic thermostat. When the thermoregulatory mechanisms are not functional, lethal hyperthermia may occur very rapidly. Normal metabolism produces enough heat to kill a person in less than five hours if the heat-loss mechanisms are completely shut down.

In addition to causing brain lesions, exposure to severe, prolonged heat stress can also break down the function of hypothalamic thermoregulation. Similarly, the body can be harmed by extreme cold exposure. (For a discussion of the effects of extreme heat or cold exposure, see Concepts, Challenges, and Controversies, p. 718.)

Check Your Understanding 16.2

1. Describe the mechanisms of heat transfer.
2. Make a chart comparing the responses initiated by the posterior hypothalamus and also the anterior hypothalamus to maintain core body temperature when the environmental temperature becomes hot or cold.

Chapter in Perspective: Focus on Homeostasis

Energy can be neither created nor destroyed. For body weight and body temperature to remain constant, input must equal output in the case of the body's total energy balance and its heat energy balance, respectively. If total energy input exceeds total energy output, the extra energy is stored in the body, and

body weight increases. Similarly, if the input of heat energy exceeds its output, body temperature increases. Conversely, if output exceeds input, body weight decreases or body temperature falls. The hypothalamus is the major integrating centre for maintaining both a constant total energy balance (therefore a constant body weight) and a constant heat energy balance (therefore a constant body temperature).

Body temperature, which is one of the homeostatically regulated factors of the internal environment, must be maintained within narrow limits, because the structure and reactivity of the chemicals that compose the body are temperature sensitive. Deviations in body temperature outside a limited range result in protein denaturation and death of the individual if the temperature rises too high, or metabolic slowing and death if the temperature falls too low.

Body weight, in contrast, varies widely among individuals. Only the extremes of imbalances between total energy input and output become incompatible with life. For example, in the face of insufficient energy input in the form of ingested food during prolonged starvation, the body resorts to breaking down muscle protein to meet its needs for energy expenditure after the adipose stores are depleted. Body weight dwindles because of this self-cannibalistic mechanism, until death finally occurs as a result of loss of heart muscle, among other things. At the other extreme, when the food energy input greatly exceeds the energy expended, the extra energy is stored as adipose tissue, and body weight increases. The resultant gross obesity can also lead to heart failure. Not only must the heart work harder to pump blood to the excess adipose tissue but obesity also predisposes the person to atherosclerosis and heart attacks (p. 374).

Objective Questions (Answers in Appendix E, p. A-53)

1. If more food energy is consumed than is expended, the excess energy is lost as heat. (*True or false?*)
2. All the energy within nutrient molecules can be harnessed to perform biological work. (*True or false?*)
3. Each litre of O₂ contains 4.8 kcal of heat energy. (*True or false?*)
4. A body temperature greater than 36.8°C is always indicative of a fever. (*True or false?*)
5. Core temperature is relatively constant, but skin temperature can vary markedly. (*True or false?*)
6. Sweat that drips off the body has no cooling effect. (*True or false?*)
7. Production of goosebumps in response to cold exposure has no value in regulating body temperature. (*True or false?*)
8. The posterior region of the hypothalamus triggers shivering and skin vasoconstriction. (*True or false?*)
9. The _____ of the hypothalamus contains two populations of neurons, one that secretes appetite-enhancing NPY and another that secretes appetite-suppressing melanocortins.
10. The primary means of involuntarily increasing heat production is _____.
11. Increased heat production independent of muscle contraction is known as _____.
12. The only means of heat loss when the environmental temperature exceeds the core temperature is _____.
13. Which statement concerning heat exchange between the body and the external environment is NOT correct?
 - a. Heat gain occurs primarily by means of internal heat production.
 - b. Radiation serves as a means of heat gain, but not of heat loss.
 - c. Heat energy always moves down its concentration gradient from warmer to cooler objects.
 - d. The temperature gradient between the skin and the external air is subject to control.
 - e. Very little heat is lost from the body by conduction alone.
14. Which statement concerning fever production is NOT correct?
 - a. Endogenous pyrogen is released by macrophages in response to microbial invasion.
 - b. The hypothalamic set point is elevated.
 - c. The hypothalamus initiates cold-response mechanisms to increase the body temperature.
 - d. Prostaglandins mediate the effect.
 - e. The hypothalamus is not effective in regulating body temperature during a fever.

15. Using the answer code on the right, indicate which mechanism of heat transfer is being described:

- | | |
|--|-----------------|
| _____ 1. sitting on a cold metal chair | (a) radiation |
| _____ 2. sunbathing on the beach | (b) conduction |
| _____ 3. being in a gentle breeze | (c) convection |
| _____ 4. sitting in front of a fireplace | (d) evaporation |
| _____ 5. sweating | |
| _____ 6. riding in a car with the windows open | |
| _____ 7. lying under an electric blanket | |
| _____ 8. sitting in a wet bathing suit | |
| _____ 9. fanning yourself | |
| _____ 10. immersing yourself in cold water | |

Written Questions

1. Differentiate between external and internal work.
2. Define *metabolic rate* and *basal metabolic rate*. Explain the process of indirect calorimetry.
3. Describe the three states of energy balance.
4. By what means is energy balance primarily maintained?
5. List the sources of heat input and output for the body.
6. Describe the source and role of the following in the long-term regulation of energy balance and the short-term control of the timing and size of meals: neuropeptide Y, melanocortins, leptin, insulin, ghrelin, PYY₃₋₃₆, orexins, corticotropin-releasing hormone, and cholecystokinin.
7. Discuss the compensatory measures that occur in response to a fall in core temperature as a result of cold exposure and in response to a rise in core temperature as a result of heat exposure.

Quantitative Exercise (Solutions in Appendix E, p. A-54)

1. The basal metabolic rate (BMR) is a measure of how much energy the body consumes to maintain its rate at rest. The normal BMR for men is about 70 cal/h (p. 701). The vast majority of this energy is converted to heat. Our thermoregulatory systems function to eliminate this heat to keep body temperature constant. If our body were not able to lose this heat, our temperature would rise until we boiled (of course, a person would die before reaching that temperature). It is relatively easy to calculate how long it would take to reach the hypothetical boiling point. If an amount of energy ΔU is put into a liquid of mass m , the temperature change ΔT (in °C) is given by the following formula:

$$\Delta T = \Delta U / m \times C$$

2. In this equation, C is the specific heat of the liquid. For water, C is 1 kcal/kg °C. Use this information to calculate how long it would take for the heat from the BMR to boil your body fluids (assume 42 L of water in your

body and a starting point of normal body temperature at 37°C). When exercising maximally, a person consumes about 1000 cal/h. How long would it take to boil in this case?

POINTS TO PONDER

(Explanations in Appendix E, p. A-54)

1. Explain how drugs that selectively inhibit CCK increase feeding behaviour in experimental animals.
2. What advice would you give an overweight friend who asks for your help in designing a safe, sensible, inexpensive program for losing weight?
3. Why is it dangerous to engage in heavy exercise on a hot, humid day?
4. Describe the avenues for heat loss in a person soaking in a hot bath.
5. Consider the difference between you and a fish in a local pond with regard to control of body temperature. Humans are *thermoregulators*; we can maintain a remarkably

constant, rather high, internal body temperature despite the body's exposure to a wide range of environmental temperatures. To maintain thermal homeostasis, the human body physiologically manipulates mechanisms to adjust heat production, heat conservation, and heat loss. In contrast, fish are *thermoconformers*; their body temperatures conform to the temperature of their surroundings. Thus, their body temperature varies capriciously with changes in the environmental temperature. Even though fish produce heat, they cannot physiologically regulate internal heat production, nor can they control heat exchange with their environment to maintain a constant body temperature when the temperature in their surroundings rises or falls. Knowing this, do you think fish run a fever when they have a systemic infection? Why or why not?

CLINICAL CONSIDERATION

(Explanation in Appendix E, p. A-54)

Michael, F., a near-drowning victim, was pulled from icy water by rescuers 15 minutes after he fell through the thin ice on which he was skating. Michael is now alert and recuperating in the hospital.

How do you explain his “miraculous” survival, even though he was submerged for 15 minutes, and irreversible brain damage, soon followed by death, normally occurs if the brain is deprived of its critical oxygen supply for more than four or five minutes?

- 17.3 Sexual intercourse between males and females
- 17.4 Female reproductive physiology

Clinical Connections

Jourdain is a 19-year-old university student. For the past few days he has been experiencing some pain during urination. He has also noticed a cloudy discharge from the tip of his penis. Suspecting he has contracted a sexually transmitted disease, he went to the student health clinic on campus. His patient history revealed that he met his first girlfriend, Anita, about two months ago, and they had recently become sexually active. After providing a urine sample that tested positive for chlamydia trachomatis, he was prescribed antibiotics to clear up the infection. Concerned for Anita, the physician insisted that Jourdain tell her about the infection so that she could also be tested.

17.1 Introduction

The central theme of this book has been the physiologic processes aimed at maintaining homeostasis to ensure survival of the individual. In this chapter, we depart from this theme to discuss the **reproductive system**. Sexual reproduction is the process of producing offspring for the purpose of the species' survival.

Even though the reproductive system does not contribute to homeostasis and is not essential for survival of an individual, it still plays an important role in a person's life. For example, the manner in which people relate as sexual beings contributes in significant ways to psychosocial behaviour and has important influences on how people view themselves and how they interact with others. Reproductive function also has a profound effect on society.

The universal organization of societies into family units provides a stable environment that is conducive for perpetuating our species. On the other hand, the population explosion and its resultant drain on dwindling resources have recently led to worldwide concern with the means by which reproduction can be limited.

Reproductive capability depends on intricate relationships among the hypothalamus, anterior pituitary, reproductive organs, and target cells of the sex hormones. These relationships employ many of the regulatory mechanisms used by other body systems for maintaining homeostasis, such as negative-feedback control. In addition to these basic biological processes, sexual behaviour and attitudes are deeply influenced by emotional factors and the sociocultural mores of the society in which the individual lives. Here we focus on the basic sexual and reproductive functions that are under nervous and hormonal control.

The reproductive system

Reproduction depends on the union of male and female **gametes (reproductive or germ cells)**—each with a half set of chromosomes—to form a new individual with a full, unique set of chromosomes. Unlike the other body systems, which are essentially identical in the two sexes, the reproductive systems of males and females are remarkably different, befitting their different roles in the reproductive process. The **male and female reproductive systems** are designed to enable union of genetic material from the two sexual partners, and the female system is equipped to house and nourish the offspring to the developmental point at which it can survive independently in the external environment.

The **primary reproductive organs (gonads)** consist of a pair of **testes** in the male and a pair of **ovaries** in the female. In both sexes, the mature gonads perform the dual function of (1) producing gametes (**gametogenesis**), specifically, **spermatozoa (sperm)** in the male and **ova (eggs)** in the female; and (2) secreting sex hormones, specifically, **testosterone** in males and **estrogen** and **progesterone** in females.

In addition to the gonads, the reproductive system in each sex includes a **reproductive tract**, which encompasses a system of ducts that are specialized to transport or house the gametes after they are produced, plus **accessory sex glands**, which empty their supportive secretions into these passageways. In females, the **breasts** are also considered accessory reproductive organs. The externally visible portions of the reproductive system are known as **external genitalia**.

SECONDARY SEXUAL CHARACTERISTICS

Secondary sexual characteristics distinguish males and females and are the external characteristics not directly involved in the reproductive process. Examples of these are hair-distribution patterns. In humans, for example, males have broader shoulders, whereas females have curvier hips; and males have beards, whereas females do not. Testosterone in the male and estrogen in the female govern the development and maintenance of these characteristics. Even though the growth of axillary and pubic hair at puberty is promoted in both sexes by androgens—testosterone in males and adrenocortical dehydroepiandrosterone in females (p. 258)—this

hair growth is not a secondary sexual characteristic, because both sexes display this feature. Thus, testosterone and estrogen alone govern the nonreproductive distinguishing features.

In some species, the secondary sexual characteristics are of great importance in courting and mating behaviour; for example, the rooster's headcrest, or comb, attracts the female's attention, and the stag's antlers are useful to ward off other males. In humans, the differentiating marks between males and females do serve to attract a sexual partner, but attraction is also strongly influenced by the complexities of human society and cultural behaviour.

OVERVIEW OF MALE REPRODUCTIVE FUNCTIONS AND ORGANS

The male reproductive system comprises the testes and a series of ducts and glands. The essential reproductive functions of the male are as follows:

1. Production of sperm (*spermatogenesis*)
2. Delivery of sperm to the female

The sperm-producing organs, the testes, are suspended outside the abdominal cavity in a skin-covered sac, the **scrotum**, which lies within the angle between the legs. The scrotum, which is divided internally into two sacs, is a continuation of the abdomen. Initially, the testes are in the abdomen, but at approximately the seventh month of gestation the testes drop into the scrotum, one in each sac. The male reproductive system is designed to deliver sperm to the female reproductive tract in a liquid vehicle, *semen*, which is conducive to sperm viability. The major **male accessory sex glands**, whose secretions provide the bulk of the semen, are the *seminal vesicles*, *prostate gland*, and *bulbourethral glands* (► Figure 17-1). The **penis** is the organ used to deposit semen in the female. Sperm exit each testis through the **male reproductive tract**, consisting on each side of an *epididymis*, *ductus (vas) deferens*, and *ejaculatory duct*. These pairs of reproductive tubes empty into a single *urethra*, the canal that runs the length of the penis and empties to the exterior. These parts of the male reproductive system are described thoroughly when their functions are discussed in Section 17.2.

OVERVIEW OF FEMALE REPRODUCTIVE FUNCTIONS AND ORGANS

The female's role in reproduction is more complicated than the male's. The essential female reproductive functions include the following:

1. Cyclical production of ova (*oogenesis*)
2. Reception of sperm
3. Transport of the sperm and ovum to a common site for union (*fertilization* or *conception*)
4. Maintenance of the developing fetus until it can survive in the outside world (*gestation* or *pregnancy*), including formation of the *placenta*, the organ of exchange between mother and fetus
5. Giving birth to the baby (*parturition*)
6. Nourishing the infant after birth by milk production (*lactation*)

► **FIGURE 17-1** The male reproductive system. (a) The pelvis in sagittal section. (b) Posterior view of the reproductive organs. Portions of some organs have been removed.

The product of fertilization is known as an **embryo** during the first two months of intrauterine development when tissue differentiation is taking place. Beyond this time, the developing living being is recognizable as human and is known as a **fetus** during the remainder of gestation. Although no further tissue differentiation takes place during fetal life, it is a time of tremendous tissue growth and maturation.

The ovaries and female reproductive tract lie within the pelvic cavity (► Figures 17-2a and 17-2b). The female reproductive tract consists of two *Fallopian tubes*, a **uterus**, a **cervix**, and a **vagina**. Two **oviducts (uterine or Fallopian tubes)**, which are in close association with the two ovaries, pick up ova on ovulation

(ovum release from an ovary) and serve as the site for fertilization. The thick-walled, hollow **uterus** is primarily responsible for maintaining the fetus during its development and expelling it at the end of pregnancy. The **vagina** is a muscular, expandable tube that connects the uterus to the external environment. The lowest portion of the uterus, the **cervix**, projects into the vagina and contains a single, small opening, the **cervical canal**. Sperm are deposited in the vagina by the penis during sexual intercourse. The cervical canal serves as a pathway for sperm to enter the uterus where it can then access the site of fertilization in the oviduct and, when greatly dilated during parturition, serves as the passageway for delivery of the baby from the uterus.

© 2016 Cengage

FIGURE 17-2 The female reproductive system. (a) The pelvis in sagittal section. (b) Posterior view of the reproductive organs. (c) Perineal view of the external genitalia

The **vaginal opening** is located in the **perineal region** between the urethral opening anteriorly and the anal opening posteriorly (► Figure 17-2c). It is partially covered by a thin mucous membrane, the **hymen**, which typically is physically disrupted by the first sexual intercourse. The vaginal and urethral openings are surrounded laterally by two pairs of skin folds, the **labia minora** and **labia majora**. The smaller labia minora are located medially to the more prominent labia majora. The **clitoris**, a small erectile structure composed of tissue similar to that of the penis, lies at the anterior end of the folds of the labia minora. The female external genitalia are collectively referred to as the **vulva**.

Reproductive cells

The DNA molecules that carry the cell's genetic code are not randomly crammed into the nucleus but are precisely organized into **chromosomes** (Appendix C, p. A-19). Each chromosome consists of a different DNA molecule that contains a unique set of genes. Somatic (body) cells contain 46 chromosomes (the **diploid number**), which can be sorted into 23 pairs on the basis of various distinguishing features. Chromosomes composing a matched pair are termed **homologous chromosomes**—one member of each pair having been derived from the individual's maternal parent and the other member from the paternal parent. Gametes (i.e., sperm and eggs) contain only one member of each homologous pair, for a total of 23 chromosomes (the **haploid number**).

Gametogenesis

Most cells in the human body have the ability to reproduce themselves, a process important in growth, replacement, and repair of tissues. Cell division involves two components: division of the nucleus and division of the cytoplasm. Nuclear division in somatic cells is accomplished by **mitosis**. In mitosis, the chromosomes replicate (make duplicate copies of themselves); then the identical chromosomes are separated so that a complete set of genetic information (i.e., a diploid number of chromosomes) is distributed to each of the two new daughter cells. Nuclear division in the specialized case of gametes is accomplished by **meiosis**, in which only a half set of genetic information (i.e., a haploid number of chromosomes) is distributed to each of four new daughter cells (Appendix C, p. A-27).

During meiosis, a specialized diploid germ cell undergoes one chromosome replication followed by two nuclear divisions. In the first meiotic division, the replicated chromosomes do not separate into two individual, identical chromosomes but remain joined. The doubled chromosomes sort themselves into homologous pairs, and the pairs separate so that each of two daughter cells receives a half set of doubled chromosomes. During the second meiotic division, the doubled chromosomes within each of the two daughter cells separate and are distributed into two cells, yielding four daughter cells, each containing a half set of chromosomes, that is, a single member of each pair. During this process, the maternally and paternally derived chromosomes of each homologous pair are distributed to the daughter cells in random assortments containing one member of each chromosome pair without regard for its original derivation. That is, not all of the

mother-derived chromosomes go to one daughter cell and the father-derived chromosomes to the other cell. More than 8 million (2^{23}) different mixtures of the 23 paternal and maternal chromosomes are possible. This genetic mixing provides novel combinations of chromosomes. Crossing-over contributes even further to genetic diversity. *Crossing-over* refers to the physical exchange of chromosome material between the homologous pairs prior to their separation during the first meiotic division (Appendix C, p. A-27).

Thus, sperm and ova each have a unique haploid number of chromosomes. When fertilization takes place, a sperm and ovum fuse to form the start of a new individual with 46 chromosomes—one member of each chromosomal pair having been inherited from the mother and the other member from the father (► Figure 17-3).

Sex chromosomes

Whether individuals are destined to be males or females is a genetic phenomenon determined by the sex chromosomes they possess. As the 23 chromosome pairs are separated during meiosis, each sperm or ovum receives only one member of each chromosome pair. Of the chromosome pairs, 22 are **autosomal chromosomes** that code for general human characteristics as well as for specific traits, such as eye colour. The remaining pair of chromosomes consists of the **sex chromosomes**, of which

► FIGURE 17-3 Chromosomal distribution in sexual reproduction

there are two genetically different types: a larger **X chromosome**, and a smaller **Y chromosome**.

Sex determination depends on the combination of sex chromosomes. **Genetic males** have both an X and a Y sex chromosome; **genetic females** have two X sex chromosomes. Therefore, the genetic difference responsible for all the anatomic and functional distinctions between males and females is the single Y chromosome. Males have it; females do not.

As a result of meiosis during gametogenesis, all chromosome pairs are separated so that each daughter cell contains only one member of each pair, including the sex chromosome pair. When the XY sex chromosome pair separates during sperm formation, half the sperm receive an X chromosome and the other half a Y chromosome. In contrast, during oogenesis, every ovum receives an X chromosome, because separation of the XX sex chromosome pair yields only X chromosomes. During fertilization, the combination of an X-bearing sperm with an X-bearing ovum produces a genetic female, XX, whereas union of a Y-bearing sperm with an X-bearing ovum results in a genetic male, XY. Consequently, genetic sex is determined at the time of conception and depends on which type of sex chromosome is contained within the fertilizing sperm (an X or a Y).

Sexual differentiation

Differences between males and females exist at three levels: genetic, gonadal, and phenotypic (anatomic) sex (► Figure 17-4).

GENETIC AND GONADAL SEX

Genetic sex, which depends on the combination of sex chromosomes at the time of conception, in turn, determines **gonadal sex**, that is, whether testes or ovaries develop. The presence or absence of a Y chromosome determines gonadal differentiation. For the first month and a half of gestation, all embryos have the potential to differentiate along either male or female lines, because the developing reproductive tissues of both sexes are identical and indifferent. Gonadal specificity appears during the seventh week of intrauterine life when the indifferent gonadal tissue of a genetic male begins to differentiate into testes under the influence of the **sex-determining region of the Y chromosome (SRY)**—the single gene, found in the urogenital ridge cells, that is responsible for sex determination. The SRY gene is found in all mammals and shows little variation over time (evolution). This gene triggers a chain of reactions that leads to physical development of a male. SRY “masculinizes” the gonads (i.e., induces their development into testes) by stimulating production of **H-Y antigen** by primitive gonadal cells. H-Y antigen, a specific plasma membrane protein found only in males, directs differentiation of the gonads into testes.

Because genetic females lack the SRY gene and consequently do not produce H-Y antigen, their gonadal cells never receive a signal for testicular formation, so by default during the ninth week, the undifferentiated gonadal tissue starts developing into ovaries instead.

PHENOTYPIC SEX

Phenotypic sex, the apparent anatomic sex of an individual, depends on the genetically determined gonadal sex. The term **sexual differentiation** refers to the embryonic development of the external genitalia and reproductive tract along either male or female lines. As with the undifferentiated gonads, embryos of both sexes have the potential to develop either male or female external genitalia and reproductive tracts. Differentiation into a male-type reproductive system is induced by **androgens**, which are masculinizing hormones secreted by the developing testes. Testosterone is the most potent androgen. The absence of these testicular hormones in female fetuses results in the development of a female-type reproductive system. By 10 to 12 weeks of gestation, the sexes can easily be distinguished by the anatomic appearance of the external genitalia.

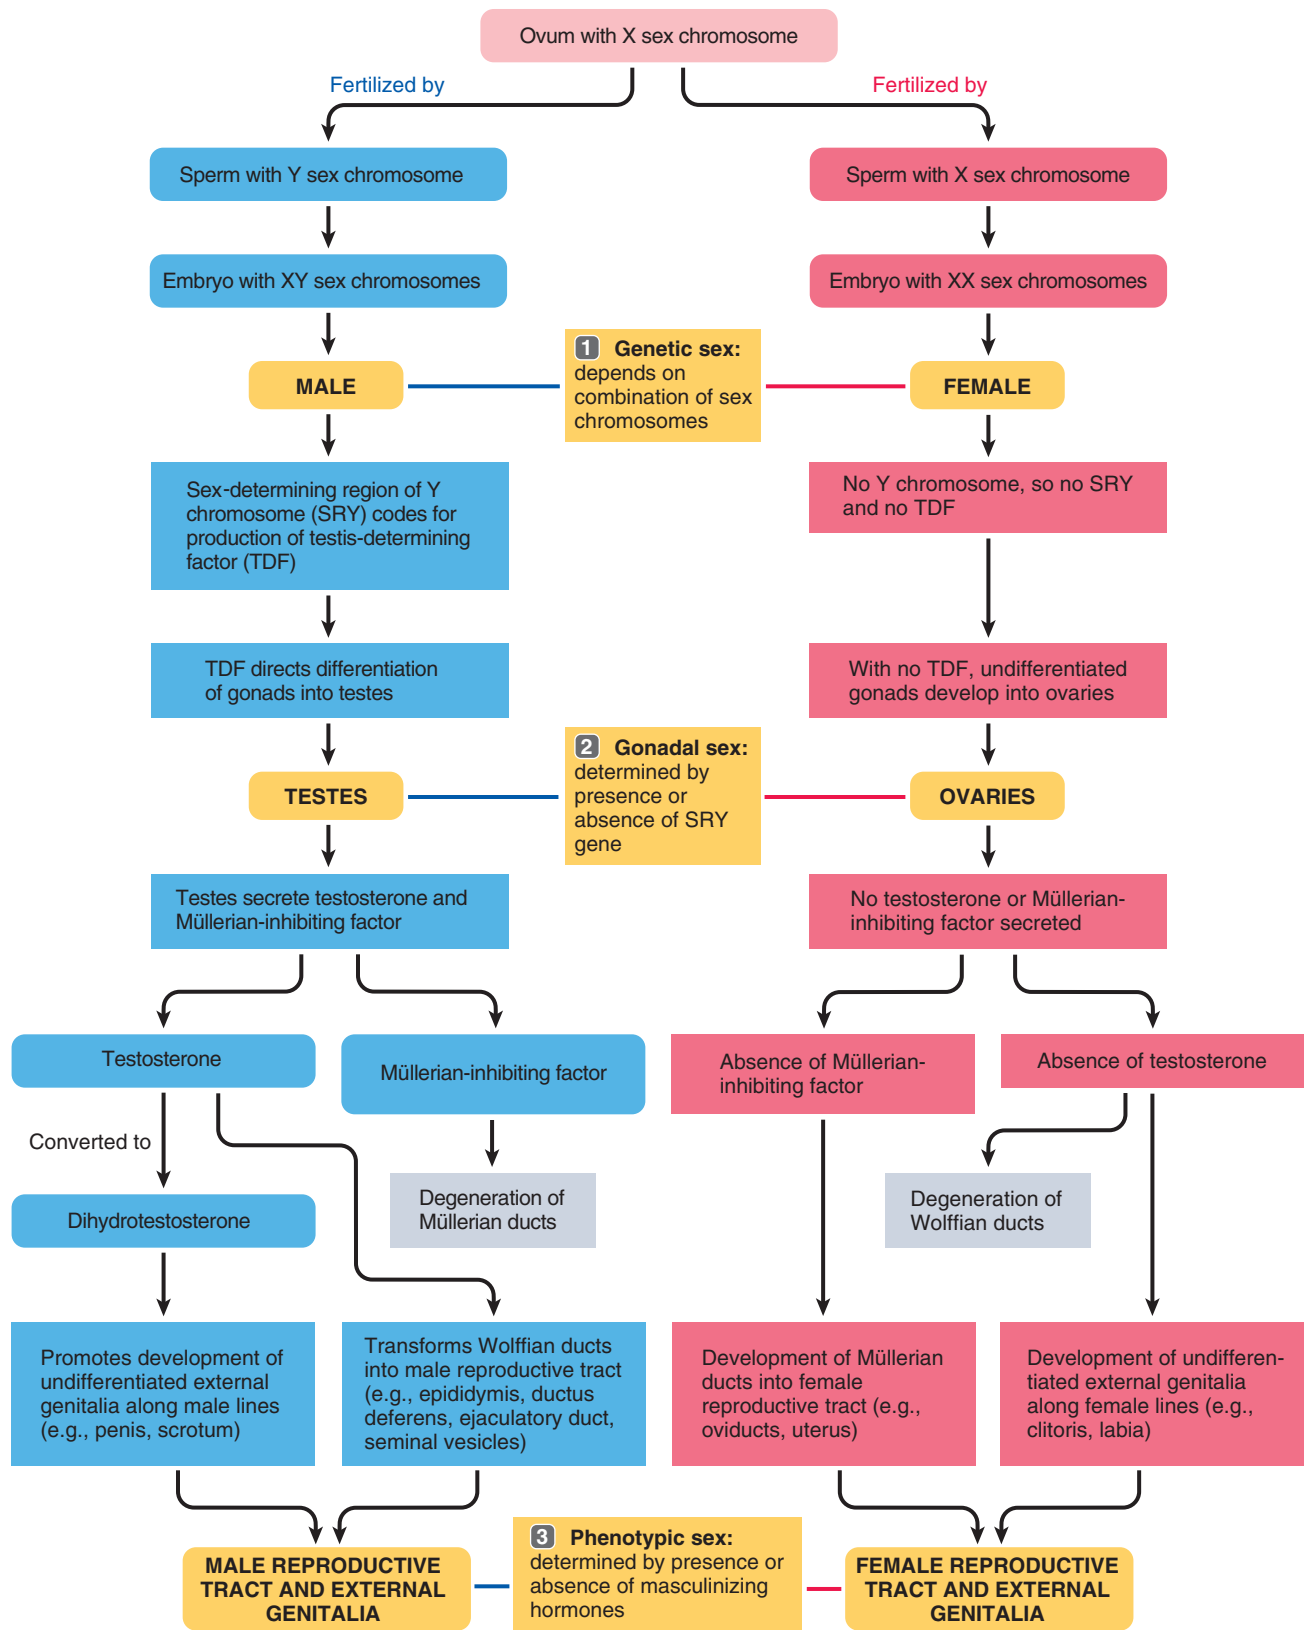

SEXUAL DIFFERENTIATION OF THE EXTERNAL GENITALIA

Male and female external genitalia develop from the same embryonic tissue. In both sexes, the undifferentiated external genitals consist of a *genital tubercle*, paired *urethral folds* surrounding a urethral groove, and, more laterally, *genital (labio-scrotal) swellings* (► Figure 17-5). The **genital tubercle** gives rise to exquisitely sensitive erotic tissue—in males, the **glans penis** (the cap at the distal end of the penis) and in females, the clitoris. The major distinctions between the glans penis and clitoris are the smaller size of the clitoris and the urethral opening through the glans penis. The urethra is the tube through which urine is transported from the bladder to the outside and also serves in males as a passageway for exit of semen through the penis to the outside. In males, the **urethral folds** fuse around the urethral groove to form the penis, which encircles the urethra. The **genital swellings** similarly fuse to form the scrotum and **prepuce**, a fold of skin that extends over the end of the penis and more or less completely covers the glans penis. In females, the urethral folds and genital swellings do not fuse at midline but develop instead into the labia minora and labia majora, respectively. The urethral groove remains open, providing access to the interior through both the urethral opening and the vaginal opening.

SEXUAL DIFFERENTIATION OF THE REPRODUCTIVE TRACT

Although the male and female external genitalia develop from the same undifferentiated embryonic tissue, this is not the case with the reproductive tracts. Two primitive duct systems—Wolffian ducts and the Müllerian ducts—develop in all embryos. In males, the reproductive tract develops from the **Wolffian ducts**, and the Müllerian ducts degenerate. In females the **Müllerian ducts** differentiate into the reproductive tract, and the Wolffian ducts regress (► Figure 17-6). Because both duct systems are present before sexual differentiation occurs, the early embryo has the potential to develop either a male or a female reproductive tract.

Development of the reproductive tract along male or female lines is determined by the presence or absence of two hormones secreted by the fetal testes—*testosterone* and *Müllerian-inhibiting*

(a) Male sex determination and sexual differentiation

(b) Female sex determination and sexual differentiation

FIGURE 17-4 Sexual differentiation

© 2016 Cengage

FIGURE 17-5 Sexual differentiation of the external genitalia

factor (see Figure 17-4). A hormone released by the placenta, *human chorionic gonadotropin*, is the stimulus for this early testicular secretion. Testosterone induces development of the Wolffian ducts into the male reproductive tract (epididymis, ductus deferens, and seminal vesicles). This hormone, after being converted into **dihydrotestosterone (DHT)**, is also responsible for differentiating the external genitalia into the penis and scrotum. Meanwhile, Müllerian-inhibiting factor causes regression of the Müllerian ducts.

In females, the absence of testosterone causes the Wolffian ducts to degrade and allows the Müllerian ducts to develop into the female reproductive tract (oviducts, uterus, and superior portion of vagina) and the external genitalia to differentiate into the clitoris and labia.

Note that the undifferentiated embryonic reproductive tissue passively develops into a female structure unless actively acted

on by masculinizing factors. In the absence of male testicular hormones, a female reproductive tract and external genitalia develop regardless of the genetic sex of the individual. For feminization of the fetal genital tissue, ovaries do not even need to be present. Such a control pattern for determining sex differentiation is appropriate, considering that fetuses of both sexes are exposed to high concentrations of female sex hormones throughout gestation. If female sex hormones influenced the development of the reproductive tract and external genitalia, all fetuses would be feminized.

ERRORS IN SEXUAL DIFFERENTIATION

Genetic sex and phenotypic sex are usually compatible; that is, a genetic male anatomically appears to be a male and functions as a male, and the same compatibility holds true for females. Occasionally, however, discrepancies

► **FIGURE 17-6** Sexual differentiation of the reproductive tract

occur between genetic and anatomic sexes because of errors in sexual differentiation, as the following examples illustrate:

- If testes in a genetic male fail to properly differentiate and secrete hormones, the result is the development of an apparent anatomic female in a genetic male, who, of course, will be sterile. Similarly, genetic males whose target cells lack receptors for testosterone are feminized, even though their testes secrete adequate testosterone (see *testicular feminization syndrome*, p. 214).
- Because testosterone acts on the Wolffian ducts to convert them into a male reproductive tract but the testosterone derivative DHT is responsible for masculinization of the external genitalia, a genetic deficiency of the enzyme that converts testosterone into DHT results in a genetic male with testes and a male reproductive tract, but with female external genitalia.
- The adrenal gland normally secretes a weak androgen, *dehydroepiandrosterone*, in insufficient quantities to masculinize

females. However, pathologically excessive secretion of this hormone in a genetically female fetus during critical developmental stages imposes differentiation of the reproductive tract and genitalia along male lines (see *adrenogenital syndrome*, p. 259).

Sometimes these discrepancies between genetic sex and apparent sex are not recognized until puberty, when the discovery produces a psychologically traumatic gender identity crisis. For example, a masculinized genetic female with ovaries but with male-type external genitalia may be reared as a boy until puberty, when breast enlargement (caused by estrogen secretion by the awakening ovaries) and lack of beard growth (caused by lack of testosterone secretion in the absence of testes) signal an apparent problem. Therefore, it is important to diagnose any problems in sexual differentiation in infancy. Once a sex has been assigned, it can be reinforced, if necessary, with surgical and hormonal treatment so that psychosexual development can proceed as normally as possible. Less dramatic cases of inappropriate sex differentiation often appear as sterility problems.

In some circumstances, such as athletics, it is considered performance enhancing to be a phenotypic female but genetic male due to the greater production of testosterone. Consequently, genetic testing of female athletes is sometimes required to establish genotypic sex (see ► Concepts, Challenges, and Controversies, p. 732).

Check Your Understanding 17.1

1. Name the primary reproductive organs in males and in females, and state the dual function of these organs in each sex.
2. Prepare a table comparing what reproductive structures are derived from the gonadal ridge, genital tubercle, urethral folds, genital swellings, Wolffian ducts, and Müllerian ducts during embryonic development in males and in females.

17.2 | Male Reproductive Physiology

In the embryo, the testes develop from the gonadal ridge located at the rear of the abdominal cavity. In the last months of fetal life, they begin a slow descent, passing out of the abdominal cavity through the **inguinal canal** into the scrotum; one testis drops into each pocket of the scrotal sac. Testosterone from the fetal testes induces the descent of the testes into the scrotum.

After the testes descend into the scrotum, the opening in the abdominal wall through which the inguinal canal passes closes

SEX VERIFICATION (SEX DETERMINATION) IN SPORTS means verifying the eligibility of an athlete to compete in a sporting event that is limited to a single sex—in essence, making sure that female athletes are actually female. Sex verification began at the 1966 European Track and Field Championships in response to suspicions that some of the top female athletes—primarily from the Soviet Union—were actually men; more suspicion was raised when some of the participants unexpectedly retired when the testing began.

The most recognized case of a male impersonating a female in an international athletic competition involved a German athlete (Hermann Ratjen), who took the name Dora and placed fourth in the high jump event in the 1936 Olympics. The deception was not discovered until 1955. Testing was introduced at the Olympics in 1968, in Mexico City. In those days, the athlete had to stand unclothed in front of a panel of gynaecologists, who would together make the determination. Later, this crude method gave way to much more sophisticated and objective laboratory tests (i.e., testing for two X chromosomes).

By the 1980s, testing methods had changed yet again. The International Olympic Committee (IOC) replaced the X chromosome test with the polymerase chain reaction test (for the Y-linked gene SRY), using the cells from a buccal smear. This test was introduced during the 1992 Winter Olympics in Albertville, France. In contrast, the International

Association of Athletics Federations (IAAF) stopped genetic testing for sex verification in 1992, because mandatory urine samples made the deception virtually impossible.

Although the polymerase chain reaction test is less intrusive, many experts feel the test is meaningless and that it can cause serious psychological damage to females who may unknowingly have certain disorders of sexual differentiation. Data indicate that sex tests for approximately 1 in 500–600 athletes are abnormal and might result in their disqualification. For example, androgen insensitivity syndrome (testicular feminization) may provide a false positive test. In this case, an individual is genetically male (i.e., has both an X and a Y chromosome), but his or her tissues are unable to respond to the androgens, and thus he or she develops into a woman.

snugly around the sperm-carrying duct and blood vessels that traverse between each testis and the abdominal cavity. Incomplete closure or rupture of this opening permits abdominal viscera to slip through, resulting in an **inguinal hernia**.

Although the time varies somewhat, descent is usually complete by the seventh month of gestation. As a result, descent is complete in 98 percent of full-term baby boys.

 However, in a substantial percentage of premature male infants, the testes are still within the inguinal canal at birth. In most instances of retained testes, the descent occurs naturally before puberty or can be encouraged with administration of testosterone. Rarely, a testis remains undescended into adulthood, a condition known as **cryptorchidism** (hidden testis).

Scrotal location of the testes

The temperature within the scrotum averages several degrees Celsius less than normal body (core) temperature. Descent of the testes into this cooler environment is essential, because spermatogenesis is temperature sensitive and cannot occur at normal body temperature. Therefore, a person with cryptorchidism is unable to produce viable sperm.

The position of the scrotum in relation to the abdominal cavity can be varied by two muscles and a spinal reflex mechanism that play an important role in regulating testicular temperature. Reflex contraction of the two scrotal muscles on exposure to a cold environment raises the scrotal sac to bring the testes closer to the warmer abdomen. The scrotum will take on a smaller, more wrinkled appearance. Conversely, relaxation of the muscles on exposure to heat permits the scrotal sac to become more pendulous, moving the testes farther from the warm core of the body.

Leydig cells

The testes perform the dual function of producing sperm and secreting testosterone. About 80 percent of the testicular mass consists of highly coiled **seminiferous tubules**, within which spermatogenesis and meiosis take place. The endocrine cells that produce testosterone (androgen)—the **Leydig (interstitial) cells**—lie in the connective tissue (interstitial tissue) between the seminiferous tubules (► Figure 17-7). The production of testosterone by the Leydig cells is under the control of the pituitary gland's secretion of luteinizing hormone. Thus, the portions of the testes that produce sperm and secrete testosterone are structurally and functionally distinct.

FIGURE 17-7 Testicular anatomy depicting the site of spermatogenesis. (a) Longitudinal section of a testis showing the location and arrangement of the seminiferous tubules, the sperm-producing portion of the testis. (b) Light micrograph of a cross-section of a seminiferous tubule. The undifferentiated germ cells (the spermatogonia) lie in the periphery of the tubule, and the differentiated spermatozoa are in the lumen, with the various stages of sperm development in between. (c) Scanning electron micrograph of a cross-section of a seminiferous tubule. (d) Relationship of the Sertoli cells to the developing sperm cells

Testosterone is a steroid hormone derived from a cholesterol precursor molecule, as are the female sex hormones, estrogen and progesterone. Once produced, some of the testosterone is secreted into the blood, where it is transported—primarily bound to plasma proteins—to its target sites of action. A substantial portion of the newly synthesized testosterone goes into

the lumen of the seminiferous tubules, where it plays an important role in sperm production.

Most but not all of testosterone's actions ultimately function to ensure delivery of sperm to the female. The effects of testosterone can be grouped into five categories: (1) effects on the reproductive system before birth, (2) effects on sex-specific

■ **TABLE 17-1** Effects of Testosterone

Effects before Birth

- Masculinizes the reproductive tract and external genitalia
- Promotes descent of the testes into the scrotum

Effects on Sex-Specific Tissues after Birth

- Promotes growth and maturation of the reproductive system at puberty
- Is essential for spermatogenesis
- Maintains the reproductive tract throughout adulthood

Other Reproduction-Related Effects

- Develops the sex drive at puberty
- Controls gonadotropin hormone secretion

Effects on Secondary Sexual Characteristics

- Induces the male pattern of hair growth (e.g., beard)
- Causes the voice to deepen because of thickening of the vocal folds
- Promotes muscle growth responsible for the male body configuration

Nonreproductive Actions

- Exerts a protein anabolic effect
- Promotes bone growth at puberty
- Closes the epiphyseal plates after its conversion to estrogen by aromatase
- May induce aggressive behaviour

tissues after birth, (3) other reproduction-related effects, (4) effects on secondary sexual characteristics, and (5) nonreproductive actions (■ Table 17-1).

EFFECTS ON THE REPRODUCTIVE SYSTEM BEFORE BIRTH

Before birth, testosterone secretion by the fetal testes masculinizes the reproductive tract and external genitalia and promotes descent of the testes into the scrotum, as already described. After birth, testosterone secretion ceases, and the testes and the rest of the reproductive system remain small and nonfunctional until puberty.

EFFECTS ON SEX-SPECIFIC TISSUES AFTER BIRTH

Puberty is the period of arousal and maturation of the previously nonfunctional reproductive system, culminating in sexual maturity and the ability to reproduce. It usually begins sometime between the ages of 10 and 14; on average, it begins about two years earlier in females than in males. Usually lasting three to five years, puberty encompasses a complex sequence of endocrine, physical, and behavioural events. **Adolescence** is a broad concept that refers to the entire transition period between childhood and adulthood, not just to the time of sexual maturation.

At puberty, the Leydig cells start secreting testosterone once again. Testosterone is responsible for growth and maturation of the entire male reproductive system. Under the influence of the pubertal surge in testosterone secretion, the testes enlarge and start producing sperm for the first time, the accessory sex glands enlarge and become secretory, and the penis and scrotum enlarge.

Ongoing testosterone secretion is essential for spermatogenesis and for maintaining a mature male reproductive tract throughout adulthood. Once initiated at puberty, testosterone secretion and spermatogenesis occur continuously throughout the male's life. Testicular efficiency gradually declines after 45 to 50 years of age, even though men in their 70s and beyond may continue to enjoy an active sex life, and some even father a child at this late age. The gradual reduction in circulating testosterone levels and in sperm production is not caused by a decrease in stimulation of the testes, but probably arises instead from degenerative changes associated with aging that occur in the small testicular blood vessels. This gradual decline is often termed “male menopause” or “andropause,” although it is not specifically programmed, as is female menopause. Recently the androgen decline in males has been more aptly termed **androgen deficiency in aging males (ADAM)**.

Following **castration** (surgical removal of the testes) or testicular failure caused by disease, the other sex organs regress in size and function.

OTHER REPRODUCTION-RELATED EFFECTS

Testosterone governs the development of sexual libido at puberty and helps maintain the sex drive in the adult male. Stimulation of this behaviour by testosterone is important for facilitating delivery of sperm to females. In humans, libido is also influenced by many interacting social and emotional factors. Once libido has developed, testosterone is no longer absolutely required for its maintenance. Castrated males often remain sexually active but at a reduced level.

In another reproduction-related function, testosterone participates in the normal negative-feedback control of gonadotropin hormone secretion by the anterior pituitary, a topic covered in the section LH and FSH.

EFFECTS ON SECONDARY SEXUAL CHARACTERISTICS

All male secondary sexual characteristics depend on testosterone for their development and maintenance. These nonreproductive male characteristics induced by testosterone include (1) the male pattern of hair growth (e.g., beard and chest hair and, in genetically predisposed men, baldness); (2) a deep voice caused by enlargement of the larynx and thickening of the vocal folds; (3) thick skin; and (4) the male body configuration (e.g., broad shoulders and heavy arm and leg musculature) as a result of protein deposition. A male castrated before puberty (a **eunuch**) does not mature sexually, nor does he develop secondary sexual characteristics.

NONREPRODUCTIVE ACTIONS

Testosterone exerts several important effects not related to reproduction. It has a general protein anabolic (synthesis) effect and promotes bone growth, thereby contributing to the

more muscular physique of males and to the pubertal growth spurt. Ironically, testosterone not only stimulates bone growth but eventually prevents further growth by sealing the growing ends of the long bones (i.e., ossifying, or closing, the epiphyseal plates; p. 233). Testosterone also stimulates oil secretion by the sebaceous glands. This effect is most striking during the adolescent surge of testosterone secretion, predisposing the young man to develop acne. Testosterone also stimulates erythropoietin release, which is a contributing factor to the higher haematocrit in males.

In animals, testosterone induces aggressive behaviour, but whether it influences human behaviour other than in the area of sexual behaviour is an unresolved issue. Even though some athletes and body builders who take testosterone-like anabolic androgenic steroids to increase muscle mass have been observed to display more aggressive behaviour, it is unclear to what extent general behavioural differences between the sexes are hormonally induced or a result of social conditioning.

CONVERSION OF TESTOSTERONE TO ESTROGEN IN MALES

Although testosterone is classically considered the male sex hormone and estrogen a female sex hormone, the distinctions are not as clear-cut as once thought. In addition to the small amount of estrogen produced by the adrenal cortex (p. 258), a portion of the testosterone secreted by the testes is converted to estrogen outside the testes by the enzyme **aromatase**, which is widely distributed. Because of this conversion, it is sometimes difficult to distinguish between the cellular effects of testosterone and those of testosterone-turned-estrogen. For example, scientists recently learned that closure of the epiphyseal plates in males is induced not by testosterone per se but by testosterone turned into estrogen by aromatization. Estrogen is also produced in adipose tissue in both sexes. Estrogen receptors have been identified in the testes, prostate, bone, and elsewhere in males. Recent findings suggest that estrogen plays an essential role in male reproductive health; for example, it is important in spermatogenesis and surprisingly contributes to male heterosexuality. Also, it likely contributes to bone homeostasis (p. 286). The depth, breadth, and mechanisms of action of estrogen in males are only beginning to be explored. (Likewise, in addition to the weak androgenic hormone DHEA produced by the adrenal cortex in both sexes, the ovaries in females secrete a small amount of testosterone, the functions of which remain unclear.)

We now shift attention from testosterone secretion to the other function of the testes—sperm production.

Spermatogenesis

About 250 m of sperm-producing seminiferous tubules are packed within the testes (see ▶ Figure 17-7a). Two functionally important cell types are present in these tubules: *germ cells*, most of which are in various stages of sperm development; and *Sertoli cells*, which provide crucial support for spermatogenesis (see ▶ Figures 17-7b, 17-7c, and 17-7d). **Spermatogenesis** is a complex process by which relatively undifferentiated primordial germ cells—the **spermatogonia** (each of which contains

a diploid complement of 46 chromosomes)—proliferate and are converted into extremely specialized, motile spermatozoa (sperm), each bearing a randomly distributed haploid set of 23 chromosomes.

Microscopic examination of a seminiferous tubule reveals layers of germ cells in an anatomic progression of sperm development, starting with the least differentiated in the outer layer and moving inward through various stages of division to the lumen, where the highly differentiated sperm are ready for exit from the testis. Spermatogenesis takes 64 days for development from a spermatogonium to a mature sperm. Up to several hundred million sperm may reach maturity daily. Spermatogenesis encompasses three major stages: *mitotic proliferation*, *meiosis*, and *packaging* (▶ Figure 17-8).

MITOTIC PROLIFERATION

Spermatogonia located in the outermost layer of the tubule continuously divide mitotically, with all new cells bearing the full complement of 46 chromosomes identical to those of the parent cell. Such proliferation provides a continual supply of new germ cells. Following mitotic division of a spermatogonium, one of the daughter cells remains at the outer edge of the tubule as an undifferentiated spermatogonium, thus maintaining the germ-cell line. The other daughter cell starts moving toward the lumen while undergoing the various steps required to form sperm, which will be released into the lumen. In humans, the sperm-forming daughter cell divides mitotically twice more to form four identical **primary spermatocytes**. After the last mitotic division, the primary spermatocytes enter a resting phase, during which the chromosomes are duplicated and the doubled strands remain together in preparation for the first meiotic division.

MEIOSIS

During meiosis, each primary spermatocyte (with a diploid number of 46 doubled chromosomes) forms two **secondary spermatocytes** (each with a haploid number of 23 doubled chromosomes) during the first meiotic division, finally yielding four **spermatids** (each with 23 single chromosomes) as a result of the second meiotic division.

No further division takes place beyond this stage of spermatogenesis. Each spermatid is remodelled into a single spermatozoon. Because each sperm-producing spermatogonium mitotically produces four primary spermatocytes and each primary spermatocyte meiotically yields four spermatids (spermatozoa-to-be), the spermatogenic sequence in humans can theoretically produce 16 spermatozoa each time a spermatogonium initiates this process. Usually, however, some cells are lost at various stages, so the efficiency of productivity is rarely this high.

PACKAGING

Even after meiosis, spermatids still resemble undifferentiated spermatogonia structurally, except for their half complement of chromosomes. Production of extremely specialized, mobile spermatozoa from spermatids requires extensive remodelling, or **packaging**, of cell elements, a process known as **spermiogenesis**. Sperm are essentially stripped-down cells in which most of the cytosol and any organelles not needed for delivering the

FIGURE 17-8 Spermatogenesis

sperm's genetic information to an ovum have been extruded. So the sperm travel with only what's essential to accomplish fertilization.

A spermatozoon has four parts (Figure 17-9): a head, an acrosome, a midpiece, and a tail. The **head** consists primarily of the nucleus, which contains the sperm's complement of genetic information. The **acrosome**, an enzyme-filled vesicle that caps the tip of the head, is used as an "enzymatic drill" for penetrating the ovum. The acrosome is formed by aggregation of vesicles produced by the endoplasmic reticulum/Golgi complex before these organelles are discarded. Mobility for the spermatozoon is provided by a long, whiplike **tail**. Movement of the tail is powered by energy generated by the mitochondria concentrated within the **midpiece** of the sperm.

Until sperm maturation is complete, the developing germ cells arising from a single primary spermatocyte remain joined by cytoplasmic bridges. These connections, which result from incomplete cytoplasmic division, permit the four developing sperm to exchange cytoplasm. This linkage is important, because the X chromosome, but not the Y chromosome, contains genes that code for cell products essential for sperm development. (Whereas the large X chromosome contains several thousand genes, the small Y chromosome has only a few dozen, the most important of which are the SRY gene and others that play critical roles in male fertility.) During meiosis, half the sperm receive an X and the other half a Y chromosome. Were it not for the sharing of cytoplasm so that all the haploid cells are provided with the products coded for by X chromosomes until sperm development is complete, the Y-bearing, male-producing sperm could not develop and survive.

(b) Parts of spermatozoon

► **FIGURE 17-9 Anatomy of a spermatozoon.** (a) A phase-contrast photomicrograph of human spermatozoa. (b) A spermatozoon has three functional parts: a head with its acrosome cap, a midpiece, and a tail.

Clinical Connections

Chlamydia infections in males can lead to infertility. If the infection is asymptomatic or ignored, it can spread from the urethra further into the male reproductive tract. If it reaches the testicles, chlamydia can affect sperm in a few ways. DNA is normally packaged very tightly within the head of sperm. However, chlamydia infections can cause DNA fragmentation by reducing how tightly the DNA is packed, which can result in the breakage of DNA strands. Chlamydia can also lead to physical abnormalities in sperm that reduces their mobility. Either of these, individually or combined, can drastically reduce male fertility.

Sertoli cells

The seminiferous tubules house the **Sertoli cells** in addition to the spermatogonia and developing sperm cells. The Sertoli cells lie side by side and form a ring that extends from the outer surface of the tubule to the lumen. Each Sertoli cell spans the entire distance from the outer surface membrane of the seminiferous tubule to the fluid-filled lumen (see ► Figures 17-7b and 17-7d). Adjacent Sertoli cells are joined by tight junctions at a point slightly beneath the outer membrane. Developing sperm cells are tucked between adjacent Sertoli cells, with spermatogonia lying at the outer perimeter of the tubule, outside the tight junction (see ► Figures 17-7b and 17-7d). The Sertoli cells form a barrier that prevents the immune system from becoming sensitized to antigens associated with sperm development. During spermatogenesis, the developing sperm cells arising from spermatogonial mitotic activity pass through the tight junctions, which transiently separate to make a path for them. They then migrate toward the lumen in close association with the adjacent Sertoli cells and, during this migration, undergo further divisions. The cytoplasm of the Sertoli cells envelops the migrating sperm cells, which remain buried within these cytoplasmic recesses throughout their development. At all stages of spermatogenic maturation, the developing sperm and Sertoli cells communicate with one another by means of direct cell-to-cell binding

and through paracrine secretions (p. 51). A recently identified carbohydrate on the surface membrane of the developing sperm enables them to bind to the supportive Sertoli cells.

Sertoli cells perform the following functions essential for spermatogenesis:

1. The tight junctions between adjacent Sertoli cells form a **blood–testes barrier** that prevents blood-borne substances from passing between the cells to gain entry to the lumen of the seminiferous tubule. Because of this barrier, only selected molecules that can pass through the Sertoli cells reach the intratubular fluid. As a result, the composition of the intratubular fluid varies considerably from that of the blood. The unique composition of this fluid that bathes the germ cells is critical for later stages of sperm development. The blood–testes barrier also prevents the antibody-producing cells in the ECF from reaching the tubular sperm factory, thus preventing the formation of antibodies against the highly differentiated spermatozoa.
2. Because the secluded developing sperm cells do not have direct access to blood-borne nutrients, the Sertoli cells provide nourishment for them.
3. Sertoli cells have an important phagocytic function. They engulf the cytoplasm extruded from the spermatids during their remodelling, and they destroy defective germ cells that fail to successfully complete all stages of spermatogenesis.
4. Sertoli cells secrete into the lumen **seminiferous tubule fluid**, which flushes the released sperm from the tubule into the epididymis for storage and further processing.
5. An important component of this Sertoli secretion is **androgen-binding protein (ABP)**. As the name implies, this protein binds androgens—specifically, testosterone—and thereby maintains a very high level of this hormone within the seminiferous tubule lumen. Testosterone is 100 times more concentrated in the seminiferous tubule fluid than in the blood. This high local concentration of testosterone is essential for sustaining sperm production.

ABP is necessary to retain testosterone within the lumen, because this steroid hormone is lipid soluble and could easily diffuse across the plasma membranes and leave the lumen.

- Sertoli cells are the site of action for control of spermatogenesis by both testosterone and follicle-stimulating hormone (FSH). This production of FSH is associated with the production of ABP. The Sertoli cells themselves release another hormone, *inhibin*, which acts in negative-feedback fashion to regulate FSH secretion.

LH and FSH

The testes are controlled by the two gonadotropic hormones secreted by the anterior pituitary, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which are named for their functions in females (p. 227). These two hormones are important to male reproductive function too. For example, testosterone is essential for maintaining spermatogenesis in the adult male, and it is under the direct control of LH.

FEEDBACK CONTROL OF TESTICULAR FUNCTION

LH and FSH act on separate components of the testes (► Figure 17-10). LH acts on the Leydig (interstitial) cells to regulate testosterone secretion; this accounts for its alternative name in males—*interstitial cell-stimulating hormone (ICSH)*. FSH acts on the seminiferous tubules, specifically the Sertoli cells, to enhance spermatogenesis. (There is no alternative name for FSH in males.) Secretion of both LH and FSH from the anterior pituitary is stimulated in turn by a single hypothalamic hormone, **gonadotropin-releasing hormone (GnRH)** (p. 229).

Even though GnRH stimulates both LH and FSH secretion, the blood concentrations of these two gonadotropic hormones do not always parallel each other because two other regulatory factors besides GnRH—*testosterone* and *inhibin*—differentially influence the secretory rate of LH and FSH. Testosterone, the product of LH stimulation of the Leydig cells, acts in negative-feedback fashion to inhibit LH secretion in two ways. The predominant negative-feedback effect of testosterone is to decrease GnRH release by acting on the hypothalamus, which indirectly decreases both LH and FSH release by the anterior pituitary. In addition, testosterone acts directly on the anterior pituitary to reduce the responsiveness of the LH secretory cells to GnRH. The latter action explains why testosterone exerts a greater inhibitory effect on LH secretion than on FSH secretion.

The testicular inhibitory signal specifically directed at controlling FSH secretion is the peptide hormone **inhibin**, which is secreted by the Sertoli cells. Inhibin acts directly on the anterior pituitary to inhibit FSH secretion. This feedback inhibition of FSH by a Sertoli cell product is appropriate, because FSH stimulates spermatogenesis by acting on the Sertoli cells.

ROLES OF TESTOSTERONE AND FSH IN SPERMATOGENESIS

Both testosterone and FSH play critical roles in controlling spermatogenesis, each exerting its effect by acting on the Sertoli cells. Testosterone is essential for both mitosis and meiosis of the germ cells, whereas FSH is needed for spermatid remodelling. Testosterone concentration is much higher in the testes than in the blood, because a substantial portion of this hormone produced locally by the Leydig cells is retained in the intratubular fluid complexed with androgen-binding protein secreted by the Sertoli cells. Only this high concentration of testicular testosterone is adequate to sustain sperm production.

Gonadotropin-releasing hormone

Even though the fetal testes secrete testosterone, which directs masculine development of the reproductive system, after birth the testes become dormant until puberty. During the prepubertal period, LH and FSH are not secreted at adequate levels to stimulate any significant testicular activity. The prepubertal

► FIGURE 17-10 Control of testicular function

© 2016 Cengage

delay in the onset of reproductive capability allows time for the individual to mature physically enough to handle child rearing. (This physical maturation is especially important in the female, whose body must support the developing fetus.)

During the prepubertal period, GnRH activity is inhibited. The pubertal process is initiated by an increase in GnRH activity sometime between 8 and 12 years of age. Early in puberty, GnRH secretion occurs only at night, causing a brief nocturnal increase in LH secretion and, accordingly, testosterone secretion. The extent of GnRH secretion gradually increases as puberty progresses until the adult pattern of GnRH, FSH, LH, and testosterone secretion is established. Under the influence of the rising levels of testosterone during puberty, the physical changes that encompass the secondary sexual characteristics and reproductive maturation become evident.

The factors responsible for initiating puberty in humans remain unclear. The leading proposal focuses on a potential role for the hormone *melatonin*, which is secreted by the *pineal gland* within the brain (p. 241). Melatonin, whose secretion decreases during exposure to the light and increases during exposure to the dark, has an antigonadotropic effect in many species. Light striking the eyes inhibits the nerve pathways that stimulate melatonin secretion. In many seasonally breeding species, the overall decrease in melatonin secretion in connection with longer days and shorter nights initiates the mating season. Some researchers suggest that an observed reduction in the overall rate of melatonin secretion at puberty in humans—particularly during the night, when the peaks in GnRH secretion first occur—is the trigger for the onset of puberty.

This completes our discussion of testicular function, and we now shift our attention to the roles of other components of the male reproductive system.

The reproductive tract

The remainder of the male reproductive system (i.e., besides the testes) is designed to deliver sperm to the female reproductive tract. Essentially, it consists of (1) a tortuous pathway of tubes (the reproductive tract), which transports sperm from the testes to outside the body; (2) several accessory sex glands, which contribute secretions that are important to the viability and motility of the sperm; and (3) the penis, which is designed to penetrate and deposit the sperm within the vagina of the female. We will examine each of these parts in detail, beginning with the reproductive tract.

COMPONENTS OF THE MALE REPRODUCTIVE TRACT

A comma-shaped **epididymis** is loosely attached to the rear surface of each testis (see ► Figures 17-1 and 17-7a). The epididymis is about 5 m in length and tightly coiled. After sperm have been produced in the seminiferous tubules, they are swept into the epididymis due to the pressure created by the continual secretion of tubular fluid by the Sertoli cells. The spermatozoa entering the epididymis are nonmotile, which is in part a result of the low pH associated with the epididymis and vas deferens. The epididymal ducts from each testis converge to form a large, thick-walled, muscular duct called the **ductus (vas) deferens**. The ductus deferens from each testis passes up out of the scrotal sac and runs back through the inguinal canal into the abdominal cavity, where it eventually empties into the urethra at the neck of the bladder (see ► Figure 17-1). The urethra carries sperm out of the penis during ejaculation, the forceful expulsion of semen from the body.

FUNCTIONS OF THE EPIDIDYMIS AND DUCTUS DEFERENS

These ducts perform several important functions. The epididymis and ductus deferens serve as the sperm's exit route from the testis. As they leave the testis, the sperm are capable of neither movement nor fertilization. They gain both capabilities during their passage through the epididymis. This maturational process is stimulated by the testosterone retained within the tubular fluid bound to androgen-binding protein. Sperm's capacity to fertilize is enhanced even further by exposure to secretions of the female reproductive tract. This enhancement of sperm's capacity in the male and female reproductive tracts is known as **capacitation**. Scientists believe that *defensin*, a protein secreted by the epididymis that defends sperm from microorganisms, may serve a second role by boosting sperm's motility. The epididymis also concentrates the sperm a hundredfold by absorbing most of the fluid that enters from the seminiferous tubules. The maturing sperm are slowly moved through the epididymis into the ductus deferens by rhythmic contractions of the smooth muscle in the walls of these tubes.

The ductus deferens serves as an important site for sperm storage. Because the tightly packed sperm are relatively inactive and their metabolic needs are accordingly low, they can be stored in the ductus deferens for many days, even though they have no nutrient blood supply and are nourished only by simple sugars present in the tubular secretions.

Why It Matters Vasectomy

In a vasectomy, a common sterilization procedure in males, a small segment of each ductus deferens (alias vas deferens, hence the term *vasectomy*) is surgically removed. The segment removed is the part of the duct between the testis and the inguinal canal, so the surgery effectively blocks the exit of sperm from the testes. The sperm that build up behind

the tied-off testicular end of the severed ductus are removed by phagocytosis. Although this procedure blocks sperm exit, it does not interfere with testosterone activity, because the Leydig cells secrete testosterone into the blood, not through the ductus deferens. Thus, testosterone-dependent masculinity or libido should not diminish after a vasectomy.

The accessory sex glands

Several accessory sex glands—the seminal vesicles and prostate—empty their secretions into the duct system before it joins the urethra (see ▶ Figure 17-1). A pair of saclike *seminal vesicles* empty into the last portion of the two ductus deferens, one on each side. The short segment of duct that passes beyond the entry point of the seminal vesicle to join the urethra is called the *ejaculatory duct*. The *prostate* is a large, single gland that completely surrounds the ejaculatory ducts and urethra. In a significant number of men, the prostate enlarges in middle to older age. Difficulty in urination is often encountered as the enlarging prostate impinges on the portion of the urethra that passes through the prostate. Another pair of accessory sex glands, the *bulbourethral glands*, drain into the urethra after it has passed through the prostate and just before it enters the penis. Numerous mucus-secreting glands also lie along the length of the urethra.

SEMEN

During ejaculation, the accessory sex glands contribute secretions that provide support for the continuing viability of the sperm inside the female reproductive tract. These secretions constitute the bulk of the **semen**, which is a mixture of accessory sex gland secretions, sperm, and mucus. Sperm make up only a small percentage of the total ejaculated fluid.

FUNCTIONS OF THE MALE ACCESSORY SEX GLANDS

Although the accessory sex gland secretions are not absolutely essential for fertilization, they do greatly facilitate the process:

- The **seminal vesicles** (1) supply fructose, which serves as the primary energy source for ejaculated sperm; (2) secrete

prostaglandins, which stimulate contractions of the smooth muscle in both the male and female reproductive tracts, thereby helping to transport sperm from their storage site in the male to the site of fertilization in the female oviduct; (3) provide more than half the semen, which helps wash the sperm into the urethra and also dilutes the thick mass of sperm, enabling them to become mobile; and (4) secrete fibrinogen, a precursor of fibrin, which forms the meshwork of a clot (p. 449).

- The **prostate gland** (1) secretes an alkaline fluid that neutralizes the acidic vaginal secretions, an important function because sperm are more viable in a slightly alkaline environment; and (2) provides clotting enzymes and fibrinolysin. The prostatic clotting enzymes act on fibrinogen from the seminal vesicles to produce fibrin, which “clots” the semen, thus helping keep the ejaculated sperm in the female reproductive tract during withdrawal of the penis. Shortly thereafter, the seminal clot is broken down by fibrinolysin, a fibrin-degrading enzyme from the prostate, thus releasing mobile sperm within the female tract.
- During sexual arousal, the **bulbourethral glands** secrete a clear, mucus-like substance, the primary role of which is to lubricate the urethra for spermatozoa to pass through.

■ Table 17-2 summarizes the locations and functions of the components of the male reproductive system.

Before turning to the act of delivering sperm to the female (sexual intercourse), we are going to briefly discuss the diverse roles of prostaglandins, which were first discovered in semen but are abundant throughout the body.

■ TABLE 17-2 Location and Functions of the Components of the Male Reproductive System

Component	Number and Location	Functions
Testis	Pair; located in the scrotum, a skin-covered sac suspended within the angle between the legs	Produce sperm Secrete testosterone
Epididymis and Ductus Deferens	Pair; one epididymis attached to the rear of each testis; one ductus deferens travels from each epididymis up out of the scrotal sac through the inguinal canal and empties into the urethra at the neck of the bladder	Serve as the sperm’s exit route from the testis Serve as the site for maturation of the sperm for motility and fertility Concentrate and store the sperm
Seminal Vesicle	Pair; both empty into the last portion of the ductus deferens, one on each side	Supply fructose to nourish the ejaculated sperm Secrete prostaglandins that stimulate motility to help transport the sperm within the male and the female Provide the bulk of the semen Provide precursors for the clotting of semen
Prostate Gland	Single; completely surrounds the urethra at the neck of the bladder	Secretes an alkaline fluid that neutralizes the acidic vaginal secretions Triggers clotting of the semen to keep the sperm in the vagina during penis withdrawal
Bulbourethral Gland	Pair; both empty into the urethra, one on each side, just before the urethra enters the penis	Secrete mucus for lubrication

Prostaglandins

Although **prostaglandins** were first identified in the semen and were believed to be of prostate gland origin (hence their name, even though they are actually secreted into the semen by the seminal vesicles), their production and actions are by no means limited to the reproductive system. These 20-carbon fatty acid derivatives are among the most ubiquitous chemical messengers in the body. They are produced in virtually all tissues from arachidonic acid, a fatty acid constituent of the phospholipids within the plasma membrane. On appropriate stimulation, arachidonic acid is split from the plasma membrane by a membrane-bound enzyme and then is converted into the appropriate prostaglandin, which acts as a paracrine locally within or near its site of production. After prostaglandins act, they are rapidly inactivated by local enzymes before they gain access to the blood; or if they do reach the circulatory system, they are swiftly degraded on their first pass through the lungs so that they are not dispersed through the systemic arterial system.

Prostaglandins are designated as belonging to one of three groups—PGA, PGE, or PGF—according to structural variations in the five-carbon ring that they contain at one end (► Figure 17-11). Within each group, prostaglandins are further identified by the number of double bonds present in the two side chains that project from the ring structure (e.g., PGE₁ has one double bond and PGE₂ has two double bonds).

Prostaglandins and other closely related arachidonic acid derivatives—namely, *prostacyclins*, *thromboxanes*, and *leukotrienes*—are collectively known as **eicosanoids**, and they are among the most biologically active compounds known. Prostaglandins exert a bewildering variety of effects. Not only are slight variations in prostaglandin structure accompanied by profound differences in biological action, but the same prostaglandin molecule may even exert opposite effects in different tissues. Besides enhancing sperm transport in semen, these abundant chemical messengers are known or suspected to exert other actions in the female reproductive system and in the respiratory, urinary, digestive, nervous, and endocrine systems, in addition to affecting platelet aggregation, fat metabolism, and inflammation (■ Table 17-3).

Clinical Note As scientists better understand the various actions of prostaglandins, new ways of manipulating them therapeutically are becoming available. A classic example is the use of Aspirin, which blocks the conversion of arachidonic acid into prostaglandins, for fever reduction and pain relief. Prostaglandin action is also therapeutically inhibited in the treatment of premenstrual symptoms and menstrual cramping. Furthermore, specific prostaglandins have been medically

administered in such diverse situations as inducing labour, treating asthma, and treating gastric ulcers.

Check Your Understanding 17.2

1. List the functions of testosterone.
2. Define *seminiferous tubules*, *Leydig cells*, *Sertoli cells*, *spermatogenesis*, *spermiogenesis*, *spermatogonia*, *primary spermatocytes*, *secondary spermatocytes*, *spermatids*, and *spermatozoa*.

17.3 Sexual Intercourse between Males and Females

Ultimately, union of male and female gametes to accomplish reproduction in humans requires delivery of sperm-laden semen into the female vagina through the **sex act**, also known as **sexual intercourse**, **coitus**, or **copulation**.

The male sex act

- 1. The *male sex act* involves two components: (1) **erection**, or hardening of the normally flaccid penis to permit its entry into the vagina; and (2) **ejaculation**, or forceful expulsion of semen into the urethra and out of the penis (■ Table 17-4). In addition to these strictly reproduction-related components, the **sexual response cycle** encompasses broader physiologic responses that can be divided into four phases:
- 2. The *excitement phase* includes erection and heightened sexual awareness.
- 3. The *plateau phase* is characterized by intensification of these responses, plus more generalized body responses, such as steadily increasing heart rate, blood pressure, respiratory rate, and muscle tension.
- 4. The *orgasmic phase* includes ejaculation as well as other responses that culminate the mounting sexual excitement and are collectively experienced as an intense physical pleasure.
- 5. The *resolution phase* returns the genitalia and body systems to their prearousal state.

The human sexual response is a multicomponent experience that, in addition to these physiologic phenomena, encompasses emotional, psychological, and sociological factors. We will examine only the physiological aspects of sex.

Erection

Erection is accomplished by engorgement of the penis with blood. The penis consists almost entirely of **erectile tissue** made up of three columns of spongelike vascular spaces extending the length of the organ (see ▶ Figure 17-1). In the absence of sexual excitation, the erectile tissues contain little blood, because the arterioles that supply these vascular chambers are constricted. As a result, the penis remains small and flaccid. During sexual arousal, these arterioles reflexly dilate and the erectile tissue fills with blood, causing the penis to enlarge both in length and width and to become more rigid. The reflexive dilation of the arterioles is initiated by

the nervous system. The process typically takes about 10 seconds. During this erectile process, sympathetic input to the arterioles is inhibited, and nonadrenergic neurons release nitric oxide, thereby relaxing the arterioles. The veins that drain the erectile tissue are mechanically compressed by this engorgement and expansion of the vascular spaces; this reduces venous outflow and thereby contributes even further to the buildup of blood, or *vasocongestion*. These local vascular responses transform the penis into a hardened, elongated organ capable of penetrating the vagina.

ERECTION REFLEX

The erection reflex is a spinal reflex triggered by stimulation of highly sensitive mechanoreceptors located in the *glans penis*, which caps the tip of the penis. A recently identified **erection-generating centre** lies in the lower spinal cord. Tactile stimulation of the glans reflexly triggers, by means of this centre, increased parasympathetic vasodilator activity and decreased sympathetic vasoconstrictor activity to the penile arterioles. The result is rapid, pronounced vasodilation of these arterioles and an ensuing erection (▶ Figure 17-12). As long as this spinal reflex arc remains intact, erection is possible even in men paralyzed by a higher spinal cord injury.

This parasympathetically induced vasodilation is the major instance of direct parasympathetic control over blood vessel diameter in the body. Parasympathetic stimulation brings about relaxation of penile arteriolar smooth muscle by nitric oxide, which causes arteriolar vasodilation in response to local tissue changes elsewhere in the body (p. 398). Arterioles are typically supplied only by sympathetic nerves; increased sympathetic activity produces vasoconstriction, and decreased sympathetic activity results in vasodilation (p. 401). Concurrent parasympathetic stimulation and sympathetic inhibition of penile arterioles accomplish vasodilation more rapidly and in greater magnitude than is possible in other arterioles supplied only by sympathetic nerves. Through this efficient means of rapidly increasing blood flow into the penis, the penis can become completely erect in as little as 5–10 seconds. At the same time, parasympathetic impulses promote secretion of lubricating mucus from the bulbo-urethral glands and the urethral glands in preparation for coitus.

■ TABLE 17-4 Components of the Male Sex Act

Components of Male Sex Act	Definition	How Accomplished
Erection	Hardening of the normally flaccid penis to permit its entry into the vagina	Engorgement of the penis erectile tissue with blood as a result of marked parasympathetically induced vasodilation of the penile arterioles and mechanical compression of the veins
Ejaculation		
<i>Emission phase</i>	Emptying of sperm and accessory sex gland secretions (semen) into the urethra	Sympathetically induced contraction of the smooth muscle in the walls of the ducts and accessory sex glands
<i>Expulsion phase</i>	Forceful expulsion of semen from the penis	Motor neuron–induced contraction of the skeletal muscles at the base of the penis

► FIGURE 17-12 Erection reflex

A flurry of recent research has led to the discovery of numerous regions throughout the brain that can influence the male sexual response. The erection-influencing brain sites appear extensively interconnected and function as a unified network to either facilitate or inhibit the basic spinal erection reflex, depending on the momentary circumstances. As an example of facilitation, psychic stimuli, such as viewing something sexually exciting, can induce an erection in the complete absence of tactile stimulation of the penis. In contrast, failure to achieve an erection despite appropriate stimulation may result from inhibition of the erection reflex by higher brain centres. Let's examine erectile dysfunction in detail.

ERECTILE DYSFUNCTION

Clinical Note A pattern of failing to achieve or maintain an erection suitable for sexual intercourse—**erectile dysfunction (impotence)**—may be attributable to psychological or physical factors. An occasional episode of a failed erection does not constitute impotence, but a man who becomes overly anxious about his ability to perform the sex act may well be on his way to chronic failure. Anxiety can lead to erectile dysfunction, which fuels the man's anxiety level and thus perpetuates the problem. Impotence may also arise from physical limitations, including nerve damage, certain medications that interfere with autonomic function, and problems with blood flow through the penis.

Erectile dysfunction is widespread. More than 50 percent of men between ages 40 and 70 experience some impotence, climbing to nearly 70 percent by age 70. No wonder, then, that more prescriptions were written for the much-publicized drug *sildenafil* (Viagra) during its first year on the market after its approval in 1998 for treating erectile dysfunction than for any other new drug in history. Sildenafil does not produce an erection, but it amplifies and prolongs an erectile response triggered by usual means of stimulation. Here's how the drug works: nitric oxide released in response to parasympathetic stimulation activates a membrane-bound enzyme, *guanylate cyclase*, within nearby arteriolar smooth muscle cells. This enzyme activates *cyclic guanosine monophosphate (cGMP)*, an intracellular second messenger similar to cAMP (p. 217). Cyclic GMP, in turn, leads to relaxation of the penile arteriolar smooth muscle, bringing about pronounced local vasodilation. Under normal circumstances, once cGMP is activated and brings about an erection, this second messenger is broken down by the intracellular enzyme *phosphodiesterase 5 (PDE5)*. Sildenafil inhibits PDE5. As a result, cGMP remains active longer, so that penile arteriolar vasodilation continues and the erection is sustained long enough for a formerly impotent man to accomplish the sex

act. Just as pushing a pedal on a piano does not cause a note to be played but does prolong a played note, sildenafil cannot cause the release of nitric oxide and subsequent activation of erection-producing cGMP, but it can prolong the triggered response. The drug has no benefit for those who do not have erectile dysfunction, but its success rate has been high among sufferers of the condition.

Ejaculation

The second component of the male sex act is *ejaculation*. Like erection, ejaculation is a spinal reflex. The same types of tactile and psychic stimuli that induce erection cause ejaculation when the level of excitation intensifies to a critical peak. The overall ejaculatory response occurs in two phases: *emission* and *expulsion* (see ■ Table 17-4).

EMISSION

First, sympathetic impulses cause sequential contraction of smooth muscles in the prostate, reproductive ducts, and seminal vesicles. This contractile activity delivers prostatic fluid, then sperm, and finally seminal vesicle fluid (collectively, semen) into the urethra. This phase of the ejaculatory reflex is called **emission**. During this time, the sphincter at the neck of the bladder is tightly closed to prevent semen from entering the bladder and urine from being expelled along with the ejaculate through the urethra.

EXPULSION

Second, filling of the urethra with semen triggers nerve impulses that activate a series of skeletal muscles at the base of the penis. Rhythmic contractions of these muscles occur at intervals of 0.8 seconds and increase the pressure within the penis, forcibly expelling the semen through the urethra to the exterior. This is the **expulsion** phase of ejaculation.

ORGASM

The rhythmic contractions that occur during semen expulsion are accompanied by involuntary rhythmic throbbing of pelvic muscles and peak intensity of the overall body responses that were climbing during the earlier phases. Heavy breathing, a heart rate of up to 180 beats per minute, marked generalized skeletal muscle contraction, and heightened emotions are characteristic. These pelvic and overall systemic responses that culminate the sex act are associated with an intense pleasure characterized by a feeling of release and complete gratification, an experience known as **orgasm**.

RESOLUTION

During the resolution phase following orgasm, sympathetic vasoconstrictor impulses slow the inflow of blood into the penis, causing the erection to subside. A deep relaxation ensues, often accompanied by a feeling of fatigue. Muscle tone returns to normal, while the cardiovascular and respiratory systems return to their prearousal level of activity. Once ejaculation has occurred, a temporary refractory period of variable duration ensues before sexual stimulation can trigger another erection. Males therefore cannot experience multiple orgasms within a matter of minutes, as females sometimes do.

VOLUME AND SPERM CONTENT OF THE EJACULATE

The volume and sperm content of the ejaculate depend on the length of time between ejaculations. The average volume of semen is 2.75 mL, ranging from 2 mL to 6 mL, the higher volumes following periods of abstinence. An average human ejaculate contains about 180 million sperm (66 million/mL), but some ejaculates contain as many as 400 million sperm.

Both quantity and quality of sperm are important determinants of fertility. A man is considered clinically infertile if his sperm concentration falls below 20 million/mL of semen. Even though only one spermatozoon actually fertilizes the ovum, large numbers of accompanying sperm are needed to provide sufficient acrosomal enzymes to break down the barriers surrounding the ovum until the victorious sperm penetrates into the ovum's cytoplasm. The quality of sperm also must be taken into account when assessing the fertility potential of a semen sample. The presence of substantial numbers of sperm with abnormal motility or structure, such as sperm with distorted tails, reduces the chances of fertilization.

The female sexual cycle

Both sexes experience the same four phases of the sexual cycle—excitement, plateau, orgasm, and resolution. Furthermore, the physiologic mechanisms responsible for orgasm are fundamentally the same in males and females.

The excitement phase in females can be initiated by either physical or psychological stimuli. Tactile stimulation of the clitoris and surrounding perineal area is an especially powerful sexual stimulus. These stimuli trigger spinal reflexes that bring about parasympathetically induced vasodilation of arterioles throughout the vagina and external genitalia, especially the clitoris. The resultant inflow of blood becomes evident as the swelling of the labia and the erection of the clitoris. The latter—like its male homologue, the penis—is composed largely of erectile tissue. Vasocongestion of the vaginal capillaries forces fluid out of the vessels into the vaginal lumen. This fluid, which is the first positive indication of sexual arousal, serves as the primary lubricant for intercourse. Additional lubrication is provided by the **Bartholin's gland**, the female equivalent of the bulbourethral gland, located at the outer opening of the vagina. Also during the excitement phase in the female, the nipples become erect and the breasts enlarge as a result of vasocongestion. In addition, the majority of women show a *sex flush* during this time, which is caused by increased blood flow through the skin.

During the plateau phase, the changes initiated during the excitement phase intensify, while systemic responses similar to those in the male (such as increased heart rate, blood pressure, respiratory rate, and muscle tension) occur. Further vasocongestion of the lower third of the vagina during this time reduces its inner capacity so that it tightens around the thrusting penis, heightening tactile sensation for both the female and the male. Simultaneously, the uterus raises upward, lifting the cervix and enlarging the upper two-thirds of the vagina. This ballooning, or **tenting effect**, creates a space for ejaculate deposition.

If erotic stimulation continues, the sexual response culminates in orgasm as sympathetic impulses trigger rhythmic contractions of the pelvic musculature at 0.8 second intervals, the same rate as in males. The contractions occur most intensely in the engorged lower third of the vaginal canal. Systemic responses identical to those of the male orgasm also occur. In fact, the orgasmic experience in females parallels that of males with two exceptions. First, there is no female counterpart to ejaculation. Second, females do not become refractory following an orgasm, so they can respond immediately to continued erotic stimulation and achieve multiple orgasms. If stimulation continues, the sexual intensity only diminishes to the plateau level following orgasm and can quickly be brought to a peak again. Women have been known to achieve as many as 12 successive orgasms in this manner.

During resolution, pelvic vasocongestion and the systemic manifestations gradually subside. As with males, this is a time of great physical relaxation for females.

Next we examine the female part of the reproductive process.

Check Your Understanding 17.3

1. List and describe the four phases of the sexual response cycle.
2. Define the components of the male sex act, and explain how each is accomplished.

17.4 | Female Reproductive Physiology

Female reproductive physiology is more complex than male reproductive physiology.

Complex cycling

Unlike the continuous sperm production and essentially constant testosterone secretion characteristic of the male, release of ova is intermittent, and secretion of female sex hormones displays wide cyclic swings. The tissues influenced by these sex hormones also undergo cyclic changes, the most obvious of which is the monthly menstrual cycle. During each cycle, the female reproductive tract is prepared for the fertilization and implantation of an ovum that's released from the ovary at ovulation. If fertilization does not occur, the cycle repeats. If fertilization does occur, the cycles are interrupted while the female system adapts to nurture and protect the newly conceived human being until it has developed into an individual capable of living outside the maternal environment. Furthermore, the female continues her reproductive functions after birth by producing milk (lactation) for the baby's nourishment. Thus, the female reproductive system is characterized by complex cycles that are interrupted by even more complex changes when pregnancy occurs.

The ovaries are the primary female reproductive organs, performing the dual function of producing ova (oogenesis) and secreting estrogen and progesterone. These hormones act together to promote fertilization of the ovum and to prepare the female reproductive system for pregnancy. Estrogen in the female governs many functions similar to those carried out by testosterone in the male, such as maturation and maintenance of the entire female reproductive system and establishment of female secondary sexual characteristics. In general, the actions of estrogen are important to preconception events. Estrogen is essential for ova maturation and release, development of physical characteristics that are sexually attractive to males, and transport of sperm from the vagina to the site of fertilization in the oviduct. Furthermore, estrogen contributes to breast development in anticipation of lactation. The other ovarian steroid, progesterone, is important in preparing a suitable environment for nourishing a developing embryo/fetus and for contributing to the breasts' ability to produce milk.

As in males, reproductive capability begins at puberty in females, but unlike males, who have reproductive potential throughout life, female reproductive potential ceases during middle age at menopause.

The steps of gametogenesis

Oogenesis contrasts sharply with spermatogenesis in several important aspects, even though the identical steps of chromosome replication and division take place during gamete production in both sexes. The undifferentiated primordial germ cells in the fetal ovaries, the **oogonia** (comparable to the spermatogonia), divide mitotically to give rise to 6 million to 7 million oogonia by the fifth month of gestation, when mitotic proliferation ceases.

FORMATION OF PRIMARY OOCYTES AND PRIMARY FOLLICLES

During the last part of fetal life, the oogonia begin the early steps of the first meiotic division, but do not complete it. Known now as **primary oocytes**, they contain the diploid number of 46 replicated chromosomes, which are gathered into homologous pairs, but do not separate. The primary oocytes remain in this state of **meiotic arrest** for years until they are prepared for ovulation.

Before birth, each primary oocyte is surrounded by a single layer of flat **granulosa cells**. Together, an oocyte and surrounding granulosa cells make up a **primordial follicle**. Oocytes that are not incorporated into follicles self-destruct by apoptosis. At birth, only about 2 million primary follicles remain, each containing a single primary oocyte capable of producing a single ovum. The traditional view is that no new oocytes or follicles appear after birth, with the follicles already present in the ovaries at birth serving as a reservoir from which all ova throughout the reproductive life of a female must arise. However, researchers recently discovered, in mice at least, that new oocytes and follicles are produced after birth from previously unknown ovarian stem cells capable of generating primordial germ cells (oogonia). Despite the potential for similar egg-generating stem cells in humans, the follicular pool gradually dwindles away as a result of processes that deplete the oocyte-containing follicles.

The pool of primordial follicles gives rise to an ongoing trickle of developing follicles. During this development phase, the granulosa cells become cuboidal, and the follicles are now referred to as **primary follicles**. Once it starts to develop, a follicle is destined for one of two fates: it will reach maturity and ovulate, or it will degenerate to form scar tissue, a process known as **atresia**. Until puberty, all the follicles that start to develop undergo atresia in the early stages without ever ovulating. Even for the first few years after puberty, many of the cycles are **anovulatory** (i.e., no ovum is released). Of the total pool of follicles, only about 400 will mature and release ova; 99.98 percent never ovulate, but instead undergo atresia at some stage in development. By menopause, which occurs on average in a woman's early 50s, few primary follicles remain, having either already ovulated or become atretic. From this point on, the woman's reproductive capacity ceases.

This limited gamete potential in females is in sharp contrast to the continual process of spermatogenesis in males, who have the potential to produce several hundred million sperm in a single day. Furthermore, considerable chromosome wastage occurs in oogenesis compared with spermatogenesis. Let's see how.

FORMATION OF SECONDARY OOCYTES AND SECONDARY FOLLICLES

The primary oocyte within a primary follicle is still a diploid cell that contains 46 doubled chromosomes. From puberty until menopause, a portion of the resting pool of follicles starts developing into **secondary (antral) follicles** on a cyclic basis. The mechanisms determining which follicles in the pool will develop during a given cycle are unknown. Development of a secondary follicle is characterized by growth of the primary oocyte and by expansion and differentiation of the surrounding cell layers. The oocyte enlarges about a

thousandfold. This oocyte enlargement is caused by a buildup of cytoplasmic materials that are needed by the early embryo.

Just before ovulation, the primary oocyte, whose nucleus has been in meiotic arrest for years, completes its first meiotic division. This division yields two daughter cells, each receiving a haploid set of 23 doubled chromosomes, analogous to the formation of secondary spermatocytes (► Figure 17-13). However, almost all the cytoplasm remains with one of the daughter cells, now called the **secondary oocyte**, which is destined to become the ovum. The chromosomes of the other daughter cell together with a small share of cytoplasm form the **first polar body**. In this way, the ovum-to-be loses half of its chromosomes to form a haploid gamete but retains all of its nutrient-rich cytoplasm. The nutrient-poor polar body soon degenerates.

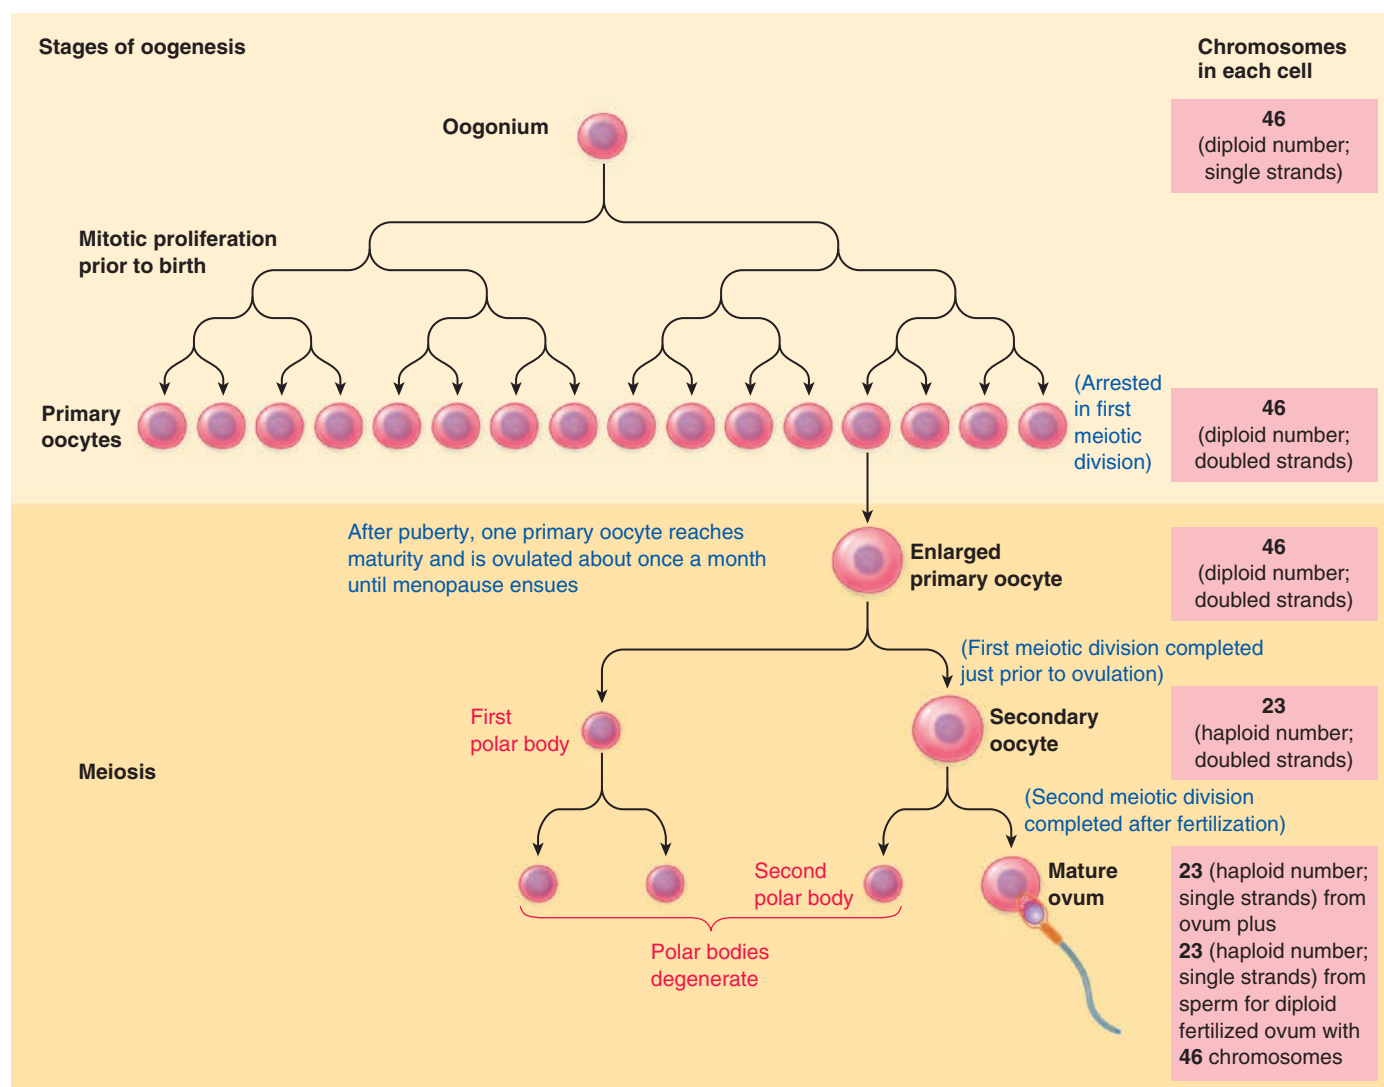

FORMATION OF A MATURE OVUM

Actually, the secondary oocyte, and not the mature ovum, is ovulated and fertilized, but common usage refers to the developing female gamete as an *ovum* even in its primary and secondary

oocyte stages. Sperm entry into the secondary oocyte is needed to trigger the second meiotic division. Unfertilized secondary oocytes never complete this final division. During this division, a half set of chromosomes and a thin layer of cytoplasm is extruded as the **second polar body**. The other half set of 23 unpaired chromosomes remains behind in what is now the **mature ovum**. These 23 maternal chromosomes unite with the 23 paternal chromosomes of the penetrating sperm to complete fertilization. If the first polar body has not already degenerated, it too undergoes the second meiotic division at the same time the fertilized secondary oocyte is dividing its chromosomes.

COMPARISON OF STEPS IN OOGENESIS AND SPERMATOGENESIS

The steps involved in chromosome distribution during oogenesis parallel those of spermatogenesis, except that the cytoplasmic distribution and time span for completion sharply differ. Just as four haploid spermatids are produced by each primary spermatocyte, four haploid daughter cells are produced by each

► FIGURE 17-13 Oogenesis. Compare with ► Figure 17-8, spermatogenesis

primary oocyte (if the first polar body does not degenerate before it completes the second meiotic division). In spermatogenesis, each daughter cell develops into a highly specialized, motile spermatozoon unencumbered by unessential cytoplasm and organelles; its only destiny is to supply half the genes for a new individual. In oogenesis, however, of the four daughter cells only the one destined to become the ovum receives cytoplasm. This uneven distribution of cytoplasm is important, because the ovum, in addition to providing half the genes, provides all the cytoplasmic components needed to support early development of the fertilized ovum. The large, relatively undifferentiated ovum contains numerous nutrients, organelles, and structural and enzymatic proteins. The three other cytoplasm-scarce daughter cells, the polar bodies, rapidly degenerate—their chromosomes deliberately wasted.

Note also the considerable difference in time to complete spermatogenesis and oogenesis. It takes about two months for a spermatogonium to develop into fully remodelled spermatozoa. In contrast, development of an oogonium (present before birth) to a mature ovum requires anywhere from 11 years (beginning of ovulation at onset of puberty) to 50 years (end of ovulation at onset of menopause). The actual length of the active steps in meiosis is the same in both males and females, but in females the developing eggs remain in meiotic arrest for a variable number of years.

The older age of ova released by women in their late 30s and 40s is believed to account for the higher incidence of genetic abnormalities, such as Down syndrome, in children born to women in this age range.

The ovarian cycle

After the onset of puberty, the ovary constantly alternates between two phases: the **follicular phase**, which is dominated by the presence of *maturing follicles*; and the **luteal phase**, which is characterized by the presence of the *corpus luteum*. Normally, this cycle is interrupted only if pregnancy occurs and is finally terminated by menopause. The average ovarian cycle lasts 28 days, but this varies among women and among cycles in any particular woman. The follicle operates in the first half of the cycle to produce a mature egg ready for ovulation at midcycle. The corpus luteum takes over during the last half of the cycle to prepare the female reproductive tract for pregnancy if fertilization of the released egg occurs.

The follicular phase

At any given time throughout the cycle, a portion of the primary follicles start to develop. However, only those that do so during the follicular phase, when the hormonal environment is right to promote their maturation, continue beyond the early stages of development. The others, lacking hormonal support, undergo atresia. During follicular development, as the primary oocyte is synthesizing and storing materials for future use if fertilized, important changes take place in the cells surrounding the reactivated oocyte in preparation for the egg's release from the ovary (► Figure 17-14).

PROLIFERATION OF GRANULOSA CELLS AND FORMATION OF THE ZONA PELLUCIDA

First, the single layer of granulosa cells in a primary follicle proliferates to form several layers that surround the oocyte. These granulosa cells and the oocyte secrete several glycoproteins that form a thick extracellular matrix that covers the oocyte and separates it from the surrounding granulosa cells. This intervening membrane is known as the **zona pellucida**.

Scientists have recently discovered gap junctions that penetrate the zona pellucida and extend between the oocyte and the surrounding granulosa cells in a developing follicle. Ions and small molecules can travel through these connecting tunnels. Recall that gap junctions between excitable cells permit the spread of action potentials from one cell to the next as charge-carrying ions pass through these connecting tunnels (p. 35). The cells in a developing follicle are not excitable, so gap junctions here serve a role other than transfer of electrical activity. Glucose, amino acids, and other important molecules are delivered to the oocyte from the granulosa cells through these tunnels, enabling the egg to stockpile these critical nutrients. Also, signalling molecules pass through the gap junctions in both directions, helping coordinate the changes that take place in the oocyte and the surrounding cells as both mature and prepare for ovulation.

PROLIFERATION OF THECAL CELLS: ESTROGEN SECRETION

At the same time as the oocyte enlarges and the granulosa cells proliferate, specialized ovarian connective tissue cells in contact with the expanding granulosa cells both proliferate and differentiate to form an outer layer of **thecal cells**. The thecal and granulosa cells, collectively known as **follicular cells**, function as a unit to secrete estrogen. Of the three physiologically important estrogens—estradiol, estrone, and estriol—**estradiol** is the principal ovarian estrogen.

FORMATION OF THE ANTRUM

The hormonal environment of the follicular phase promotes enlargement and development of the follicular cells' secretory capacity, converting the primary follicle into a **secondary (antral) follicle** capable of estrogen secretion. During this stage of follicular development, a fluid-filled cavity, or **antrum**, forms in the middle of the granulosa cells (► Figures 17-14 **6** and 17-15). The follicular fluid originates partially from plasma that passes through capillary pores and partially from follicular cell secretions. As the follicular cells start producing estrogen, some of this hormone is secreted into the blood for distribution throughout the body. However, a portion of the estrogen collects in the hormone-rich antral fluid.

The oocyte has reached full size by the time the antrum begins to form. The shift to an antral follicle initiates a period of rapid follicular growth. During this time, the follicle increases in size from a diameter of less than 1 mm to 12–16 mm shortly before ovulation. Part of the follicular growth is due to continued proliferation of the granulosa and thecal cells, but most is due to a dramatic expansion of the antrum. As the follicle grows, estrogen is produced in increasing quantities.

1 In a primary follicle, a primary oocyte is surrounded by a single layer of granulosa cells.

2 Under the influence of local paracrine factors, granulosa cells proliferate and form the zona pellucida around the oocyte.

3 Surrounding ovarian connective tissue differentiates into theca cells, converting a primary follicle into a preantral follicle.

4 Follicles reaching the preantral stage are recruited for further development under the influence of FSH at the beginning of the follicular phase of the ovarian cycle. A recruited follicle develops into an antral, or secondary,

follicle as an estrogen-rich antrum starts to form.

5 The antrum continues to expand as the secondary follicle rapidly grows.

6 After about two weeks of rapid growth under the influence of FSH, the follicle has developed into a mature follicle, which has a greatly expanded antrum; the oocyte, which by now has developed into a secondary oocyte, is displaced to one side.

7 At midcycle, in response to a burst in LH secretion, the mature follicle, bulging on the ovarian surface, ruptures and releases the

oocyte, resulting in ovulation and ending the follicular phase.

8 Ushering in the luteal phase, the ruptured follicle develops into a corpus luteum under the influence of LH.

9 The corpus luteum continues to grow and secrete progesterone and estrogen that prepare the uterus for implantation of a fertilized ovum.

10 After 14 days, if a fertilized ovum does not implant in the uterus, the corpus luteum degenerates, the luteal phase ends, and a new follicular phase begins under the influence of a changing hormonal milieu.

© 2016 Cengage

► **FIGURE 17-15** Scanning electron micrograph of a developing secondary follicle

FORMATION OF A MATURE FOLLICLE

One of the follicles usually grows more rapidly than the others, developing into a **mature (preovulatory, tertiary, or Graafian) follicle** within about 14 days after the onset of follicular development. The antrum occupies most of the space in a mature follicle. The oocyte, surrounded by the zona pellucida and a single layer of granulosa cells, is displaced asymmetrically at one side of the growing follicle, in a little mound that protrudes into the antrum.

OVULATION

The greatly expanded mature ovarian follicle bulges on the ovarian surface, creating a thin area that ruptures to release the oocyte at **ovulation**. The process of ovulation is controlled by the release of hormones (LH and FSH) from the anterior pituitary gland. Rupture of the follicle is facilitated by the release from the follicular cells of enzymes that digest the connective tissue in the follicular wall. The bulging wall is thus weakened so that it balloons out even farther, to the point that it can no longer contain the rapidly expanding follicular contents.

Just before ovulation, the oocyte completes its first meiotic division. The ovum (secondary oocyte), still surrounded by its tightly adhering zona pellucida and granulosa cells (now called the **corona radiata**, meaning “radiating crown”), is swept out of the ruptured follicle into the abdominal cavity by the leaking antral fluid (► Figure 17-14 **7**). The released ovum is quickly drawn into the oviduct, where fertilization may or may not take place.

The other developing follicles that failed to reach maturation and ovulate undergo degeneration, never to be reactivated. Occasionally, two (or perhaps more) follicles reach maturation and ovulate at about the same time. If both are fertilized, **fraternal twins** result. Because fraternal twins arise from separate ova fertilized by separate sperm, they share no more in common than any other two siblings except for the same birth date. **Identical twins**, in contrast, develop from a single fertilized ovum

that completely divides into two separate, genetically identical embryos at a very early stage in development.

Rupture of the follicle at ovulation signals the end of the follicular phase and ushers in the luteal phase.

The luteal phase

The ruptured follicle left behind in the ovary after release of the ovum changes rapidly. The granulosa and thecal cells remaining in the remnant follicle first collapse into the emptied antral space that has been partially filled by clotted blood.

FORMATION OF THE CORPUS LUTEUM; ESTROGEN AND PROGESTERONE SECRETION

These old follicular cells soon undergo a dramatic structural transformation to form the **corpus luteum**, in a process called **luteinization** (► Figure 17-14 **8** and **9**). The follicular-turned-luteal cells enlarge and are converted into very active steroid hormone-producing tissue. Abundant storage of cholesterol, the steroid precursor molecule, in lipid droplets within the corpus luteum gives this tissue a yellowish appearance, hence its name (*corpus* means “body”; *luteum* means “yellow”).

The corpus luteum becomes highly vascularized as blood vessels from the thecal region invade the luteinizing granulosa. These changes are appropriate for the corpus luteum’s function: to secrete into the blood abundant quantities of progesterone along with smaller amounts of estrogen. Estrogen secretion in the follicular phase followed by progesterone secretion in the luteal phase is essential for preparing the uterus for implantation of a fertilized ovum. The corpus luteum becomes fully functional within four days after ovulation, but it continues to increase in size for another four or five days.

DEGENERATION OF THE CORPUS LUTEUM

If the released ovum is not fertilized and does not implant, the corpus luteum degenerates within about 14 days after its formation (► Figure 17-14 **10**). The luteal cells degenerate and are phagocytized, the vascular supply is withdrawn, and connective tissue rapidly fills in to form a fibrous tissue mass known as the **corpus albicans** (white body). The luteal phase is now over, and one ovarian cycle is complete. A new wave of follicular development—which begins when the degeneration of the old corpus luteum has completed—signals the onset of a new follicular phase.

CORPUS LUTEUM OF PREGNANCY

If fertilization and implantation do occur, the corpus luteum continues to grow and produce increasing quantities of progesterone and estrogen, instead of degenerating. Now called the *corpus luteum of pregnancy*, this ovarian structure persists until pregnancy ends. It provides the hormones essential for maintaining pregnancy until the developing placenta can take over this crucial function.

The ovarian cycle

The ovary has two related endocrine units: the estrogen-secreting follicle during the first half of the cycle, and the corpus luteum, which secretes both progesterone and estrogen, during the last

half of the cycle. These units are sequentially triggered by complex cyclic hormonal relationships among the hypothalamus, the anterior pituitary, and these two ovarian endocrine units.

As in the male, gonadal function in the female is directly controlled by the anterior pituitary gonadotropic hormones, namely, follicle-stimulating hormone (FSH) and luteinizing hormone (LH). These hormones, in turn, are regulated by hypothalamic gonadotropin-releasing hormone (GnRH) and feedback actions of gonadal hormones. Unlike in the male, however, control of the female gonads is complicated by the cyclic nature of ovarian function. For example, the effects of FSH and LH on the ovaries depend on the stage of the ovarian cycle. Furthermore, estrogen exerts negative-feedback effects during part of the cycle and positive-feedback effects during another part of the cycle, depending on the concentration of estrogen. Also in contrast to the male, FSH is not strictly responsible for gametogenesis, nor is LH solely responsible for gonadal hormone secretion. We will consider the control of follicular function, ovulation, and the corpus luteum separately, using Figure 17-16 as a means of integrating the various concurrent and sequential activities that take place throughout the cycle. To facilitate correlation between this rather intimidating figure and the accompanying text description of this complex cycle, the grey numbers in the figure and its legend correspond to the grey numbers in the text description.

CONTROL OF FOLLICULAR FUNCTION

We begin with the follicular phase of the ovarian cycle [1]. The factors that initiate follicular development are poorly understood. The early stages of preantral follicular growth and oocyte maturation do not require gonadotropic stimulation. Hormonal support is required, however, for antrum formation, further follicular development [2], and estrogen secretion [3]. Estrogen, FSH [4], and LH [5] are all needed. Antrum formation is induced by FSH. Both FSH and estrogen stimulate proliferation of the granulosa cells. Both LH and FSH are required for synthesis and secretion of estrogen by the follicle, but these hormones act on different cells and at different steps in the estrogen production pathway (Figure 17-17). Both granulosa and thecal cells participate in estrogen production. The conversion of cholesterol into estrogen requires a number of sequential steps, the last of which is conversion of androgens into estrogens. Thecal cells readily produce androgens but have limited capacity to convert them into estrogens. Granulosa cells, in contrast, contain the enzyme *aromatase*, so they can readily convert androgens into estrogens, but they cannot produce androgens in the first place. LH acts on the thecal cells to stimulate androgen production, whereas FSH acts on the granulosa cells to promote conversion of thecal androgens (which diffuse into the granulosa cells from the thecal cells) into estrogens. Because low basal levels of FSH [6] are sufficient to promote this final conversion to estrogen, the rate of estrogen secretion by the follicle primarily depends on the circulating level of LH, which continues to rise during the follicular phase [7]. Furthermore, as the follicle continues to grow, more estrogen is produced simply due to the presence of more estrogen-producing follicular cells.

Part of the estrogen produced by the growing follicle is secreted into the blood and is responsible for the steadily increasing plasma estrogen levels during the follicular phase 8.

The rest of the estrogen remains within the follicle, contributing to the antral fluid and stimulating further granulosa cell proliferation (Figure 17-17).

The secreted estrogen, in addition to acting on sex-specific tissues such as the uterus, inhibits the hypothalamus and anterior pituitary in typical negative-feedback fashion (Figure 17-18). The rising, moderate levels of estrogen that characterize the follicular phase act directly on the hypothalamus to inhibit GnRH secretion, thereby suppressing GnRH-prompted release of FSH and LH from the anterior pituitary. However, estrogen's primary effect is directly on the pituitary itself. Estrogen reduces the sensitivity to GnRH of the cells that produce gonadotropic hormones, especially the FSH-secreting cells.

This differential sensitivity of FSH- and LH-secreting cells induced by estrogen is at least in part responsible for the fact that the plasma FSH level, unlike the plasma LH concentration, declines during the follicular phase as the estrogen level rises [6]. Another contributing factor to the fall in FSH during the follicular phase is secretion of *inhibin* by the follicular cells. Inhibin preferentially inhibits FSH secretion by acting at the anterior pituitary, just as it does in the male. The decline in FSH secretion brings about atresia of all except the single most mature of the developing follicles.

In contrast to FSH, LH secretion continues to rise slowly during the follicular phase [7], despite inhibition of GnRH (and thus, indirectly, LH) secretion. This seeming paradox is due to the fact that estrogen alone cannot completely suppress **tonic LH secretion** (*tonic* here meaning “low-level, ongoing”); to completely inhibit tonic LH secretion, both estrogen and progesterone are required. Because progesterone does not appear until the luteal phase of the cycle, the basal level of circulating LH slowly increases during the follicular phase under incomplete inhibition by estrogen alone.

CONTROL OF OVULATION

Ovulation and subsequent luteinization of the ruptured follicle are triggered by an abrupt, massive increase in LH secretion [9]. This **LH surge** brings about four major changes in the follicle:

1. It halts estrogen synthesis by the follicular cells [11].
2. It reinitiates meiosis in the oocyte of the developing follicle, apparently by blocking release of an *oocyte maturation inhibiting factor* produced by the granulosa cells. This substance is believed to be responsible for arresting meiosis in the primary oocytes once they are wrapped within granulosa cells in the fetal ovary.
3. It triggers production of locally acting prostaglandins, which induce ovulation by promoting vascular changes that cause rapid swelling of the follicle while inducing enzymatic digestion of the follicular wall. Together, these actions lead to rupture of the weakened wall that covers the bulging follicle [10].
4. It causes differentiation of follicular cells into luteal cells. Because the LH surge triggers both ovulation and luteinization, formation of the corpus luteum automatically follows ovulation [12]. Thus, the midcycle burst in LH secretion is a dramatic point in the cycle; it terminates the follicular phase and initiates the luteal phase [15].

FIGURE 17-16 Correlation between hormonal levels and cyclic ovarian and uterine changes. During the follicular phase (the first half of the ovarian cycle **1**), the ovarian follicle **2** secretes estrogen **3** under the influence of FSH **4**, LH **5**, and estrogen **3** itself. The rising, moderate levels of estrogen inhibit FSH secretion, which declines during the last part of the follicular phase **6**, and incompletely suppress tonic LH secretion, which continues to rise throughout the follicular phase **7**. When the follicular output of estrogen reaches its peak **8**, the high levels of estrogen trigger a surge in LH secretion at midcycle **9**. This LH surge brings about ovulation of the mature follicle **10**. Estrogen secretion plummets **11** when the follicle meets its demise at ovulation.

The old follicular cells are transformed into the corpus luteum **12**, which secretes progesterone **13** as well as estrogen **14** during the luteal phase of the last half of the ovarian cycle **15**. Progesterone strongly inhibits both FSH **16** and LH **17**, which continue to decrease throughout the luteal phase. The corpus luteum degenerates **18** in about two weeks if the released ovum has not been fertilized and implanted in the uterus. Progesterone **19** and estrogen **20** levels sharply decrease when the corpus luteum degenerates, removing the inhibitory influences on FSH and LH. As these anterior pituitary hormone levels start to rise again **21, 22** on the withdrawal of inhibition, they begin to stimulate the development of a new batch of follicles as a new follicular phase is ushered in **1, 2**.

Concurrent uterine phases reflect the influences of the ovarian hormones on the uterus. Early in the follicular phase, the highly vascularized, nutrient-rich endometrial lining is sloughed off (the uterine menstrual phase) **23**. This sloughing results from the withdrawal of estrogen and progesterone **19, 20** when the old corpus luteum degenerated at the end of the preceding luteal phase **18**. Late in the follicular phase, the rising levels of estrogen **3** cause the endometrium to thicken (the uterine proliferative phase) **24**. After ovulation **10**, progesterone from the corpus luteum **13** brings about vascular and secretory changes in the estrogen-primed endometrium to produce a suitable environment for implantation (the uterine secretory, or progesterational, phase) **25**. When the corpus luteum degenerates **18**, a new ovarian follicular phase **1, 2** and uterine menstrual phase **23** begin.

The two different modes of LH secretion—the tonic secretion of LH **7** responsible for promoting ovarian hormone secretion and the LH surge **9** that causes ovulation—not only occur at different times and produce different effects on the ovaries but also are controlled by different mechanisms. Tonic LH secretion is partially suppressed **7** by the inhibitory action of the rising, moderate levels of estrogen **3** during the follicular phase, and

is completely suppressed **17** by the increasing levels of progesterone during the luteal phase **13**. Because tonic LH secretion stimulates both estrogen and progesterone secretion, this is a typical negative-feedback control system.

In contrast, the LH surge is triggered by a *positive-feedback effect*. Whereas the rising, moderate levels of estrogen early in the follicular phase *inhibit* LH secretion, the high level of estrogen

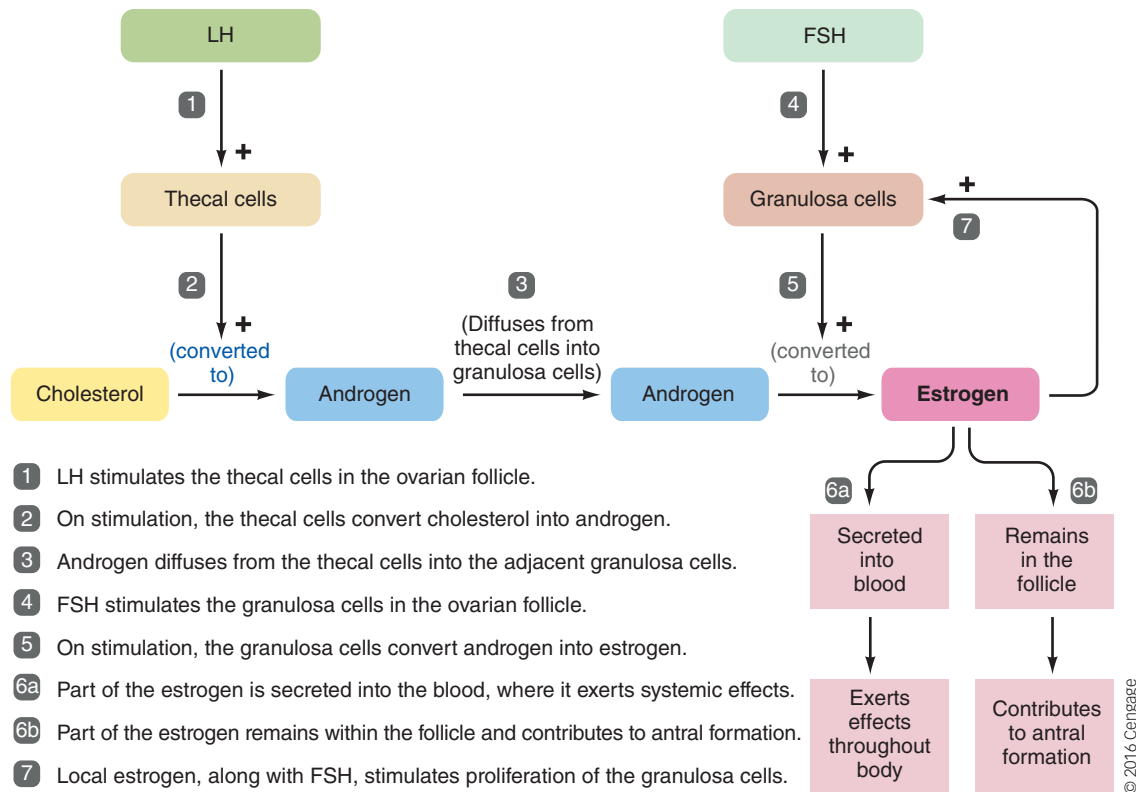

FIGURE 17-17 Production of estrogen by an ovarian follicle

that occurs during peak estrogen secretion late in the follicular phase [8] *stimulates* LH secretion and initiates the LH surge (Figure 17-19). Thus, LH enhances estrogen production by the follicle, and the resultant peak estrogen concentration stimulates LH secretion. The high plasma concentration of estrogen acts directly on the hypothalamus to increase GnRH, thereby increasing both LH and FSH secretion. It also acts directly on the anterior pituitary to specifically increase the sensitivity of LH-secreting cells to GnRH. The latter effect accounts in large part for the much greater surge in LH secretion compared to FSH secretion at midcycle [9]. Also, continued inhibin secretion by the follicular cells preferentially inhibits the FSH-secreting cells, keeping the FSH levels from rising as high as the LH levels. There is no known role for the modest midcycle surge in FSH that accompanies the pronounced and pivotal LH surge. Because only a mature, preovulatory follicle, not follicles in earlier stages of development, can secrete high-enough levels of estrogen to trigger the LH surge, ovulation is not induced until a follicle has reached the proper size and degree of maturation. In a way, then, the follicle lets the hypothalamus know when it is ready to be stimulated to ovulate. The LH surge lasts for about a day at midcycle, just before ovulation.

CONTROL OF THE CORPUS LUTEUM

LH maintains the corpus luteum; that is, after triggering development of the corpus luteum, LH stimulates ongoing steroid hormone secretion by this ovarian structure. Under the influence of LH, the corpus luteum secretes both progesterone [13]

and estrogen [14], with progesterone being its most abundant hormonal product. The plasma progesterone level increases for the first time during the luteal phase. No progesterone is secreted during the follicular phase. Therefore, the follicular phase is dominated by estrogen, and the luteal phase by progesterone.

A transitory drop in the level of circulating estrogen occurs at midcycle [11] as the estrogen-secreting follicle meets its demise at ovulation. The estrogen level climbs again during the luteal phase because of the corpus luteum's activity, although it does not reach the same peak as during the follicular phase. What keeps the modestly high estrogen level during the luteal phase from triggering another LH surge? Progesterone. Even though a high level of estrogen stimulates LH secretion, progesterone, which dominates the luteal phase, powerfully inhibits LH secretion as well as FSH secretion [17], [16] (Figure 17-20). Inhibition of FSH and LH by progesterone prevents new follicular maturation and ovulation during the luteal phase. Under progesterone's influence, the reproductive system is gearing up to support the just-released ovum, should it be fertilized, instead of preparing other ova for release. No inhibin is secreted by the luteal cells.

The corpus luteum functions for an average of two weeks, then degenerates if fertilization does not occur [18]. The mechanisms that govern degeneration of the corpus luteum are not fully understood. The declining level of circulating LH [17], driven down by inhibitory actions of progesterone, undoubtedly contributes to the degeneration of the corpus luteum. Prostaglandins and estrogen released by the luteal cells themselves may

► **FIGURE 17-18** Feedback control of FSH and tonic LH secretion during the follicular phase

play a role. Demise of the corpus luteum terminates the luteal phase and sets the stage for a new follicular phase. As the corpus luteum degenerates, plasma progesterone [19] and estrogen [20] levels fall rapidly, because these hormones are no longer being produced. Withdrawal of the inhibitory effects of these hormones on the hypothalamus allows FSH [21] and tonic LH [22] secretion to modestly increase once again. Under the influence of these gonadotropic hormones, another batch of primary follicles [2] is induced to mature as a new follicular phase begins [1].

Cyclic uterine changes

The fluctuations in circulating levels of estrogen and progesterone during the ovarian cycle induce profound changes in the uterus, giving rise to the **menstrual (uterine) cycle**. Because it

reflects hormonal changes during the ovarian cycle, the menstrual cycle averages 28 days, as does the ovarian cycle, although even healthy women vary considerably from this mean. The outward manifestation of the cyclic changes in the uterus is the menstrual bleeding once during each menstrual cycle (i.e., once a month). Less obvious changes take place throughout the cycle, however, as the uterus is prepared for implantation should a released ovum be fertilized, then is stripped clean of its prepared lining (menstruation) if implantation does not occur, only to repair itself and start preparing for the ovum that will be released during the next cycle.

We now briefly examine the influences of estrogen and progesterone on the uterus, and then we consider the effects of cyclic fluctuations of these hormones on uterine structure and function.

INFLUENCES OF ESTROGEN AND PROGESTERONE ON THE UTERUS

The uterus consists of two main layers: the **myometrium**, the outer smooth muscle layer; and the **endometrium**, the inner lining that contains numerous blood vessels and glands. Estrogen stimulates growth of both the myometrium and the endometrium. It also induces the synthesis of progesterone receptors in the endometrium. Therefore, the endometrium needs to be primed by estrogen before progesterone can exert an effect on it. Progesterone acts on the estrogen-primed endometrium to convert it into a hospitable and nutritious lining suitable for implantation of a fertilized ovum. Under the influence of progesterone, the endometrial connective tissue becomes loose and oedematous as a result of an accumulation of electrolytes and water, which facilitates implantation of the fertilized ovum. Progesterone further prepares the endometrium to sustain an early-developing embryo by inducing the endometrial glands to secrete and store large quantities of glycogen and by causing tremendous growth of the endometrial blood vessels. Progesterone also reduces the contractility of the uterus to provide a quiet environment for implantation and embryonic growth.

The menstrual cycle consists of three phases: the *menstrual phase*, the *proliferative phase*, and the *secretory, or pregestational, phase*.

MENSTRUAL PHASE

The menstrual phase is the most overt phase, characterized by discharge of blood and endometrial debris from the vagina. By convention, the first day of menstruation is considered the start of a new cycle. It coincides with termination of the ovarian luteal phase and onset of the follicular phase [23], ► Figure 17-16. As the corpus luteum degenerates because fertilization and implantation of the ovum released during the preceding cycle did not take place [18], circulating levels of progesterone and estrogen drop precipitously [19], [20]. Because the net effect of progesterone and estrogen is

► FIGURE 17-19 Control of the LH surge at ovulation

to prepare the endometrium for implantation of a fertilized ovum, withdrawal of these steroids deprives the highly vascular, nutrient-rich uterine lining of its hormonal support.

The fall in ovarian hormone levels also stimulates release of a uterine prostaglandin that causes vasoconstriction of the endometrial vessels, disrupting the blood supply to the endometrium. The subsequent reduction in oxygen delivery causes death of the endometrium, including its blood vessels. The resulting bleeding through the disintegrating vessels flushes the dying endometrial tissue into the uterine lumen. Most of the uterine lining sloughs off during each menstrual period except for a deep, thin layer of epithelial cells and glands, from which the endometrium will regenerate. The same local uterine prostaglandin also stimulates mild rhythmic contractions of the uterine myometrium. These contractions help expel the blood and endometrial debris from the uterine cavity out through the vagina as **menstrual flow**. Excessive

uterine contractions caused by prostaglandin overproduction produce the menstrual cramps (**dysmenorrhoea**) some women experience. Menstrual dysfunction, or abnormal menstruation, is common in female athletes. There is a high prevalence of amenorrhoea (stopping of menstrual flow), oligomenorrhoea (sporadic or slight menstrual flow), and delayed menarche in athletes who restrict caloric intake and/or have very low body fat. Amenorrhoea and other dysfunctions are likely to occur in athletes who exercise too much.

The average blood loss during a single menstrual period is 50–150 mL. Blood seeps slowly through the degenerating endometrium clots within the uterine cavity and is then acted on by fibrinolysin, a fibrin dissolver that breaks down the fibrin that forms the meshwork of the clot. Therefore, blood in the menstrual flow usually does not clot, because it has already clotted and the clot has been dissolved before it passes out of the vagina. When blood flows rapidly through the leaking vessels, however, it may not be exposed to sufficient fibrinolysin, so when the menstrual flow is most profuse, blood clots may appear. In addition to the blood and endometrial debris, large numbers

of leukocytes are found in the menstrual flow. These white blood cells play an important defence role in helping the raw endometrium resist infection.

Menstruation typically lasts for about five to seven days after degeneration of the corpus luteum, coinciding in time with the early portion of the ovarian follicular phase [23], [1]. Withdrawal of progesterone and estrogen [19], [20] on degeneration of the corpus luteum leads simultaneously to sloughing of the endometrium (menstruation) [23] and development of new follicles in the ovary [1], [2] under the influence of rising gonadotropic hormone levels [21], [22]. The drop in gonadal hormone secretion removes inhibitory influences from the hypothalamus and anterior pituitary, so FSH and LH secretion increases, and a new follicular phase begins. After five to seven days under the influence of FSH and LH, the newly growing follicles are secreting enough estrogen [3] to induce repair and growth of the endometrium.

FIGURE 17-20 Feedback control during the luteal process

PROLIFERATIVE PHASE

Menstrual flow ceases, and the **proliferative phase** of the uterine cycle begins concurrent with the last portion of the ovarian follicular phase as the endometrium starts to repair itself and proliferate [24] under the influence of estrogen from the newly growing follicles. When the menstrual flow ceases, a thin endometrial layer less than 1 mm thick remains. Estrogen stimulates proliferation of epithelial cells, glands, and blood vessels in the endometrium, increasing this lining to a thickness of 3–5 mm. The estrogen-dominant proliferative phase lasts from the end of menstruation to ovulation. Peak estrogen levels [8] trigger the LH surge [9] responsible for ovulation [10].

SECRETORY, OR PROGESTATIONAL, PHASE

After ovulation, when a new corpus luteum is formed [12], the uterus enters the **secretory (progestational) phase**, which coincides in time with the ovarian luteal phase [25], [15]. The corpus

luteum secretes large amounts of progesterone [13] and estrogen [14]. Progesterone converts the thickened, estrogen-primed endometrium to a richly vascularized, glycogen-filled tissue. This period is called either the *secretory phase*, because the endometrial glands are actively secreting glycogen, or the *progestational (before pregnancy) phase*, referring to the development of a lush endometrial lining capable of supporting an early embryo. If fertilization and implantation do not occur, the corpus luteum degenerates and a new follicular phase and menstrual phase begin once again.

Hormonal fluctuations

Hormonally induced changes also take place in the cervix during the ovarian cycle. Under the influence of estrogen during the follicular phase, the mucus secreted by the cervix becomes abundant, clear, and thin. This change—which is most pronounced when estrogen is at its peak and ovulation is approaching—facilitates passage of sperm through the cervical canal. After ovulation, under the influence of progesterone from the corpus luteum, the mucus becomes thick and sticky, essentially plugging up the cervical opening. This plug is an important defence mechanism, preventing bacteria (which might threaten a possible pregnancy) from entering the uterus from the vagina. Sperm also cannot penetrate this thick mucus barrier.

Pubertal changes in females

Regular menstrual cycles are absent in both young and aging females, but for different reasons. The female reproductive system does not become active until puberty. Unlike the fetal testes, the fetal ovaries need not be functional, because in the absence of fetal testosterone secretion in a female, the reproductive system is automatically feminized, without requiring the presence of female sex hormones. The female reproductive system remains quiescent from birth until puberty, which occurs at about 12 years of age when hypothalamic GnRH activity increases for the first time. As in the male, the mechanisms that govern the onset of puberty are not clearly understood but are believed to involve the pineal gland and melatonin secretion.

GnRH begins stimulating release of anterior pituitary gonadotropic hormones, which in turn stimulate ovarian activity. The resulting secretion of estrogen by the activated ovaries induces growth and maturation of the female reproductive tract as well as development of the female secondary sexual characteristics. Estrogen's prominent action in the latter regard is to promote fat deposition in specific locations, such as the breasts, buttocks, and thighs, giving rise to the typical curvaceous female figure. Enlargement of the breasts at puberty is due primarily to fat deposition in the breast tissue, not to functional development of the mammary glands. The pubertal rise in estrogen also closes the epiphyseal plates, halting further growth in height; this is similar to the effect of testosterone-turned-estrogen in males. Three other pubertal

changes in females—growth of axillary and pubic hair, the pubertal growth spurt, and development of libido—are attributable to a spurt in adrenal androgen secretion at puberty, not to estrogen.

Menopause

Menopause is a physiological event in which the menstrual cycle stops (pauses) permanently. Menopause is also known as the “change of life” and typically occurs between the ages of 45 and 55. It has traditionally been attributed to the limited supply of ovarian follicles present at birth. According to this proposal, once this reservoir is depleted, ovarian cycles—and hence, menstrual cycles—cease. Thus, the termination of reproductive potential in a middle-aged woman is already determined at her birth. Recent evidence suggests, however, that a midlife hypothalamic change, instead of aging ovaries, may trigger the onset of menopause. Evolutionarily, menopause may have developed as a mechanism that prevented pregnancy in women beyond the time that they could likely rear a child before their own death.

Males do not experience complete gonadal failure as females do, for two reasons. First, a male’s germ cell supply is unlimited because mitotic activity of the spermatogonia continues. Second, gonadal hormone secretion in males is not inextricably dependent on gametogenesis, as in females. If female sex hormones were produced by separate tissues unrelated to those governing gametogenesis, as are male sex hormones, estrogen and progesterone secretion would not automatically stop when oogenesis stopped.

Menopause is preceded by a period of progressive ovarian failure characterized by increasingly irregular cycles and dwindling estrogen levels. This entire period of transition from sexual maturity to cessation of reproductive capability is known as the **climacteric (perimenopause)**. Ovarian estrogen production declines from as much as 300 mg per day to essentially nothing. Postmenopausal women are not completely devoid of estrogen, however, because adipose tissue, the liver, and the adrenal cortex continue to produce up to 20 mg of estrogen per day. In addition

to the ending of ovarian and menstrual cycles, the loss of ovarian estrogen following menopause brings about many physical and emotional changes. These changes include vaginal dryness, which can cause discomfort during sex, and gradual atrophy of the genital organs. However, postmenopausal women still have a sex drive, because of their adrenal androgens.

Clinical Note Because estrogen has widespread physiological actions beyond the reproductive system, the dramatic loss of ovarian estrogen in menopause affects other body systems, most notably the skeleton and the cardiovascular system. Estrogen helps build strong bones, shielding premenopausal women from the bone-thinning condition of **osteoporosis** (p. 286). The postmenopausal reduction in estrogen increases activity of the bone-dissolving osteoclasts and diminishes activity of the bone-building osteoblasts. The result is decreased bone density and a greater incidence of bone fractures.

Estrogen also helps modulate the actions of epinephrine and norepinephrine on the arteriolar walls. The menopausal diminution of estrogen leads to unstable control of blood flow, especially in the skin vessels. Transient increases in the flow of warm blood through these superficial vessels are responsible for the **hot flashes** that frequently accompany menopause. Vasomotor stability is gradually restored in postmenopausal women so that hot flashes eventually cease.

You have now learned about the events that take place if fertilization does not occur. Because reproduction is the primary function of the reproductive system, we next turn to the sequence of events that take place when fertilization does occur.

The oviduct

Fertilization, the union of male and female gametes, normally occurs in the ampulla, the upper third of the oviduct (Figure 17-21). Both the ovum and the sperm must be transported from their gonadal site of production to the ampulla.

FIGURE 17-21 Ovum and sperm transport to the site of fertilization

OVUM TRANSPORT TO THE OVIDUCT

When the ovum is released at ovulation, it is quickly picked up by the oviduct. The dilated end of the oviduct cups around the ovary and contains **fimbriae**, finger-like projections that contract in a sweeping motion to guide the released ovum into the oviduct (▶ Figure 17-21; see also ▶ Figure 17-2b). Furthermore, the fimbriae are lined by cilia—fine, hairlike projections that beat in waves toward the interior of the oviduct—further assuring the ovum's passage into the oviduct. Within the oviduct, the ovum is rapidly propelled by peristaltic contractions and ciliary action to the ampulla.

Conception can take place during a very limited time span in each cycle (the **fertile period**). If not fertilized, the ovum begins to disintegrate within 12 to 24 hours and is subsequently phagocytized by cells that line the reproductive tract. Fertilization must therefore occur within 24 hours after ovulation, when the ovum is still viable. Sperm typically survive about 48 hours but can survive up to five days in the female reproductive tract, so sperm deposited from five days before ovulation to 24 hours after ovulation may be able to fertilize the released ovum, although these times vary considerably.

 Occasionally an ovum fails to be transported into the oviduct and remains instead in the peritoneal cavity. Rarely, such an ovum gets fertilized, resulting in an **ectopic abdominal pregnancy**, in which the fertilized egg implants in the rich vascular supply to the digestive organs rather than in its usual site in the uterus (*ectopic* means “out of place”). An abdominal pregnancy often leads to life-threatening haemorrhage because the digestive organ blood supply is not primed to respond appropriately to implantation as the endometrium is. If this unusual pregnancy proceeds to term, the baby must be delivered surgically, because the normal vaginal exit is not available. The probability of maternal complications at birth is greatly increased because the digestive vasculature is not designed to seal itself off after birth as the endometrium does.

SPERM TRANSPORT TO THE OVIDUCT

After sperm are deposited in the vagina at ejaculation, they must travel through the cervical canal, through the uterus, and then to the egg in the upper third of the oviduct (▶ Figure 17-21). The first sperm arrive in the oviduct within half an hour after ejaculation. Even though sperm are mobile by means of whiplike contractions of their tails, 30 minutes is much too soon for a sperm's mobility to transport itself to the site of fertilization. To make this formidable journey, sperm need the help of the female reproductive tract.

The first hurdle is passage through the cervical canal. Throughout most of the cycle, because of high progesterone or low estrogen levels, the cervical mucus is too thick to permit sperm penetration. The cervical mucus becomes thin and watery enough to permit sperm to penetrate only when estrogen levels are high, as in the presence of a mature follicle about to ovulate. Sperm migrate up the cervical canal under their own power. The canal remains penetrable for only two or three days during each cycle, around the time of ovulation.

Once sperm have entered the uterus, contractions of the myometrium churn them around in “washing-machine” fashion. This action quickly disperses sperm throughout the uterine cavity. When sperm reach the oviduct, they are propelled to the fertilization site in the upper end of the oviduct by upward contractions of the oviduct

smooth muscle. These myometrial and oviduct contractions that facilitate sperm transport are induced by the high estrogen level just before ovulation, aided by seminal prostaglandins.

New research indicates that when sperm reach the ampulla, ova are not passive partners in conception. Mature eggs release **allurin**, a recently identified chemical that attracts sperm and causes them to propel themselves toward the waiting female gamete. Scientists also recently found the sperm receptor that detects and responds to the ovum-released chemoattractant. Interestingly, this receptor, called **hOR17-4**, is an olfactory receptor (OR) similar to those found in the nose for smell perception (p. 184). Therefore, sperm “smell” the egg. According to current thinking, the activation of the hOR17-4 receptor on binding with allurin (or another signal) from the egg triggers a second-messenger pathway in sperm that brings about intracellular Ca^{2+} release. This Ca^{2+} turns on the microtubule sliding that brings about tail movement and sperm swimming in the direction of the chemical signal.

Even around ovulation time, when sperm can penetrate the cervical canal, of the several hundred million sperm deposited in a single ejaculate, only a few thousand make it to the oviduct (▶ Figure 17-21). That only a very small percentage of the deposited sperm ever reach their destination is one reason why sperm concentration must be so high (20 million/mL of semen) for a man to be fertile. The other reason is that the acrosomal enzymes of many sperm are needed to break down the barriers surrounding the ovum (▶ Figure 17-22).

FERTILIZATION

The tail of the sperm is used to manoeuvre for final penetration of the ovum. To fertilize an ovum, a sperm must first pass through the corona radiata and zona pellucida surrounding it. The sperm penetrates the corona radiata by means of membrane-bound enzymes in the surface membrane that surrounds the head (▶ Figure 17-23a, step 1; also see chapter-opening photo). Sperm can penetrate the zona pellucida only after binding with specific binding sites on the surface of this layer. The binding partners between the sperm and ovum were recently identified. **Fertilin**, a protein found on the plasma membrane of the sperm, binds with glycoproteins known as ZP3 in the outer layer of the zona pellucida. Only sperm of the same species can bind to these zona pellucida sites and pass through. Binding of sperm triggers the Ca^{2+} -dependent acrosome reaction, in which the acrosomal membrane disrupts and the acrosomal

David Phillips/Science Source

▶ **FIGURE 17-22** Scanning electron micrograph of sperm amassed at the surface of an ovum

enzymes are released (step 2). Calcium that enters the sperm tail through the opened cation channels rapidly moves within a few seconds to the head, where it participates in the acrosome reaction. The acrosomal enzymes digest the zona pellucida, enabling the sperm, with its tail still beating, to tunnel a path through this protective barrier (step 3). The first sperm to reach the ovum itself fuses with the plasma membrane of the ovum (actually a secondary oocyte), and its head (bearing its DNA) enters the ovum's cytoplasm (step 4). The sperm's tail is frequently lost in this process, but the head carries the crucial genetic information. Sperm-egg fusion triggers a chemical change in the ovum's surrounding membrane that makes this outer layer impenetrable to the entry of any more sperm. This phenomenon is known as **block to polyspermy** (many sperm). Fertilization-induced release of intracellular Ca^{2+} into the ovum cytosol triggers the exocytosis of enzyme-filled **cortical granules** from the outermost, or cortical, region of the ovum and into the space between the egg membrane and the zona pellucida (step 5). These enzymes diffuse into the zona pellucida, where they inactivate the ZP3 receptors so that other sperm reaching the zona pellucida cannot bind with it. The enzymes also harden the zona pellucida and seal off tunnels in the process to keep other penetrating sperm from advancing.

The released Ca^{2+} in the ovum cytosol also triggers the second meiotic division of the egg, which is now ready to unite with the sperm to complete the fertilization process.

Within an hour, the sperm and egg nuclei fuse, thanks to a centrosome (microtubule organizing centre) provided by the sperm that forms microtubules; this brings the male and female chromosome sets together for uniting. In addition to contributing its half of the chromosomes to the fertilized ovum, now called a **zygote**, the victorious sperm also activates the ovum enzymes that are essential for early embryonic development. In this way, fertilization accomplishes the dual events of combining genes from the two parents to form a genetically unique organism and setting in motion the development of that organism.

The blastocyst

During the first three to four days following fertilization, the zygote remains within the ampulla, because a constriction between the ampulla and the remainder of the oviduct canal prevents further movement of the zygote toward the uterus.

THE BEGINNING STEPS IN THE AMPULLA

The zygote is not idle during this time, however. It rapidly undergoes a number of mitotic cell divisions to form a solid ball of cells called the **morula** (▶ Figure 17-24). Meanwhile, the rising levels of progesterone from the newly developing corpus luteum that formed after ovulation stimulate release of glycogen from the endometrium into the reproductive tract lumen for use as energy by the early embryo. The nutrients stored in the cytoplasm of the ovum can sustain the product of conception for less than a day. The concentration of secreted nutrients increases more rapidly in the small confines of the ampulla than in the uterine lumen.

DESCENT OF THE MORULA TO THE UTERUS

About three to four days after ovulation, progesterone is produced in sufficient quantities to relax the oviduct constriction,

thereby permitting the morula to be rapidly propelled into the uterus by oviductal peristaltic contractions and ciliary activity. The temporary delay before the developing embryo passes into the uterus lets enough nutrients accumulate in the uterine lumen to support the embryo until implantation can take place. If the morula arrives prematurely, it dies.

When the morula descends to the uterus, it floats freely within the uterine cavity for another three to four days, living on endometrial secretions and continuing to divide. During the first six to seven days after ovulation, while the developing embryo is in transit in the oviduct and floating in the uterine lumen, the uterine lining is simultaneously being prepared for implantation under the influence of luteal-phase progesterone. During this time, the uterus is in its secretory, or progestational, phase, storing up glycogen and becoming richly vascularized.

 **Clinical Note** Occasionally the morula fails to descend into the uterus and continues to develop and implant in the lining of the oviduct. This leads to an **ectopic tubal pregnancy**, which must be terminated. Ninety-five percent of ectopic pregnancies are tubal pregnancies. Such a pregnancy can never succeed, because the oviduct cannot expand as the uterus does to accommodate the growing embryo. The first warning of a tubal pregnancy is pain caused by the growing embryo stretching the oviduct. If not removed, the enlarging embryo will rupture the oviduct, causing possibly lethal haemorrhage.

IMPLANTATION OF THE BLASTOCYST IN THE PREPARED ENDOMETRIUM

By the time the endometrium is suitable for implantation (about a week after ovulation), the morula has descended to the uterus and continued to proliferate and differentiate into a **blastocyst** capable of implantation. The week's delay after fertilization and before implantation allows time for both the endometrium and the developing embryo to prepare for implantation.

A **blastocyst** is a single-layer hollow ball of about 50 cells encircling a fluid-filled cavity, with a dense mass of cells grouped together at one side (▶ Figure 17-24). This dense mass, known as the **inner cell mass**, becomes the embryo/fetus itself. The rest of the blastocyst is never incorporated into the fetus; instead it serves a supportive role during intrauterine life. The thin outermost layer, the **trophoblast**, accomplishes implantation, after which it develops into the fetal portion of the placenta.

Before a blastocyst can implant, it must shed the zona pellucida and undergo a process called zona hatching. By this time the endometrium is ready to accept the early embryo. The blastocyst adheres to the uterine lining on the side of its inner cell mass (▶ Figure 17-25, step 1). **Implantation** begins when, on contact with the endometrium, the trophoblastic cells overlying the inner cell mass release protein-digesting enzymes. These enzymes digest pathways between the endometrial cells, permitting finger-like cords of trophoblastic cells to penetrate into the depths of the endometrium, where they continue to digest uterine cells (▶ Figure 17-25, step 2). Through its cannibalistic actions, the trophoblast performs the dual functions of (1) accomplishing implantation as it carves out a hole in the endometrium for the blastocyst and (2) making metabolic fuel and raw materials available for the developing embryo while the advancing trophoblastic projections break

➤ **FIGURE 17-23 Process of fertilization.** (a) Schematic representation of sperm tunnelling the barriers surrounding the ovum. (b) Scanning electron micrograph of a spermatozoon in which the acrosomal membrane has been disrupted and the acrosomal enzymes (in red) are exposed

down the nutrient-rich endometrial tissue. The cell walls of the advancing trophoblastic cells break down, forming a multinucleated syncytium that eventually becomes the fetal portion of the placenta.

Stimulated by the invading trophoblast, the endometrial tissue at the contact site undergoes dramatic changes that enhance its ability to support the implanting embryo. In response to a chemical messenger released by the blastocyst, the underlying endometrial cells secrete prostaglandins, which locally increase vascularization, produce oedema, and enhance nutrient storage. The endometrial tissue so modified at the implantation site is called the **decidua**. It is into this super-rich decidual tissue that the blastocyst becomes embedded. After the blastocyst burrows into the decidua by means of trophoblastic activity, a layer of endometrial cells covers over the surface of the hole, completely burying the blastocyst within the uterine lining (➤ Figure 17-25, step 3). The trophoblastic layer continues

to digest the surrounding decidual cells, providing energy for the embryo until the placenta develops.

■ Clinical Connections

The physician was insistent that Jourdain tell Anita right away because chlamydia infections in women are frequently (70–80 percent) asymptomatic for months or even years, but they can have serious consequences. Infections can lead to pelvic inflammatory disease, which can include infection of the uterus, the ovaries, or the fallopian tubes. Such infections can result in chronic pelvic pain and scarring of the female reproductive system. Scarring in the uterus can cause infertility by preventing the implantation of the blastocyst in the uterine endometrium. Chlamydia infections can also increase the chances of an ectopic pregnancy.

► **FIGURE 17-24** Early stages of development from fertilization to implantation. Note that the fertilized ovum progressively divides and differentiates into a blastocyst as it moves from the site of fertilization in the upper oviduct to the site of implantation in the uterus.

PREVENTING REJECTION OF THE EMBRYO/FETUS

What prevents the mother from immunologically rejecting the embryo/fetus, which is actually a “foreigner” to the mother’s immune system—being half derived from the genetically different paternal chromosomes? Following are several proposals under investigation. New evidence indicates that the trophoblasts produce **Fas ligand**, which binds with **Fas**, a specialized receptor on the surface of approaching, activated, maternal cytotoxic T cells. Cytotoxic T cells are the immune cells that destroy foreign cells (p. 482). This binding of the trophoblasts with Fas triggers the apoptosis of the cytotoxic T immune cells that are targeted to destroy the developing foreigner, thus sparing the embryo/fetus from immune rejection. Other researchers have found that the fetal portion of the placenta, which is derived from trophoblasts, produces an enzyme, **indoleamine 2,3-dioxygenase (IDO)**, which destroys tryptophan. Tryptophan, an amino acid, is a critical factor in the activation of maternal cytotoxic T cells. So the embryo/fetus, through its trophoblast connection, is believed to defend itself against rejection by shutting down the activity of the mother’s cytotoxic T cells in the placenta that would otherwise attack the developing foreign tissues. Furthermore, recent studies demonstrate that production of regulatory T cells is doubled or tripled in pregnant experimental animals. Regulatory T cells suppress maternal cytotoxic T cells that might target the fetus (p. 481).

CONTRACEPTION

Clinical Note Couples wishing to engage in sexual intercourse but avoid pregnancy have a number of available methods of **contraception** (against conception). These methods act by blocking one of three major steps in the reproductive process: sperm transport to the ovum, ovulation, or implantation. (See Concepts, Challenges, and Controversies, pp. 764–765, for further details on the ways and means of contraception.)

Now let’s examine the placenta in further detail.

The placenta

The glycogen stores in the endometrium are sufficient to nourish the embryo only during its first few weeks. To sustain the growing embryo/fetus for the duration of its intrauterine life, the **placenta**, a specialized organ of exchange between the maternal and fetal blood, rapidly develops (► Figure 17-26). The placenta is derived from both trophoblastic and decidual tissue.

FORMATION OF THE PLACENTA AND AMNIOTIC SAC

By day 12, the embryo is completely embedded in the decidua. By this time the trophoblastic layer is two cell layers thick and is called the **chorion**. As the chorion continues to release enzymes and expand, it forms an extensive network of cavities within the decidua. As the expanding chorion erodes decidual capillary walls, maternal blood leaks from the capillaries and fills these cavities. The blood is kept from clotting by an anticoagulant produced by

- 1 When the free-floating blastocyst adheres to the endometrial lining, cords of trophoblastic cells begin to penetrate the endometrium.

- 2 Advancing cords of trophoblastic cells tunnel deeper into the endometrium, carving out a hole for the blastocyst. The boundaries between the cells in the advancing trophoblastic tissue disintegrate.

- 3 When implantation is finished, the blastocyst is completely buried in the endometrium.

© 2016 Cengage

► FIGURE 17-25 Implantation of the blastocyst

the chorion. Finger-like projections of chorionic tissue extend into the pools of maternal blood. Soon the developing embryo sends out capillaries into these chorionic projections to form **placental villi**. Some villi extend completely across the blood-filled spaces to anchor the fetal portion of the placenta to the endometrial tissue, but most simply project into the pool of maternal blood.

Each placental villus contains embryonic (later fetal) capillaries surrounded by a thin layer of chorionic tissue, which separates the embryonic/fetal blood from the maternal blood in the intervillous spaces. Maternal and fetal blood do not actually mingle, but the barrier between them is extremely thin. To visualize this relationship, think of your hands (the fetal capillary blood vessels) in rubber gloves (the chorionic tissue) immersed in water (the pool of maternal blood). Only the rubber gloves separate your hands from the water. In the same way, only the thin chorionic tissue (plus the capillary wall of the fetal vessels) separates the fetal and maternal blood. All exchanges between these two bloodstreams take place across this extremely thin barrier. This entire system of interlocking maternal (decidual) and fetal (chorionic) structures makes up the placenta.

Even though not fully developed, the placenta is well established and operational by five weeks after implantation. By this time, the heart of the developing embryo is pumping blood into the placental villi as well as to the embryonic tissues. Throughout gestation, fetal blood continuously traverses between the placental villi and the circulatory system of the fetus by means of the **umbilical arteries** (there are usually two) and **umbilical vein**, which are wrapped within the **umbilical cord**—a lifeline between the fetus and the placenta (► Figure 17-26). The maternal blood within the placenta is continuously replaced as fresh blood enters through the uterine arterioles; percolates through the intervillous spaces, where it exchanges substances with fetal blood in the surrounding villi; and then exits through the uterine vein.

Meanwhile, during the time of implantation and early placental development, the inner cell mass forms a fluid-filled **amniotic cavity** between the chorion and the portion of the inner cell mass destined to become the fetus. The epithelial layer that encloses the amniotic cavity is called the **amniotic sac (amnion)**. As it continues to develop, the amniotic sac eventually fuses with the chorion, forming a single combined membrane that surrounds the embryo/fetus. The fluid in the amniotic cavity, the **amniotic fluid**, which is similar in composition to normal ECF, surrounds and cushions the fetus throughout gestation (► Figure 17-27; also see ► Figures 17-25 and 17-26).

FUNCTIONS OF THE PLACENTA

During intrauterine life, the placenta performs the functions of the digestive system, the respiratory system, and the kidneys for the fetus. The fetus has these organ systems, but within the uterine environment they cannot (and do not need to) function. Nutrients and oxygen diffuse from the maternal blood across the thin placental barrier into the fetal blood, whereas carbon dioxide and other metabolic wastes simultaneously diffuse from the fetal blood into the maternal blood. The nutrients and oxygen brought to the fetus in the maternal blood are acquired by the mother's digestive and respiratory systems, and the carbon dioxide and wastes transferred into the maternal

FIGURE 17-26 Placentation. (a) Relationship between the developing fetus and uterus as pregnancy progresses. (b) Schematic representation of interlocking maternal and fetal structures that form the placenta. Finger-like projections of chorionic (fetal) tissue form the placental villi, which protrude into a pool of maternal blood. Decidual (maternal) capillary walls are broken down by the expanding chorion so that maternal blood oozes through the spaces between the placental villi. Fetal placental capillaries branch off the umbilical arteries and project into the placental villi. Fetal blood flowing through these vessels is separated from the maternal blood by the thin chorionic layer that forms the placental villi. Maternal blood enters through the maternal arterioles, then percolates through the pool of blood in the intervillous spaces. Here, exchanges are made between the fetal and maternal blood before the fetal blood leaves through the umbilical vein and maternal blood exits through the maternal venules.

blood are eliminated by the mother's lungs and kidneys, respectively. Thus, the mother's digestive tract, respiratory system, and kidneys serve the fetus's needs as well as her own.

Some substances traverse the placental barrier by special mediated transport systems in the placental membranes, whereas others move across by simple diffusion. Unfortunately, many drugs, environmental pollutants, other chemical agents, and microorganisms in the mother's bloodstream can also cross

the placental barrier, and some of them may harm the developing fetus. Individuals born limbless as a result of exposure to *thalidomide*, a tranquilizer prescribed for pregnant women before this drug's devastating effects on the growing fetus were known, serve as a grim reminder of this fact. Similarly, newborns who have been exposed during gestation to their mother's abuse of a drug, such as heroin, suffer addiction withdrawal symptoms after birth. Even more common chemical agents, such as

► **FIGURE 17-27** A human fetus surrounded by the amniotic sac. The fetus is near the end of the first trimester of development.

Aspirin, alcohol, and agents in cigarette smoke, can reach the fetus and have adverse effects. Likewise, fetuses can acquire AIDS before birth if their mothers are infected with the virus. A pregnant woman should therefore be very cautious about potentially harmful exposure from any source.

The placenta assumes yet another important responsibility; it becomes a temporary endocrine organ during pregnancy, a topic to which we now turn.

Hormones and the placenta

The fetally derived portion of the placenta has the remarkable capacity to secrete a number of peptide and steroid hormones essential for maintaining pregnancy. The most important are *human chorionic gonadotropin*, *estrogen*, and *progesterone* (■ Table 17-5). Serving as the major endocrine organ of pregnancy, the placenta is unique among endocrine tissues in two ways. First, it is a transient tissue. Second, secretion of its hormones is not subject to extrinsic control, this in contrast to the stringent, often complex mechanisms that regulate the secretion of other hormones. Instead, the type and rate of placental hormone secretion depend primarily on the stage of pregnancy.

SECRETION OF HUMAN CHORIONIC GONADOTROPIN

One of the first endocrine events is secretion by the developing chorion of **human chorionic gonadotropin (hCG)**, a peptide hormone that prolongs the lifespan of the corpus luteum. Recall that during the ovarian cycle, the corpus luteum degenerates and the highly prepared, luteal-dependent uterine lining sloughs off if fertilization and implantation do not occur. When fertilization does occur, the implanted blastocyst saves itself from being flushed out in menstrual flow by producing hCG. This hormone is functionally similar to LH and structurally similar enough that it can also bind to LH receptors. It is because of

these similarities that hCG stimulates and maintains the corpus luteum so it does not degenerate. Now called the **corpus luteum of pregnancy**, this ovarian endocrine unit grows even larger and produces increasingly greater amounts of estrogen and progesterone for an additional 10 weeks until the placenta takes over secretion of these steroid hormones. Because of the persistence of estrogen and progesterone, the thick, pulpy endometrial tissue is maintained rather than shed. Accordingly, menstruation ceases during pregnancy.

Stimulation by hCG is necessary to maintain the corpus luteum of pregnancy because LH, which maintains the corpus luteum during the normal luteal phase of the uterine cycle, is suppressed through feedback inhibition by the high levels of progesterone.

Maintenance of a normal pregnancy depends on high concentrations of progesterone and estrogen. Therefore, hCG production is critical during the first trimester to maintain ovarian output of these hormones. In a male fetus, hCG also stimulates the precursor Leydig cells in the fetal testes to secrete testosterone, which masculinizes the developing reproductive tract.

The secretion rate of hCG increases rapidly during early pregnancy to save the corpus luteum from demise. Peak secretion of hCG occurs about 60 days after the end of the last menstrual period (► Figure 17-28). By the tenth week of pregnancy, hCG output declines to a low rate of secretion that is maintained for the duration of gestation. The fall in hCG occurs at a time when the corpus luteum is no longer needed for its steroid hormone output, because the placenta has begun to secrete substantial quantities of estrogen and progesterone. The corpus luteum of pregnancy partially regresses as hCG secretion dwindles, but it is not converted into scar tissue until after delivery of the baby.

► **FIGURE 17-28** Secretion rates of placental hormones

The Ways and Means of Contraception

THE TERM **CONTRACEPTION** REFERS TO THE PROCESS of avoiding pregnancy while engaging in sexual intercourse. The available methods of contraception range in ease of use and effectiveness (see the accompanying table). These methods can be grouped into three categories based on the means by which they prevent pregnancy: (1) blockage of sperm transport to the ovum, (2) prevention of ovulation, or (3) blockage of implantation. After examining the most common ways that contraception can be accomplished by these means, we will briefly look at future contraceptive possibilities and then discuss termination of unwanted pregnancies.

Blockage of Sperm Transport to the Ovum

- *Natural contraception* or the *rhythm method* of birth control relies on abstinence from intercourse during the woman's fertile period. The woman can predict when ovulation will occur by keeping careful records of her menstrual cycles. Because of variability in cycles, this technique is only partially effective. The time of ovulation can be determined more precisely by recording body temperature each morning before getting up. Body temperature rises slightly about a day after ovulation has taken place. The temperature rhythm method is not useful in determining when it is safe to engage in intercourse before ovulation, but it can be helpful in determining when it is safe to resume sex after ovulation.
- *Coitus interruptus* involves withdrawal of the penis from the vagina before ejaculation occurs. This method is only moderately effective, however, because timing is difficult, and some sperm may pass out of the urethra prior to ejaculation.
- *Chemical contraceptives*, such as spermicidal (sperm-killing) jellies, foams, creams, and suppositories, when inserted into the vagina are toxic to sperm for about an hour after application.

- *Barrier methods* mechanically prevent sperm transport to the oviduct. For males, the *condom* is a thin, strong, rubber or latex sheath placed over the erect penis before ejaculation to prevent sperm from entering the vagina. For females, the *diaphragm*, which must be fitted by a trained professional, is a flexible rubber dome that is inserted through the vagina and positioned over the cervix to block sperm entry into the cervical canal. It is held in position by lodging snugly against the vaginal wall and must be left in place for at least 6 hours, but no longer than 24 hours, after intercourse. Barrier methods are often used in conjunction with spermicidal agents for increased effectiveness. The *cervical cap* is a recently developed alternative to the diaphragm. Smaller than a diaphragm, the cervical cap—coated with a film of spermicide—cups over the cervix and is held in place by suction.
- The *female condom* (or *vaginal pouch*) is the latest barrier method developed. It is a polyurethane, cylindrical pouch, 18 cm long, closed on one end and open on the other end, with a flexible ring at both ends. The ring at the closed end of the device is inserted into the vagina and fits over the cervix, similar to a diaphragm. The ring at the open end of the pouch is positioned outside the vagina over the external genitalia.
- *Sterilization*, which involves surgical disruption of either the ductus deferens (*vasectomy*) in men or the oviduct (*tubal ligation*) in women, is considered a permanent method of preventing sperm and ovum from uniting.

Prevention of Ovulation

- *Oral contraceptives*, or *birth control pills*, available only by prescription, prevent ovulation primarily by suppressing gonadotropin secretion. These pills, which contain synthetic estrogen-like and progesterone-like steroids, are taken for three weeks, either in combination or in sequence, and then withdrawn for one week. These steroids, like the natural steroids produced during the ovarian cycle, inhibit GnRH and thus FSH and LH secretion. As a result, follicle maturation and ovulation do not take place, so conception is impossible. The endometrium responds to the exogenous steroids by thickening and developing secretory capacity, just as it would to the natural hormones. When these synthetic steroids are withdrawn after three weeks, the endometrial lining sloughs and menstruation occurs, as it normally would on degeneration of the corpus luteum. In addition to blocking ovulation, oral contraceptives prevent pregnancy by increasing the viscosity of cervical mucus, which makes sperm penetration more difficult, and by decreasing muscular contractions in the female reproductive tract, which reduces sperm transport to the oviduct. Oral contraceptives have been shown to increase the risk of intravascular clotting, especially in women who also smoke tobacco.
- Several other contraceptive methods contain synthetic female sex hormones and act similarly to birth control pills to prevent ovulation. These include (1) *long-acting subcutaneous*

■ Average Failure Rate of Various Contraceptive Techniques

Contraceptive Method	Average Failure Rate (Annual Pregnancies/100 Women)
None	90
Natural (rhythm) methods	20–30
Coitus interruptus	23
Chemical contraceptives	20
Barrier methods	10–15
Oral contraceptives	2–2.5
Implanted contraceptives	1
Intrauterine device	4

(under the skin) *implantation* of hormone-containing capsules that gradually release hormones at a nearly steady rate for five years and (2) *birth control patches* impregnated with hormones that are absorbed through the skin.

Blockage of Implantation

Medically, pregnancy is not considered to begin until implantation. According to this view, any mechanism that interferes with implantation is said to prevent pregnancy. Not all hold this view, however. Some consider pregnancy to begin at time of fertilization. To these people, any interference with implantation is a form of abortion. Therefore, methods of contraception that rely on blockage of implantation are more controversial than methods that prevent fertilization from taking place.

- Blockage of implantation is most commonly accomplished by a physician inserting a small *intrauterine device (IUD)* into the uterus. The IUD's mechanism of action is not completely understood, although most evidence suggests that the presence of this foreign object in the uterus induces a local inflammatory response that prevents implantation of a fertilized ovum.
- Implantation can also be blocked by so-called *morning-after pills*, also known as *emergency contraception*. The first term is actually a misnomer, because these pills can prevent pregnancy if taken within 72 hours after, not just the morning after, unprotected sexual intercourse. The most common form of emergency contraception in Canada is called Plan B and is available, in most provinces, at pharmacies without a prescription. Plan B contains levonorgestrel, a second-generation synthetic progestogen, which acts as a hormone that binds and activates the progesterone receptor. In addition to blocking implantation, Plan B can also prevent both ovulation and fertilization, making it an effective treatment no matter where the woman is in her cycle when she takes the pills.
- Some researchers are exploring ways to block the union of sperm and egg by interfering with a specific interaction that normally occurs between the male and the female gametes. For example, under study are chemicals introduced into the vagina that trigger premature release of the acrosomal enzymes, depriving the sperm of a means to fertilize an ovulated egg.
- Some scientists are seeking ways to manipulate hormones to block sperm production in males without depriving the man of testosterone. One example of a male contraception under development is a combination of testosterone and progestin that inhibits GnRH and the gonadotropic hormones, thereby turning off the signals that stimulate spermatogenesis.
- Another outlook for male contraception is chemical sterilization designed to be reversed, unlike surgical sterilization, which is considered irreversible. In this experimental technique, a nontoxic polymer is injected into the ductus deferens, where the chemical interferes with sperm's fertilizing capabilities. Flushing of the polymer from the ductus deferens by a solvent reverses the contraceptive effect.
- One interesting avenue being explored holds hope for a unisex contraceptive that would stop sperm in their tracks and could be used by either males or females. Based on preliminary findings, the idea is to use Ca^{2+} -blocking drugs to prevent the entry of Ca^{2+} into sperm tails. As in muscle cells, Ca^{2+} switches on the contractile apparatus responsible for the sperm's motility. With no Ca^{2+} , sperm would not be able to manoeuvre to accomplish fertilization.

Termination of Unwanted Pregnancies

Future Possibilities

On the horizon are improved varieties of currently available contraceptive techniques, such as a new birth control pill that suppresses ovulation and menstrual periods for months at a time.

- A future birth control technique is *immunocontraception*—the use of vaccines that prod the immune system to produce antibodies targeted against a particular protein critical to the reproductive process. The contraceptive effects of the vaccines are expected to last about a year. For example, in the testing stage is a vaccine that induces the formation of antibodies against human chorionic gonadotropin so that this essential corpus luteum-supporting hormone is not effective if pregnancy occurs. Another promising immunocontraception approach is aimed at blocking the acrosomal enzymes so that sperm cannot enter the ovum. Still other researchers have developed an experimental vaccine that targets a protein added by the epididymis to the surface of sperm during their maturation.
- When contraceptive practices fail or are not used and an unwanted pregnancy results, women often turn to *abortion* to terminate the pregnancy. In Canada, approximately 100 000 abortions take place each year, with about half of these occurring in hospitals and the other half in clinics. Currently, the surgical removal of the embryo/fetus by a physician is legal in Canada, but the use of the drug RU-486 is not.
- There has been much debate over the use of RU-486 (the "abortion pill," or mifepristone). Clinical trials were conducted in 2000 with women using both methotrexate and mifepristone. While both drugs had overall similar results, mifepristone was found to act faster. RU-486 and other similar drugs have been available in other countries (e.g., France) since 1989. The drug terminates an early pregnancy by chemical interference rather than by surgery. RU-486, a progesterone antagonist, binds tightly with the progesterone receptors on the target cells, but does not evoke progesterone's usual effects, and prevents progesterone from binding and acting. Deprived of progesterone activity, the highly developed endometrial tissue sloughs off, carrying the implanted embryo with it. RU-486 administration is followed in 48 hours by a prostaglandin that induces uterine contractions to help expel the endometrium and embryo.

TABLE 17-5 Placental Hormones

Hormone	Function
Human Chorionic Gonadotropin (hCG)	Maintains the corpus luteum of pregnancy; Stimulates secretion of testosterone by the developing testes in XY embryos
Estrogen (also secreted by the corpus luteum of pregnancy)	Stimulates growth of the myometrium, increasing uterine strength for parturition; Helps prepare the mammary glands for lactation
Progesterone (also secreted by the corpus luteum of pregnancy)	Suppresses uterine contractions to provide a quiet environment for the fetus Promotes formation of a cervical mucous plug to prevent uterine contamination Helps prepare the mammary glands for lactation
Human Chorionic Somatomammotropin (has a structure similar to that of both growth hormone and prolactin)	Believed to reduce maternal use of glucose and to promote the breakdown of stored fat (similar to growth hormone) so that greater quantities of glucose and free fatty acids may be shunted to the fetus Helps prepare the mammary glands for lactation (similar to prolactin)
Relaxin (also secreted by the corpus luteum of pregnancy)	Softens the cervix in preparation for cervical dilation at parturition Loosens the connective tissue between the pelvic bones in preparation for parturition
Placental PTHrp (parathyroid hormone–related peptide)	Increases maternal plasma Ca^{2+} level for use in calcifying fetal bones; if necessary, promotes localized dissolution of maternal bones, mobilizing their Ca^{2+} stores for use by the developing fetus

© 2016 Cengage

Human chorionic gonadotropin is eliminated from the body in the urine. Pregnancy diagnosis tests can detect hCG in urine as early as the first month of pregnancy, about two weeks after the first missed menstrual period. Because this is before the growing embryo can be detected by physical examination, the test permits early confirmation of pregnancy.

A frequent early clinical sign of pregnancy is morning sickness, a daily bout of nausea and vomiting that often occurs in the morning but can take place at any time of day. Because this condition usually appears shortly after implantation and coincides with the time of peak hCG production, scientists speculate that this early placental hormone may trigger the symptoms, perhaps by acting on the chemoreceptor trigger zone in the vomiting centre (p. 660).

SECRETION OF ESTROGEN AND PROGESTERONE

Why doesn't the developing placenta start producing estrogen and progesterone in the first place instead of secreting hCG, which in turn stimulates the corpus luteum to secrete these two critical hormones? The answer is that, for different reasons, the placenta cannot produce enough estrogen or progesterone in the first trimester of pregnancy. In the case of estrogen, the placenta does not have all the enzymes needed for complete synthesis of this hormone. Estrogen synthesis requires a complex interaction between the placenta and the fetus (► Figure 17-29). The placenta converts the androgen hormone produced by the fetal adrenal cortex, dehydroepiandrosterone (DHEA), into estrogen. The placenta cannot produce estrogen until the fetus has developed to the point that its adrenal cortex is secreting DHEA into the blood. The placenta extracts DHEA from the fetal blood and converts it into estrogen, which it then secretes into the maternal blood. The primary estrogen synthesized by this means is

estriol, in contrast to the main estrogen product of the ovaries, estradiol. Consequently, measurement of estriol levels in the maternal urine can be used clinically to assess the viability of the fetus.

In the case of progesterone, the placenta can synthesize this hormone soon after implantation. Even though the early placenta has the enzymes necessary to convert the cholesterol extracted from the maternal blood into progesterone, it does not produce much of this hormone, because the amount of progesterone produced is proportional to placental weight. The placenta is simply too small in the first 10 weeks of pregnancy to produce enough progesterone to maintain the endometrial tissue. The notable increase in circulating progesterone in the last seven months of gestation reflects placental growth during this period.

ROLES OF ESTROGEN AND PROGESTERONE DURING PREGNANCY

As noted earlier, high concentrations of estrogen and progesterone are essential to maintain a normal pregnancy. Estrogen stimulates growth of the myometrium, which increases in size throughout pregnancy. The stronger uterine musculature is needed to expel the fetus during labour. Estriol also promotes development of the ducts within the mammary glands, through which milk is ejected during lactation.

Progesterone performs various roles throughout pregnancy. Its main function is to prevent miscarriage by suppressing contractions of the uterine myometrium. Progesterone also promotes formation of a mucous plug in the cervical canal to prevent vaginal contaminants from reaching the uterus. Finally, placental progesterone stimulates development of milk glands in the breasts, in preparation for lactation.

FIGURE 17-29 Secretion of estrogen and progesterone by the placenta. The placenta secretes increasing quantities of progesterone and estrogen into the maternal blood after the first trimester. The placenta itself can convert cholesterol into progesterone (orange pathway) but lacks some of the enzymes necessary to convert cholesterol into estrogen. However, the placenta can convert DHEA derived from cholesterol in the fetal adrenal cortex into estrogen when DHEA reaches the placenta by means of the fetal blood (blue pathway).

Maternal body systems and gestation

The period of **gestation (pregnancy)** is about 38 weeks from conception (40 weeks from the end of the last menstrual period). During gestation, the embryo/fetus develops and grows to the point of being able to leave its maternal life-support system. Meanwhile, a number of physical changes within the mother accommodate the demands of pregnancy. The most obvious change is uterine enlargement. The uterus expands and increases in weight more than 20 times, exclusive of its contents. The breasts enlarge and develop the ability to produce milk. Body systems other than the reproductive system also make needed adjustments. The volume of blood increases by 30 percent, and the cardiovascular system responds to the increasing demands of the growing placental mass. Weight gain during pregnancy is due only in part to the weight of the fetus. The remainder is mostly from increased weight of the uterus, including the placenta, and increased blood volume. Respiratory activity increases by about 20 percent to handle the additional fetal requirements for oxygen utilization and carbon dioxide removal. Urinary output increases, and the kidneys excrete the additional wastes from the fetus.

The increased metabolic demands of the growing fetus increase nutritional requirements for the mother. In general, the fetus takes what it needs from the mother, even if this leaves the mother with a nutritional deficit. For example, the placental hormone **human chorionic somatomammotropin (hCS)** is thought responsible for the decreased use of glucose by the mother and the mobilization of free fatty acids from maternal adipose stores—similar to the actions of growth hormone (p. 232). (In fact, hCS has a structure similar to that of both growth hormone and prolactin and exerts similar actions.) The hCS-induced metabolic changes in the mother make available greater quantities of glucose and fatty acids for shunting to the fetus. Also, if the mother does not consume enough calcium, yet another placental hormone similar to parathyroid hormone, **parathyroid**

hormone-related peptide (PTHrp), mobilizes calcium from the maternal bones to ensure adequate calcification of the fetal bones (see Table 17-5).

Parturition

Parturition (labour, delivery, birth) requires (1) dilation of the cervical canal to accommodate passage of the fetus from the uterus through the vagina and to the outside and (2) contractions of the uterine myometrium that are sufficiently strong to expel the fetus.

Several changes take place during late gestation in preparation for the onset of parturition. During the first two trimesters of gestation, the uterus remains relatively quiet, because of the inhibitory effect of the high levels of progesterone on the uterine muscle. During the last trimester, however, the uterus becomes progressively more excitable, so that mild contractions (**Braxton-Hicks contractions**) are experienced with increasing strength and frequency.

Sometimes these contractions become regular enough to be mistaken for the onset of labour, a phenomenon called false labour.

Throughout gestation, the exit of the uterus remains sealed by the rigid, tightly closed cervix. As parturition approaches, the cervix begins to soften (or ripen) as a result of the dissociation of its tough connective tissue (collagen) fibres. Because of this softening, the cervix becomes malleable so that it can gradually yield, dilating the exit, as the fetus is forcefully pushed against it during labour. This cervical softening is caused largely by **relaxin**, a peptide hormone produced by the corpus luteum of pregnancy and by the placenta. Other factors to be described shortly contribute to cervical softening. Relaxin also “relaxes” the birth canal by loosening the connective tissue between pelvic bones.

Meanwhile, the fetus shifts downward (the baby “drops”) and is normally oriented so that the head is in contact with the cervix in preparation for exiting through the birth canal. In a **breech birth**, any part of the body other than the head approaches the birth canal first.

The factors that trigger parturition

Rhythmic, coordinated contractions, usually painless at first, begin at the onset of true labour. As labour progresses, the contractions increase in frequency, intensity, and discomfort. These strong, rhythmic contractions force the fetus against the cervix, dilating the cervix. Then, after having dilated the cervix enough for the fetus to pass through, these contractions force the fetus out through the birth canal.

The exact factors triggering the increase in uterine contractility and thus initiating parturition are not fully established, although much progress has been made in unravelling the sequence of events. Let’s take a look at what is known about this process.

ROLE OF HIGH ESTROGEN LEVELS

During early gestation, maternal estrogen levels are relatively low, but as gestation proceeds, placental estrogen secretion continues to rise. In the immediate days before the onset of parturition, soaring levels of estrogen bring about changes in the uterus and cervix to prepare them for labour and delivery (► Figure 17-30; also see ► Figure 17-28). First, high levels of estrogen promote the synthesis of connexons within the uterine smooth muscle cells. These myometrial cells are not functionally linked to any extent throughout most of gestation. The newly manufactured connexons are inserted in the myometrial plasma membranes to form gap junctions that electrically link together the uterine smooth muscle cells so they become able to contract as a coordinated unit (p. 328).

Simultaneously, high levels of estrogen dramatically and progressively increase the concentration of myometrial receptors for oxytocin. Together, these myometrial changes collectively bring about the increased uterine responsiveness to oxytocin that ultimately initiates labour.

In addition to preparing the uterus for labour, the increasing levels of estrogen promote production of local prostaglandins that contribute to cervical ripening by stimulating cervical enzymes that locally degrade collagen fibres. Furthermore, these prostaglandins themselves increase uterine responsiveness to oxytocin.

ROLE OF OXYTOCIN

Oxytocin is a peptide hormone produced by the hypothalamus, stored in the posterior pituitary, and released into the blood from the posterior pituitary on nervous stimulation by the hypothalamus (p. 227). A powerful uterine muscle stimulant, oxytocin plays the key role in the progression of labour. However, this hormone was once discounted as the trigger for parturition, because the circulating levels of oxytocin remain constant prior to the onset of labour. The discovery that uterine responsiveness to oxytocin is 100 times greater at term than in nonpregnant women (because of the increased concentration of myometrial oxytocin receptors) led to the now widely accepted conclusion that labour is initiated when the oxytocin receptor concentration reaches a critical threshold that permits the onset of strong, coordinated contractions in response to ordinary levels of circulating oxytocin.

ROLE OF CORTICOTROPIN-RELEASING HORMONE

Until recently, scientists were baffled by the factors that raise levels of placental estrogen secretion. Recent research has shed new light on the probable mechanism. Evidence suggests that *corticotropin-releasing hormone (CRH)* secreted by the fetal portion of the placenta into both the maternal and fetal circulations not only drives the manufacture of placental estrogen, ultimately dictating the timing of the onset of labour, but also promotes changes in the fetal lungs needed for breathing air (► Figure 17-30). Recall that CRH is normally secreted by the hypothalamus and regulates the output of ACTH by the anterior pituitary (pp. 231). In turn, ACTH stimulates production of both cortisol and DHEA by the adrenal cortex. In the fetus, much of the CRH comes from the placenta rather than solely

from the fetal hypothalamus. The additional cortisol secretion summoned by the extra CRH promotes fetal lung maturation. Specifically, cortisol stimulates the synthesis of pulmonary surfactant, which facilitates lung expansion and reduces the work of breathing.

The bumped-up rate of DHEA secretion by the adrenal cortex in response to placental CRH leads to the rising levels of placental estrogen secretion. Recall that the placenta converts DHEA from the fetal adrenal gland into estrogen, which enters the maternal bloodstream (see ► Figure 17-29). When sufficiently high, this estrogen sets in motion the events that initiate labour. So pregnancy duration and delivery timing are determined largely by the placenta's rate of CRH production. That is, a “**placental clock**” ticks out the length of time until parturition. The timing of parturition is established early in pregnancy, with delivery at the end point of a maturational process that extends throughout the entire gestation. The ticking of the placental clock is measured by the rate of placental secretion. As the pregnancy progresses, CRH levels in maternal plasma rise. Researchers can accurately predict the timing of parturition by measuring the maternal plasma levels of CRH as early as the end of the first trimester. Higher-than-normal levels are associated with premature deliveries, whereas lower-than-normal levels indicate late deliveries. These and other data suggest that when a critical level of placental CRH is reached, parturition is triggered. This critical CRH level ensures that when labour begins, the infant is ready for life outside the womb. It does so by concurrently increasing the fetal cortisol needed for lung maturation and the estrogen needed for the uterine changes that bring on labour. The remaining unanswered puzzle regarding the placental clock is, what controls placental secretion of CRH?

ROLE OF INFLAMMATION

Surprisingly, recent research suggests that inflammation plays a central role in the labour process, in the onset of both full-term labour and premature labour. Key to this inflammatory response is activation of **nuclear factor $\kappa\beta$ (NF- $\kappa\beta$)** in the uterus. NF- $\kappa\beta$ boosts production of inflammatory cytokines, such as *interleukin 8 (IL-8)*, and prostaglandins that increase the sensitivity of the uterus to contraction-inducing chemical messengers and help soften the cervix. What activates NF- $\kappa\beta$, setting off an inflammatory cascade that helps prompt labour? Various factors associated with the onset of full-term labour and premature labour can cause an upsurge in NF- $\kappa\beta$. These include stretching of the uterine muscle and the presence of the pulmonary surfactant protein SP-A in the amniotic fluid. SP-A promotes the migration of fetal macrophages to the uterus. These macrophages, in turn, produce the inflammatory cytokine *interleukin 1 β (IL-1 β)* that activates NF- $\kappa\beta$. In this way, fetal lung maturation contributes to the onset of labour.

Premature labour can be incited by bacterial infections and allergic reactions that activate NF- $\kappa\beta$. Also, multiple-fetus pregnancies are at risk for premature labour, likely because the increased uterine stretching triggers earlier activation of NF- $\kappa\beta$.

FIGURE 17-30 Initiation and progression of parturition

Parturition and a positive-feedback cycle

Once high levels of estrogen and inflammatory cytokines increase uterine responsiveness to oxytocin to a critical level and regular uterine contractions begin, myometrial contractions progressively increase in frequency, strength, and duration throughout labour until they expel the uterine contents. At the beginning of labour, contractions lasting 30 seconds or less occur about every 25 to 30 minutes; by the end, they last 60 to 90 seconds and occur every 2 to 3 minutes.

As labour progresses, a positive-feedback cycle involving oxytocin and prostaglandin ensues, incessantly increasing myometrial contractions (see > Figure 17-30). Each uterine contraction begins at the top of the uterus and sweeps downward, forcing the fetus toward the cervix. Pressure of the fetus against the cervix does two things. First, the fetal head pushing against the softened cervix wedges open the cervical canal. Second, cervical stretch stimulates the release of oxytocin through a neuroendocrine reflex. Stimulation of receptors in the cervix in response to fetal pressure sends a neural signal up the spinal cord to the hypothalamus, which in turn triggers oxytocin release from the posterior pituitary. This additional oxytocin promotes

more powerful uterine contractions. As a result, the fetus is pushed more forcefully against the cervix, stimulating the release of even more oxytocin, and so on. This cycle is reinforced as oxytocin stimulates prostaglandin production by the decidua. As a powerful myometrial stimulant, prostaglandin further enhances uterine contractions. Oxytocin secretion, prostaglandin production, and uterine contractions continue to increase in positive-feedback fashion throughout labour until delivery relieves the pressure on the cervix.

STAGES OF LABOUR

Labour is divided into three stages: (1) cervical dilation, (2) delivery of the baby, and (3) delivery of the placenta (> Figure 17-31). At the onset of labour or sometime during the first stage, the membrane surrounding the amniotic sac, or “bag of waters,” ruptures. As amniotic fluid escapes out of the vagina, it helps lubricate the birth canal.

- *First stage.* During the first stage, the cervix is forced to dilate to accommodate the diameter of the baby’s head, usually to a maximum of 10 cm. This stage is the longest, lasting from several hours to as long as 24 hours in a first pregnancy.

> **FIGURE 17-31** Stages of labour. (a) Position of the fetus near the end of pregnancy. (b) Stages of labour

If another part of the fetus's body other than the head is oriented against the cervix, it is generally less effective than the head as a wedge. The head has the largest diameter of the baby's body. If the baby approaches the birth canal feet first, the feet may not dilate the cervix enough to let the head pass. In such a case, without medical intervention the baby's head would remain stuck behind the too-narrow cervical opening.

- **Second stage.** The second stage of labour, the actual birth of the baby, begins once cervical dilation is complete. When the infant begins to move through the cervix and vagina, stretch receptors in the vagina activate a neural reflex that triggers contractions of the abdominal wall in synchrony with the uterine contractions. These abdominal contractions greatly increase the force pushing the baby through the birth canal. The mother can help deliver the infant by voluntarily contracting the abdominal muscles at this time in unison with each uterine contraction, that is, by pushing with each labour pain. Stage 2 is usually much shorter than the first stage and lasts 30 to 90 minutes. The infant is still attached to the placenta by the umbilical cord at birth. The cord is tied and severed, with the stump shrivelling up in a few days to form the **umbilicus (navel)**.
- **Third stage.** Shortly after delivery of the baby, a second series of uterine contractions separates the placenta from the myometrium and expels it through the vagina. Delivery of the placenta, or **afterbirth**, constitutes the third stage of labour, typically the shortest stage, being completed within 15 to 30 minutes after the baby is born. After the placenta is expelled, continued contractions of the myometrium constrict the uterine blood vessels supplying the site of placental attachment, to prevent haemorrhage.

UTERINE INVOLUTION

After delivery, the uterus shrinks to its pregestational size, a process known as **involution**, which takes four to six weeks to complete. During involution, the remaining endometrial tissue not expelled with the placenta gradually disintegrates and sloughs off, producing a vaginal discharge called **lochia** that continues for three to six weeks following parturition. After this period, the endometrium is restored to its nonpregnant state.

Involution occurs largely because of the precipitous fall in circulating estrogen and progesterone when the placental source of these steroids is lost at delivery. The process is facilitated in mothers who breastfeed their infants, because oxytocin is released in response to suckling. In addition to playing an important role in lactation, this periodic nursing-induced release of oxytocin promotes myometrial contractions that help maintain uterine muscle tone, enhancing involution. Involution is usually complete in about four weeks in nursing mothers but takes about six weeks in those who do not breastfeed.

Lactation

The female reproductive system supports the new being from the moment of conception through gestation and continues to nourish it during its early life outside the supportive uterine environment. Milk (or its equivalent) is essential for survival

of the newborn. Accordingly, during gestation the **mammary glands (breasts)** are prepared for **lactation** (milk production).

The breasts in nonpregnant females consist mostly of adipose tissue and a rudimentary duct system. Breast size is determined by the amount of adipose tissue, which has nothing to do with the ability to produce milk.

PREPARATION OF THE BREASTS FOR LACTATION

Under the hormonal environment present during pregnancy, the mammary glands develop the internal glandular structure and function necessary for milk production. A breast capable of lactating has a network of progressively smaller ducts that branch out from the nipple and terminate in lobules (▶ Figure 17-32a). Each lobule is made up of a cluster of saclike epithelial-lined, milk-producing glands known as **alveoli**. Milk is synthesized by the epithelial cells, then secreted into the alveolar lumen, which is drained by a milk-collecting duct that transports the milk to the surface of the nipple (▶ Figure 17-32b).

During pregnancy, the high concentration of *estrogen* promotes extensive duct development, whereas the high level of *progesterone* stimulates abundant alveolar-lobular formation. Elevated concentrations of *prolactin* (an anterior pituitary hormone stimulated by the rising levels of estrogen) and *human chorionic somatomammotropin* (a placental hormone that has a structure similar to that of both growth hormone and prolactin) also contribute to mammary gland development by inducing the synthesis of enzymes needed for milk production.

PREVENTION OF LACTATION DURING GESTATION

Most of these changes in the breasts occur during the first half of gestation, so the mammary glands are fully capable of producing milk by the middle of pregnancy. However, milk secretion does not occur until parturition. The high estrogen and progesterone concentrations during the last half of pregnancy prevent lactation by blocking prolactin's stimulatory action on milk secretion. Prolactin is the primary stimulant of milk secretion. Thus, even though the high levels of placental steroids induce the development of the milk-producing machinery in the breasts, they prevent these glands from becoming operational until the baby is born and milk is needed.

The abrupt decline in estrogen and progesterone that occurs with loss of the placenta at parturition initiates lactation.

This completes our discussion of the functions of estrogen and progesterone during gestation and lactation and also throughout the reproductive life of females. These functions are summarized in ■ Table 17-6.

STIMULATION OF LACTATION VIA SUCKLING

- Once milk production begins after delivery, two hormones are critical for maintaining lactation: (1) *prolactin*, which promotes milk secretion, and (2) *oxytocin*, which causes milk ejection. **Milk ejection (milk letdown)** refers to the forced expulsion of milk from the lumen of the alveoli out through the ducts. Release of both of these hormones is stimulated by a neuroendocrine reflex triggered by suckling (▶ Figure 17-33). Let's examine each of these hormones and their roles in further detail.

► **FIGURE 17-32 Mammary gland anatomy.** (a) Internal structure of the mammary gland, lateral view. (b) Schematic representation of the microscopic structure of an alveolus within the mammary gland. The alveolar epithelial cells secrete milk into the lumen. Contraction of the surrounding myoepithelial cells ejects the secreted milk out through the duct.

- **Oxytocin release and milk ejection.** The infant cannot directly suck milk out of the alveolar lumen. Instead, milk must be actively squeezed out of the alveoli into the ducts, and hence toward the nipple, by contraction of specialized myoepithelial cells (muscle-like epithelial cells) that surround each alveolus (see ► Figure 17-32b). The infant's suckling of the breast

TABLE 17-6 Actions of Estrogen and Progesterone

Estrogen

Effects on Sex-Specific Tissues

- Is essential for egg maturation and release
- Stimulates growth and maintenance of entire female reproductive tract
- Stimulates granulosa cell proliferation, which leads to follicle maturation
- Thins the cervical mucus to permit sperm penetration
- Enhances transport of sperm to the oviduct by stimulating upward contractions of the uterus and oviduct
- Stimulates growth of the endometrium and myometrium
- Induces synthesis of endometrial progesterone receptors
- Triggers onset of parturition by increasing uterine responsiveness to oxytocin during late gestation through a twofold effect: by inducing synthesis of myometrial oxytocin receptors and by increasing myometrial gap junctions so that the uterus can contract as a coordinated unit in response to oxytocin

Other Reproductive Effects

- Promotes development of secondary sexual characteristics
- Controls GnRH and gonadotropin secretion
- Low levels inhibit secretion.
- High levels are responsible for triggering LH surge.
- Stimulates duct development in the breasts during gestation
- Inhibits milk-secreting actions of prolactin during gestation

Nonreproductive Effects

- Promotes fat deposition
- Increases bone density
- Closes the epiphyseal plates

Progesterone

- Prepares a suitable environment for nourishment of a developing embryo/fetus
- Promotes formation of a thick mucous plug in cervical canal
- Inhibits hypothalamic GnRH and gonadotropin secretion
- Stimulates alveolar development in the breasts during gestation
- Inhibits milk-secreting actions of prolactin during gestation
- Inhibits uterine contractions during gestation

stimulates sensory nerve endings in the nipple, thereby initiating action potentials that travel up the spinal cord to the hypothalamus. Once activated, the hypothalamus triggers a burst of oxytocin release from the posterior pituitary. Oxytocin, in turn, stimulates contraction of the myoepithelial cells in the breasts to induce milk ejection. Milk letdown continues only as

long as the infant continues to nurse. In this way, the milk-ejection reflex ensures that the breasts release milk only when and in the amount needed by the baby. Even though the alveoli may be full of milk, the milk cannot be released without oxytocin. The reflex can become conditioned to stimuli other than suckling, however. For example, the infant's cry can trigger milk letdown, causing a spurt of milk to leak from the nipples. In contrast, psychological stress, acting through the hypothalamus, can easily inhibit milk ejection. For this reason, a positive attitude toward breastfeeding and a relaxed environment are essential for successful breastfeeding.

- **Prolactin release and milk secretion.** Suckling not only triggers oxytocin release but also stimulates prolactin secretion. Prolactin output by the anterior pituitary is controlled by two hypothalamic secretions: **prolactin-inhibiting hormone (PIH)** and **prolactin-releasing hormone (PRH)**. PIH is now known to be *dopamine*, which also serves as a neurotransmitter in the brain. The chemical nature of PRH has not been identified with certainty, but scientists suspect PRH is *oxytocin* secreted by the hypothalamus into the hypothalamic–hypophyseal portal system to stimulate prolactin secretion by the anterior pituitary (p. 227). This role of oxytocin is distinct from the roles of oxytocin produced by the hypothalamus and stored in the posterior pituitary.

Throughout most of the female's life, PIH is the dominant influence, so prolactin concentrations normally remain low. During lactation, a burst in prolactin secretion occurs each time the infant suckles. Afferent impulses initiated in the nipple on suckling are carried by the spinal cord to the hypothalamus. This reflex ultimately leads to prolactin release by the anterior pituitary, although it is unclear whether this is from inhibition of PIH or stimulation of PRH secretion or both. Prolactin then acts on the alveolar epithelium to promote secretion of milk to replace the ejected milk (► Figure 17-33).

Concurrent stimulation by suckling of both milk ejection and milk production ensures that the rate of milk synthesis keeps pace with the baby's needs for milk. The more the infant nurses, the more milk is removed by letdown and the more milk is produced for the next feeding.

In addition to prolactin, which is the most important factor controlling synthesis of milk, at least four other hormones are essential for their permissive role in ongoing milk production: cortisol, insulin, parathyroid hormone, and growth hormone.

Breastfeeding

Nutritionally, **milk** is composed of water, triglyceride fat, the carbohydrate lactose (milk sugar), a number of proteins, vitamins, and the minerals calcium and phosphate.

► FIGURE 17-33 Suckling reflexes

ADVANTAGES OF BREASTFEEDING FOR THE INFANT

In addition to nutrients, milk contains a host of immune cells, antibodies, and other chemicals that help protect the infant against infection until it can mount an effective immune response on its own a few months after birth. **Colostrum**, the milk produced for the first five days after delivery, contains lower concentrations of fat and lactose but higher concentrations of immunoprotective components. All human babies acquire some passive immunity during gestation by antibodies passing across the placenta from the mother to the fetus (p. 481). These antibodies are short-lived, however, and often do not persist until the infant can fend for itself immunologically. Breastfed babies gain additional protection during this vulnerable period through a variety of mechanisms:

- Breast milk contains an abundance of *immune cells*—both B and T lymphocytes, macrophages, and neutrophils (pp. 446–447)—that produce antibodies and destroy pathogenic

microorganisms outright. These cells are especially plentiful in colostrum.

- *Secretory IgA*, a special type of antibody, is present in great amounts in breast milk. Secretory IgA consists of two IgA antibody molecules joined with a so-called secretory component that helps protect the antibodies from destruction by the infant's acidic gastric juice and digestive enzymes. The collection of IgA antibodies that a breastfed baby receives is specifically aimed against the particular pathogens in the environment of the mother—and, accordingly, of the infant as well. Appropriately, therefore, these antibodies protect against the infectious microbes that the infant is most likely to encounter.
- Some components in mother's milk, such as *mucus*, adhere to potentially harmful microorganisms, preventing them from attaching to and crossing the intestinal mucosa.
- *Lactoferrin* is a breast-milk constituent that thwarts growth of harmful bacteria by decreasing the availability of iron, a mineral needed for multiplication of these pathogens.
- *Bifidus factor* in breast milk, in contrast to lactoferrin, promotes multiplication of the nonpathogenic microorganism *Lactobacillus bifidus* in the infant's digestive tract. Growth of this harmless bacterium helps crowd out potentially harmful bacteria.
- Other components in breast milk promote maturation of the baby's digestive system so that it is less vulnerable to diarrhoea-causing bacteria and viruses.
- Still other factors in breast milk hasten the development of the infant's own immune capabilities.

Thus, breast milk helps protect infants from disease in a variety of ways.

Some studies hint that in addition to the benefits of breast milk during infancy, breastfeeding may reduce the risk of developing certain serious diseases later in life. Examples include allergies (such as asthma), autoimmune diseases (such as type 1 diabetes mellitus), and cancers (such as lymphoma).

Infants who are bottle-fed on a formula made from cow's milk or another substitute do not have the protective advantage provided by human milk and, accordingly, have a higher incidence of infections of the digestive tract, respiratory tract, and ears than breastfed babies do. Also, the digestive system of a newborn is better equipped to handle human milk than a cow milk-derived formula, so bottle-fed babies tend to have more digestive upsets.

ADVANTAGES OF BREASTFEEDING FOR THE MOTHER

Breastfeeding is also advantageous for the mother. Oxytocin release triggered by nursing hastens uterine involution. In addition, suckling suppresses the menstrual cycle by inhibiting LH and FSH secretion, probably by inhibiting GnRH. Lactation, therefore, tends to prevent ovulation, decreasing the likelihood of another pregnancy (although it is not a reliable means of contraception). This mechanism permits all the mother's resources to be directed toward the newborn instead of being shared with a new embryo.

CESSATION OF MILK PRODUCTION AT WEANING

When the infant is weaned, two mechanisms contribute to the cessation of milk production. First, without suckling, prolactin secretion is not stimulated, which removes the main stimulus for continued milk synthesis and secretion. Also, because there is no suckling and thus no oxytocin release, milk letdown does not occur. Because milk production does not immediately shut down, milk accumulates in the alveoli, engorging the breasts. The resulting pressure buildup acts directly on the alveolar epithelial cells to suppress further milk production. Therefore, the cessation of lactation at weaning results from a lack of suckling-induced stimulation of both prolactin and oxytocin secretion.

The end and a new beginning

Reproduction is an appropriate way to end our discussion of physiology from cells to systems. The single cell resulting from the union of male and female gametes divides mitotically and differentiates into a multicellular individual made up of a number of different body systems that interact cooperatively to maintain homeostasis (i.e., stability in the internal environment). All the life-supporting homeostatic processes introduced throughout this book begin all over again at the start of a new life.

Check Your Understanding 17.4

1. Indicate what ovarian hormones are secreted by the follicle and by the corpus luteum, state the effects of these hormones on the uterus, and indicate during which phase of the ovarian cycle each of the phases of the uterine cycle takes place.
2. Define *zygote*, *blastocyst*, *inner cell mass*, *trophoblast*, *decidua*, *chorion*, *placenta*, *embryo*, and *fetus*.
3. Discuss the role of oxytocin during parturition and during breastfeeding.

Chapter in Perspective: Focus on Homeostasis

The reproductive system is unique in that it is not essential for homeostasis or for survival of the individual, but it is essential for sustaining the thread of life from generation to generation. Reproduction depends on the union of male and female gametes (reproductive cells), each with a half set of chromosomes, to form a new individual with a full, unique set of chromosomes. Unlike the other body systems, which are essentially identical in the two sexes, the reproductive systems of males and females are remarkably different, befitting their different roles in the reproductive process.

The male system is designed to continuously produce huge numbers of mobile spermatozoa that are delivered to the female during the sex act. Male gametes must be produced in abundance for two reasons: (1) Only a small percentage of them survive the hazardous journey through the female reproductive tract to the site of fertilization; and (2) the cooperative effort of many spermatozoa is required to

break down the barriers surrounding the female gamete (ovum or egg) to enable one spermatozoon to penetrate and unite with the ovum.

The female reproductive system undergoes complex changes on a cyclic monthly basis. During the first half of the cycle, a single non-motile ovum is prepared for release. During the second half, the reproductive system is geared toward preparing a suitable environment for supporting the ovum if fertilization (union with a spermatozoon) occurs. If fertilization does not occur, the prepared supportive environment within the uterus sloughs off, and the cycle starts over again as a new ovum is prepared for release. If fertilization occurs, the female reproductive system adjusts to support growth and development of the new individual until it can survive on its own on the outside.

There are three important parallels in the male and female reproductive systems, even though they differ considerably in structure and function. First, the same set of undifferentiated reproductive tissues in the embryo can develop into either a male or a female system, depending on the presence or absence, respectively, of male-determining factors. Second, the same hormones—namely, hypothalamic GnRH and anterior pituitary FSH and LH—control reproductive function in both sexes. In both cases, gonadal steroids and inhibin act in negative-feedback fashion to control hypothalamic and anterior pituitary output. Third, the same events take place in the developing gamete's nucleus during sperm formation and egg formation, although males produce millions of sperm in one day, whereas females produce only about 400 ova in a lifetime.

REVIEW EXERCISES

Objective Questions (Answers on p. A-55)

1. It is possible for a genetic male to have the anatomic appearance of a female. (*True or false?*)
2. Testosterone secretion essentially ceases from birth until puberty. (*True or false?*)
3. Prostaglandins are derived from arachidonic acid found in the plasma membrane. (*True or false?*)
4. Females do not experience erection. (*True or false?*)
5. Most of the lubrication for sexual intercourse is provided by the female. (*True or false?*)
6. If a follicle does not reach maturity during one ovarian cycle, it can finish maturing during the next cycle. (*True or false?*)
7. Rising, moderate levels of estrogen inhibit tonic LH secretion, whereas high levels of estrogen stimulate the LH surge. (*True or false?*)
8. Spermatogenesis takes place within the _____ of the testes, stimulated by the hormones _____ and _____.
9. During estrogen production by the follicle, the _____ cells under the influence of the hormone _____ produce androgens, and the _____ cells under the influence of the hormone _____ convert these androgens into estrogens.
10. The source of estrogen and progesterone during the first 10 weeks of gestation is the _____.
11. Detection of _____ in the urine is the basis of pregnancy diagnosis tests.
12. Which statement concerning chromosomal distribution is NOT correct?
 - a. All human somatic cells contain 23 chromosomal pairs for a total diploid number of 46 chromosomes.
 - b. Each gamete contains 23 chromosomes, one member of each chromosomal pair.
 - c. During meiotic division, the members of the chromosome pairs regroup themselves into the original combinations derived from the individual's mother and father for separation into haploid gametes.

- d. Sex determination depends on the combination of sex chromosomes, an XY combination being a genetic male, and XX a genetic female.
 - e. The sex chromosome content of the fertilizing sperm determines the sex of the offspring.
13. What happens when the corpus luteum degenerates?
- a. Circulating levels of estrogen and progesterone rapidly increase.
 - b. FSH and LH secretion start to rise.
 - c. The endometrium thickens.
 - d. Prostaglandins are released by endometrium.

Match the following:

- | | |
|--|------------------------------------|
| _____ 1. secrete(s) prostaglandins | (a) epididymis and ductus deferens |
| _____ 2. increase(s) motility and fertility of sperm | (b) prostate gland |
| _____ 3. secrete(s) an alkaline fluid | (c) seminal vesicles |
| _____ 4. provide(s) fructose | (d) bulbourethral glands |
| _____ 5. storage site for sperm | (e) penis |
| _____ 6. concentrate(s) the sperm a hundredfold | |
| _____ 7. secrete(s) fibrinogen | |
| _____ 8. provide(s) clotting enzymes | |
| _____ 9. contain(s) erectile tissue | |

Using the answer code on the right, indicate when each event takes place during the ovarian cycle:

- | | |
|--|---|
| _____ 1. development of antral follicles | (a) occurs during the follicular phase |
| _____ 2. secretion of estrogen | |
| _____ 3. secretion of progesterone | (b) occurs during the luteal phase |
| _____ 4. menstruation | |
| _____ 5. repair and proliferation of the endometrium | (c) occurs during both the follicular and luteal phases |
| _____ 6. increased vascularization and glycogen storage in the endometrium | |

Written Questions

1. What are the primary reproductive organs, gametes, sex hormones, reproductive tract, accessory sex glands, external genitalia, and secondary sexual characteristics in males and in females?
2. List the essential reproductive functions of the male and of the female.
3. Discuss the differences between males and females with regard to genetic, gonadal, and phenotypic sex.
4. What parts of the male and female reproductive systems develop from each of the following: genital tubercle, urethral folds, genital swellings, Wolffian ducts, and Müllerian ducts?
5. Of what functional significance is the scrotal location of the testes?
6. Discuss the source and functions of testosterone.
7. Describe the three major stages of spermatogenesis. Discuss the functions of each part of a spermatozoon. What are the roles of Sertoli cells?
8. Discuss the control of testicular function.
9. Compare the sex act in males and females.
10. Compare oogenesis with spermatogenesis.
11. Describe the events of the follicular and luteal phases of the ovarian cycle. Correlate the phases of the uterine cycle with those of the ovarian cycle.
12. How are the ovum and spermatozoa transported to the site of fertilization? Describe the process of fertilization.
13. Describe the process of implantation and placenta formation.
14. What are the functions of the placenta? What hormones does the placenta secrete?
15. What is the role of human chorionic gonadotropin?
16. What factors contribute to the initiation of parturition? What are the stages of labour? What is the role of oxytocin?
17. Describe the hormonal factors that play a role in lactation.
18. Summarize the actions of estrogen and progesterone.

POINTS TO PONDER

(Explanations on p. A-55)

1. The hypothalamus releases GnRH in pulsatile bursts once every two to three hours, with no secretion occurring in between. The blood concentration of GnRH depends on the frequency of these bursts of secretion. A promising line of research for a new method of contraception involves administration of GnRH-like drugs. In what way could such drugs act as contraceptives when GnRH is the hypothalamic hormone that triggers the chain of events leading to ovulation? (*Hint: The anterior pituitary is programmed to respond only to the normal pulsatile pattern of GnRH.*)
2. Occasionally, testicular tumours composed of interstitial cells of Leydig may secrete up to 100 times the normal amount of testosterone. When such a tumour develops in young children, they grow up much shorter than their genetic potential. Explain why. What other symptoms would be present?
3. What type of sexual dysfunction might arise in men taking drugs that inhibit sympathetic nervous system activity as part of the treatment for high blood pressure?
4. Explain the physiological basis for administering a posterior pituitary extract to induce or facilitate labour.
5. The symptoms of menopause are sometimes treated with supplemental estrogen and progesterone. Why wouldn't treatment with GnRH or FSH and LH also be effective?

CLINICAL CONSIDERATION

(Explanation on p. A-55)

Maria A., who is in her second month of gestation, has been experiencing severe abdominal cramping. Her physician has diagnosed her condition as a tubal pregnancy: the developing embryo is implanted in the oviduct instead of in the uterine endometrium. Why must this pregnancy be surgically terminated?

A Review of Chemical Principles

By Spencer Seager, Weber State University, and Lauralee Sherwood

B.1 | Chemical Level of Organization in the Body

Matter is anything that occupies space and has mass, including all living and nonliving things in the universe. *Mass* is the amount of matter in an object. *Weight*, in contrast, is the effect of gravity on that mass. The more gravity exerted on a mass, the greater the weight of the mass. An astronaut has the same mass whether on Earth or in space, but is weightless in the zero gravity of space.

Atoms

All matter is made up of tiny particles called *atoms*. These particles are too small to be seen individually, even with the most powerful electron microscopes available today.

Although atoms are extremely small, they consist of three types of even smaller subatomic particles. Different types of atoms vary in the number of these various subatomic particles they contain. *Protons* and *neutrons* are particles of nearly identical mass: protons carry a positive charge and neutrons have no charge. *Electrons* have a much smaller mass than protons and neutrons and are negatively charged. An atom consists of two regions—a dense, central *nucleus* made of protons and neutrons surrounded by a three-dimensional *electron cloud*, where electrons move rapidly around the nucleus in orbitals (▶Figure B-1). The magnitude of the charge of a proton exactly matches that of an electron, but it is opposite in sign, being positive. In all atoms, the number of protons in the nucleus is equal to the number of electrons moving around the nucleus, so their charges balance, and the atoms are neutral.

Elements and atomic symbols

A pure substance composed of only one type of atom is called an **element**. A pure sample of the element carbon contains only carbon atoms, even though the atoms might be arranged in the form of diamond or in the form of graphite (pencil lead). Each element is designated by an **atomic symbol**, a one- or two-letter chemical shorthand for the element's name. Usually these symbols are easy to follow, because they are derived from the English name for the element. Thus, H stands for *hydrogen*, C for *carbon*, and O for *oxygen*. In a few cases, the atomic symbol is based on

▶ **FIGURE B-1 The atom.** The atom consists of two regions. The central nucleus contains protons and neutrons and makes up 99.9 percent of the mass. Surrounding the nucleus is the electron cloud, where the electrons move rapidly around the nucleus. (Figure not drawn to scale.)

the element's Latin name—for example, Na for *sodium* (*natrium* in Latin) and K for *potassium* (*kalium*). Of the 109 known elements, 26 are normally found in the body. Four elements—oxygen, carbon, hydrogen, and nitrogen—compose 96 percent of the body's mass.

Compounds and molecules

Pure substances composed of more than one type of atom are known as **compounds**. Pure water, for example, is a compound that contains atoms of hydrogen and atoms of oxygen in a 2-to-1 ratio, regardless of whether the water is in the form of liquid, solid (ice), or vapour (steam). A **molecule** is the smallest unit of a pure substance that has the properties of that substance and is capable of a stable, independent existence. For example, a molecule of water consists of two atoms of hydrogen and one atom of oxygen, held together by chemical bonds.

Atomic number

Exactly what are we talking about when we refer to a “type” of atom? That is, what makes carbon, hydrogen, and oxygen atoms different? The answer is the number of protons in the nucleus. Regardless of where they are found, all hydrogen

atoms have one proton in the nucleus, all carbon atoms have six, and all oxygen atoms have eight. Of course, these numbers also represent the number of electrons moving around each nucleus, because the number of electrons and number of protons in an atom are equal. The number of protons in the nucleus of an atom of an element is called the **atomic number** of the element.

Atomic weight

As expected, tiny atoms have tiny masses. For example, the actual mass of a hydrogen atom is 1.67×10^{-24} g, that of a carbon atom is 1.99×10^{-23} g, and that of an oxygen atom is 2.66×10^{-23} g. These very small numbers are inconvenient to work with in calculations, so a system of relative masses has been developed. These relative masses simply compare the actual masses of the atoms with each other. Suppose the actual masses of two people were determined to be 45.50 kg and 113.75 kg. Their relative masses are then determined by dividing each mass by the smaller mass of the two: $45.50/45.50 = 1.00$, and $113.75/45.50 = 2.50$. Thus, the relative masses of the two people are 1.00 and 2.50; these numbers simply express the fact that the mass of the heavier person is 2.50 times that of the other person. The relative masses of atoms are called *atomic masses*, or *atomic weights*, and are given in *atomic mass units (amu)*. In this system, hydrogen atoms, the least massive of all atoms, have an atomic weight of 1.01 amu. The atomic weight of carbon atoms is 12.01 amu, and that of oxygen atoms is 16.00 amu. Thus, oxygen atoms have a mass about 16 times that of hydrogen atoms. ■ Table B-1 gives the atomic weights and some other characteristics of the elements that are most important physiologically.

■ **TABLE B-1** Characteristics of Selected Elements

Name and Symbol	Number of Protons	Atomic Number	Atomic Weight (amu)
Hydrogen (H)	1	1	1.01
Carbon (C)	6	6	12.01
Nitrogen (N)	7	7	14.01
Oxygen (O)	8	8	16.00
Sodium (Na)	11	11	22.99
Magnesium (Mg)	12	12	24.31
Phosphorus (P)	15	15	30.97
Sulphur (S)	16	16	32.06
Chlorine (Cl)	17	17	35.45
Potassium (K)	19	19	39.10
Calcium (Ca)	20	20	40.08

B.2 | Chemical Bonds

Because all matter is made up of atoms, atoms must somehow be held together to form matter. The forces holding atoms together are called *chemical bonds*. Not all chemical bonds are formed in the same way, but all involve the electrons of atoms. Whether one atom will bond with another depends on the number and arrangement of its electrons. An atom's electrons are arranged in electron shells, to which we now turn our attention.

Electron shells

Electrons tend to move around the nucleus in a specific pattern. The orbitals, or pathways, travelled by electrons around the nucleus, are arranged in an orderly series of concentric layers known as *electron shells*, which consecutively surround the nucleus. Each electron shell can hold a specific number of electrons. The first (innermost) shell closest to the nucleus can contain a maximum of only two electrons, no matter what the element is. The second shell can hold a total of eight more electrons. The third, fourth, and fifth shells can hold 18, 32, and 50 electrons, respectively. However, it is important to note that atoms are most stable when the outer shell contains only eight electrons, an exception of course are atoms with only one outer shell. As the number of electrons increases with increasing atomic number, still more electrons occupy successive shells, each at a greater distance from the nucleus. Each successive shell from the nucleus has a higher *energy level*. Because the negatively charged electrons are attracted to the positively charged nucleus, it takes more energy for an electron to overcome the nuclear attraction and orbit farther from the nucleus. Therefore, the first electron shell has the lowest energy level and the outermost shell of an atom has the highest energy level.

In general, electrons belong to the lowest energy shell possible, up to the maximum capacity of each shell. For example, hydrogen atoms have only one electron, so it is in the first shell. Helium atoms have two electrons, which are both in the first shell and fill it. Carbon atoms have six electrons, two in the first shell and four in the second shell, whereas the eight electrons of oxygen are arranged with two in the first shell and six in the second shell.

Bonding characteristics of an atom and valence

Atoms tend to undergo processes that result in a filled outermost electron shell. So the electrons of the outer or higher-energy shell determine the bonding characteristics of an atom and its ability to interact with other atoms. Atoms that have a vacancy in their outermost shell tend to either give up, accept, or share electrons with other atoms (whichever is most favourable energetically) so that all participating atoms have filled outer shells. For example, an atom that has only one electron in its outermost shell may empty this shell so its remaining shells are completely full. By contrast, another atom that lacks only one electron in its outer shell may acquire the deficient electron from the first atom to fill all its shells to the maximum. The number of electrons an atom loses, gains, or shares to achieve a filled outer shell is known as

© 2016 Cengage

► **FIGURE B-2 Ions and ionic bonds.** Sodium (Na) and chlorine (Cl) atoms both have partially filled outermost shells. Therefore, sodium tends to give up its lone electron in the outer shell to chlorine. As a result, sodium becomes a positively charged ion, and chlorine becomes a negatively charged ion known as chloride. The oppositely charged ions attract each other, forming an ionic bond.

the atom's *valence*. A *chemical bond* is the force of attraction that holds participating atoms together as a result of an interaction between their outermost electrons.

Consider sodium atoms (Na) and chlorine atoms (Cl) (►Figure B-2). Sodium atoms have 11 electrons: 2 in the first shell, 8 in the second shell, and 1 in the third shell. Chlorine atoms have 17 electrons: 2 in the first shell, 8 in the second shell, and 7 in the third shell. Because 8 electrons are required to fill the second shell, sodium atoms have 1 electron more than is needed to provide a filled second shell, whereas chlorine atoms have 1 less electron than is needed to have 8 electrons in the third shell. Each sodium atom can lose an electron to a chlorine atom, leaving each sodium with 10 electrons, 8 of which are in the second shell, which is full and is now the outer shell occupied by electrons. By accepting 1 electron, each chlorine atom now has a total of 18 electrons, with 8 of them in the third, which increases its stability.

Ions and ionic bonds

Recall that atoms are electrically neutral because they have an identical number of positively charged protons and negatively charged electrons. By giving up and accepting electrons, the sodium atoms and chlorine atoms have achieved filled outer shells, but now each atom is unbalanced electrically. Although each sodium now has 10 electrons, it still has 11 protons in the nucleus and a net electrical charge, or *valence*, of +1. Similarly, each chlorine now has 18 electrons, but only 17 protons. Thus each chlorine has a -1 charge. Such charged atoms are called *ions*. Positively charged ions are called *cations*; negatively charged ions are called *anions*. As a helpful hint to keep these terms straight, imagine the “t” in *cation* as standing for a “+” sign and the first “n” in *anion* as standing for “negative.”

Note that both a cation and anion are formed whenever an electron is transferred from one atom to another. Because opposite charges attract, sodium ions (Na^+) and charged chlorine atoms, now called *chloride ions* (Cl^-), are attracted toward each other. This electrical attraction that holds cations and anions together is known as an *ionic bond*. Ionic bonds hold Na^+ and Cl^- together in the compound *sodium chloride* (NaCl), which is common table salt. A sample of sodium chloride actually

contains sodium and chloride ions in a three-dimensional geometric arrangement called a *crystal lattice*. The ions of opposite charge occupy alternate sites within the lattice (►Figure B-3).

Covalent bonds

It is not favourable, energywise, for an atom to give up or accept more than three electrons. Nevertheless, carbon atoms, which have four electrons in their outer shell, form compounds. They do so by another bonding mechanism, *covalent bonding*. Atoms that would have to lose or gain four or more electrons to achieve outer-shell stability usually bond by *sharing* electrons. Shared electrons actually orbit around *both* atoms. Thus a carbon atom can share its four outer electrons with the four electrons of four hydrogen atoms, as shown in Equation B-1, where the outer-shell electrons are shown as dots around the symbol of each atom. (The resulting compound is methane, CH_4 , a gas made up of individual CH_4 molecules.)

© 2016 Cengage

► **FIGURE B-3** Crystal lattice for sodium chloride (table salt)

Each electron that is shared by two atoms is counted toward the number of electrons needed to fill the outer shell of each atom. Thus, each carbon atom shares four pairs, or eight electrons, and so has eight in its outer shell. Each hydrogen shares one pair, or two electrons, and so has a filled outer shell. (Remember, hydrogen atoms need only two electrons to complete their outer shell, which is the first shell.) The sharing of a pair of electrons by atoms binds them together by means of a *covalent bond* (► Figure B-4). Covalent

bonds are the strongest of chemical bonds; that is, they are the hardest to break.

Covalent bonds also form between some identical atoms. For example, two hydrogen atoms can complete their outer shells by sharing one electron pair made from the single electrons of each atom, as shown in Equation B-2:

Therefore, hydrogen gas consists of individual H_2 molecules (► Figure B-4a). (A subscript following a chemical symbol indicates the number of that type of atom present in the molecule.) Several

other nonmetallic elements also exist as molecules, because covalent bonds form between identical atoms; oxygen (O_2) is an example (► Figure B-4b).

Often, an atom can form covalent bonds with more than one atom. One of the most familiar examples is water (H_2O), consisting of two hydrogen atoms each forming a single covalent bond with one oxygen atom (► Figure B-4c). Equation B-3 represents the formation of water's covalent bonds:

The water molecule is sometimes represented as

where the nonshared electron pairs are not shown and the covalent bonds, or shared pairs, are represented by dashes.

Nonpolar and polar molecules

The electrons between two atoms in a covalent bond are not always shared equally. When the atoms sharing an electron pair are identical, such as two oxygen atoms, the electrons are attracted equally by both atoms and are therefore shared equally. The result is a *nonpolar molecule*. The term *nonpolar* implies no difference at the two ends (the two poles) of the bond. Because both atoms within the molecule exert the same pull on the shared

► **FIGURE B-4 A covalent bond.** A covalent bond is formed when atoms that share a pair of electrons are both attracted toward the shared pair.

electrons, each shared electron spends the same amount of time orbiting each atom. So both atoms remain electrically neutral in a nonpolar molecule such as O₂.

When the sharing atoms are not identical, unequal sharing of electrons occurs, because atoms of different elements do not exert the same pull on shared electrons. For example, an oxygen atom strongly attracts electrons when it is bonded to other atoms. A *polar molecule* results from the unequal sharing of electrons between different types of atoms covalently bonded together. The water molecule is a good example of a polar molecule. The oxygen atom pulls the shared electrons more strongly than do the hydrogen atoms within each of the two covalent bonds. Consequently, the electron of each hydrogen atom tends to spend more time away orbiting around the oxygen atom than at home around the hydrogen atom. Because of this nonuniform distribution of electrons, the oxygen side of the water molecule where the shared electrons spend more time is slightly negative, and the two hydrogens that are visited less frequently by the electrons are slightly more positive (▶ Figure B-5). Note that the entire water molecule has the same number of electrons as it has protons, and so as a whole has no net charge. This is unlike ions, which have an electron excess or deficit. Polar molecules have a balanced number of protons and electrons but an unequal distribution of the shared electrons among the atoms making up the molecule.

Hydrogen bonds

Polar molecules are attracted to other polar molecules. In water, for example, an attraction exists between the positive hydrogen ends of some molecules and the negative oxygen ends of others. Hydrogen is not a part of all polar molecules, but when it is covalently bonded to an atom that strongly attracts electrons to form a covalent molecule, the attraction of the positive (hydrogen) end of the polar molecule to the negative end of another polar molecule is called a *hydrogen bond* (▶ Figure B-6). Thus, the polar attractions of water molecules to each other are an example of hydrogen bonding.

▶ **FIGURE B-5 A polar molecule.** A water molecule is an example of a polar molecule, in which the distribution of shared electrons is not uniform. Because the oxygen atom pulls the shared electrons more strongly than the hydrogen atoms do, the oxygen side of the molecule is slightly negatively charged, and the hydrogen sides are slightly positively charged.

▶ **FIGURE B-6 A hydrogen bond.** A hydrogen bond is formed by the attraction of a positively charged hydrogen end of a polar molecule to the negatively charged end of another polar molecule.

B.3 Chemical Reactions

Processes in which chemical bonds are broken and/or formed are called *chemical reactions*. Reactions are represented by equations in which the reacting substances (*reactants*) are typically written on the left, the newly produced substances (*products*) are written on the right, and an arrow meaning “yields” points from the reactants to the products. These conventions are illustrated in Equation B-4:

Balanced equations

A chemical equation is a “chemical bookkeeping” ledger that describes what happens in a reaction. By the *law of conservation of mass*, the total mass of all materials entering a reaction equals the total mass of all the products. Thus, the total number of atoms of each element must always be the same on the left and right sides of the equation, because no atoms are lost. Such equations in which the same number of atoms of each type appear on both sides are called *balanced equations*. When writing a balanced equation, the number *preceding* a chemical symbol designates the number of independent (unjoined) atoms, ions, or molecules of that type, whereas a number written as a subscript *following* a chemical symbol denotes the number of a particular atom within a molecule. The absence of a number indicates *one* of that particular chemical. Let’s look at a specific example, the oxidation of glucose (the sugar that cells use as fuel), as shown in Equation B-5:

According to this equation, one molecule of glucose reacts with six molecules of oxygen to produce six molecules of carbon

dioxide and six molecules of water. Note the following balance in this reaction:

- 6 carbon atoms on the left (in 1 glucose molecule) and 6 carbon atoms on the right (in 6 carbon dioxide molecules)
- 12 hydrogen atoms on the left (in 1 glucose molecule) and 12 on the right (in 6 water molecules, each containing 2 hydrogen atoms)
- 18 oxygen atoms on the left (6 in 1 glucose molecule plus 12 more in the 6 oxygen molecules) and 18 on the right (12 in 6 carbon dioxide molecules, each containing 2 oxygen atoms, and 6 more in the 6 water molecules, each containing 1 oxygen atom)

Reversible and irreversible reactions

Under appropriate conditions, the products of a reaction can be changed back to the reactants. For example, carbon dioxide gas dissolves in and reacts with water to form carbonic acid, H_2CO_3 :

Carbonic acid is not very stable, however, and as soon as some is formed, part of it decomposes to give carbon dioxide and water:

Reactions that go in both directions are called *reversible reactions*. They are usually represented by double arrows pointing in both directions:

Theoretically, every reaction is reversible. Often, however, conditions are such that a reaction, for all practical purposes, goes in only one direction; such a reaction is called *irreversible*. For example, an irreversible reaction takes place when an explosion occurs, because the products do not remain in the vicinity of the reaction site to get together to react.

Catalysts and enzymes

The rates (speeds) of chemical reactions are influenced by a number of factors, of which catalysts are one of the most important. A *catalyst* is a “helper” molecule that speeds up a reaction without being used up in the reaction. Living organisms use catalysts known as *enzymes*. These enzymes exert amazing influence on the rates of chemical reactions that take place in the organisms. Reactions that take weeks or even months to occur under normal laboratory conditions take place in seconds under the influence of enzymes in the body. One of the fastest-acting enzymes is *carbonic anhydrase*, which catalyzes the reaction between carbon dioxide and water to form carbonic acid. This reaction is important in the transport of carbon dioxide from tissue cells, where it is produced metabolically, to the lungs, where it is excreted. The equation for the reaction is shown in Equation B-6. Each molecule of carbonic anhydrase catalyzes the conversion of 36 million CO_2 molecules per minute! Enzymes are important in essentially every chemical reaction that takes place in living organisms.

B.4 Molecular and Formula Weight and the Mole

Because molecules are made up of atoms, the relative mass of a molecule is simply the sum of the relative masses (atomic weights) of the atoms found in the molecule. The relative masses of molecules are called *molecular masses* or *molecular weights*. The molecular weight of water (H_2O) is the sum of the atomic weights of two hydrogen atoms and one oxygen atom, or $1.01 \text{ amu} + 1.01 \text{ amu} + 16.00 \text{ amu} = 18.02 \text{ amu}$.

Not all compounds exist in the form of molecules. Ionically bonded substances such as sodium chloride consist of three-dimensional arrangements of sodium ions (Na^+) and chloride ions (Cl^-) in a 1-to-1 ratio. The formulas for ionic compounds reflect only the ratio of the ions in the compound and should not be interpreted in terms of molecules. Thus, the formula for sodium chloride (NaCl) indicates that the ions combine in a 1-to-1 ratio. It is convenient to apply the concept of relative masses to ionic compounds even though they do not exist as molecules. The *formula weight* for such compounds is defined as the sum of the atomic weights of the atoms found in the formula. Thus, the formula weight of NaCl is equal to the sum of the atomic weights of one sodium atom and one chlorine atom— $22.99 \text{ amu} + 35.45 \text{ amu} = 58.44 \text{ amu}$.

As you have seen, chemical reactions can be represented by equations and discussed in terms of numbers of molecules, atoms, and ions reacting with each other. To carry out reactions in the laboratory, however, a scientist cannot count out numbers of reactant particles but instead must be able to weigh out the correct amount of each reactant. Using the mole concept makes this task possible. A *mole* (abbreviated *mol*) of a pure element or compound is the amount of material contained in a sample of the pure substance that has a mass in grams equal to the substance’s atomic weight (for elements) or the molecular weight or formula weight (for compounds). Thus, 1 mol of potassium (K) would be a sample of the element with a mass of 39.10 g. Similarly, 1 mol of H_2O would have a mass of 18.02 g, and 1 mol of NaCl would be a sample with a mass of 58.44 g.

The fact that atomic weights, molecular weights, and formula weights are relative masses leads to a fundamental characteristic of moles. One mole of oxygen atoms has a mass of 16.00 g, and 1 mol of hydrogen atoms has a mass of 1.01 g. Thus, the ratio of the masses of 1 mol of each element is $16.00/1.01$, the same as the ratio of the atomic weights for the two elements. Recall that these atomic weights compare the relative masses of oxygen and hydrogen. Accordingly, the number of oxygen atoms present in 16 g of oxygen (1 mol of oxygen) is the same as the number of hydrogen atoms present in 1.01 g of hydrogen. Therefore, 1 mol of oxygen contains exactly the same number of oxygen atoms as the number of hydrogen atoms in 1 mol of hydrogen. Thus, it is possible and sometimes useful to think of a mole as a specific number of particles. This number, called *Avogadro’s number*, is equal to 6.02×10^{23} .

B.5 | Solutions, Colloids, and Suspensions

In contrast to a compound, a *mixture* consists of two or more types of elements or molecules physically blended together (intermixed) instead of being linked by chemical bonds. A compound has very different properties from the individual elements of which it is composed. For example, the solid, white NaCl (table salt) crystals you use to flavour your food are very different from either sodium (a silvery white metal) or chlorine (a poisonous yellow-green gas found in bleach). By comparison, each component of a mixture retains its own chemical properties. If you mix salt and sugar together, each retains its own distinct taste and other individual properties. The constituents of a compound can only be separated by chemical means—bond breakage. By contrast, the components of a mixture can be separated by physical means, such as filtration or evaporation. The most common mixtures in the body are mixtures of water and various other substances. These mixtures are categorized as *solutions*, *colloids*, or *suspensions*, depending on the size and nature of the substance mixed with water.

Solutions

Most chemical reactions in the body take place between reactants that have dissolved to form solutions. *Solutions* are homogenous mixtures containing a relatively large amount of one substance called the *solvent* (the dissolving medium) and smaller amounts of one or more substances called *solutes* (the dissolved particles). Salt water, for example, contains mostly water, which is thus the solvent, and a smaller amount of salt, which is the solute. Water is the solvent in most solutions found in the human body.

Electrolytes and nonelectrolytes

When ionic solutes are dissolved in water to form solutions, the resulting solution will conduct electricity. This is not true for most covalently bonded solutes. For example, a salt–water solution conducts electricity, but a sugar–water solution does not. When salt dissolves in water, the solid lattice of Na^+ and Cl^- is broken down, and the individual ions are separated and distributed uniformly throughout the solution. These mobile, charged ions conduct electricity through the solution. Solute that form ions in solution and conduct electricity are called *electrolytes*. Some very polar covalent molecules also behave this way. When sugar dissolves, however, individual covalently bonded sugar molecules become uniformly distributed throughout the solution. These uncharged molecules cannot conduct a current. Solute that do not form conductive solutions are called *nonelectrolytes*.

Measures of concentration

The amount of solute dissolved in a specific amount of solution can vary. For example, a salt–water solution might contain 1 g

of salt in 100 mL of solution, or it could contain 10 g of salt in 100 mL of solution. Both solutions are salt–water solutions, but they have different concentrations of solute. The *concentration* of a solution indicates the relationship between the amount of solute and the amount of solution. Concentrations can be given in a number of different units.

MOLARITY/MOLALITY

Concentrations given in terms of *molarity* (M) give the number of moles of solute in exactly 1 L of solution. Thus, a half molar (0.5 M) solution of NaCl would contain one-half mole, or 29.22 g, of NaCl in each litre of solution. In contrast, *molality* (m) gives the number of moles of solute in 1 kg of solvent. Converting between molality and molarity requires that you know the density of the solute. When using water as a solvent this conversion is quite simple: at room temperature, 1 kg of water occupies a volume of 1 L, meaning the molarity and molality are essentially equal. Another common laboratory solvent is dimethylsulphoxide, which has a density of 1.100 kg/L. Considering this solvent, a 1 M solution would be 0.909 m .

NORMALITY

When the solute is an electrolyte, it is sometimes useful to express the concentration of the solution in a unit that gives information about the amount of ionic charge in the solution. This is done by expressing concentration in terms of *normality* (N). The normality of a solution gives the number of equivalents of solute in exactly 1 L of solution. An *equivalent* of an electrolyte is the amount that produces 1 mol of positive (or negative) charges when it dissolves. The number of equivalents of an electrolyte can be calculated by multiplying the number of moles of electrolyte by the total number of positive charges produced when one formula unit of the electrolyte dissolves. Consider NaCl and calcium chloride (CaCl_2) as examples. The ionization reactions for one formula unit of each solute are as follows:

Thus, 1 mol of NaCl produces 1 mol of positive charges (Na^+) and so contains 1 equivalent:

$$(1 \text{ mol NaCl})(1) = 1 \text{ equivalent}$$

where the number 1 used to multiply the 1 mol of NaCl came from the +1 charge on Na^+ .

One mole of CaCl_2 produces 1 mol of Ca^{2+} , which is 2 mol of positive charge. Thus 1 mol of CaCl_2 contains 2 equivalents:

$$(1 \text{ mol CaCl}_2)(2) = 2 \text{ equivalents}$$

where the number 2 used in the multiplication came from the +2 charge on Ca^{2+} .

If two solutions were made such that one contained 1 mol of NaCl per litre and the other contained 1 mol of CaCl_2 per litre, the NaCl solution would contain 1 equivalent of solute per litre and would be 1 normal (1 N). The CaCl_2 solution would contain 2 equivalents of solute per litre and would be 2 normal (2 N).

OSMOLARITY/OSMOLALITY

Another expression of concentration frequently used in physiology is *osmolarity* (*osm*), which indicates the total *number* of solute particles in a litre of solution, instead of the relative weights of the specific solutes. The osmolarity of a solution is the product of *M* and *n*, where *n* is the number of moles of solute particles obtained when 1 mol of solute dissolves. Because nonelectrolytes such as glucose do not dissociate in solution, *n* = 1 and the osmolarity (*n* × *M*) is equal to the molarity of the solution. For electrolyte solutions, the osmolarity exceeds the molarity by a factor equal to the number of ions produced on dissociation of each molecule in solution. For example, because a NaCl molecule dissociates into two ions, Na⁺ and Cl⁻, the osmolarity of a 1 M solution of NaCl is 2 × 1 M = 2 osm. As you saw with molarity and molality, this method of expressing concentration can also be reported as the number of osmoles of solute relative to the weight of the solvent, in which case it is called *osmolality*, with the units osm/kg.

Colloids and suspensions

In solutions, solute particles are ions or small molecules. By contrast, the particles in colloids and suspensions are much larger than ions or small molecules. In colloids and suspensions, these particles are known as *dispersed-phase particles* instead of solutes. When the dispersed-phase particles are no more than about 100 times the size of the largest solute particles found in a solution, the mixture is called a *colloid*. The dispersed-phase particles of colloids generally do not settle out. All dispersed-phase particles of colloids carry electrical charges of the same sign. So they repel each other. The constant buffeting from these collisions keeps the particles from settling. The most abundant colloids in the body are small functional proteins dispersed in the body fluids. An example is the colloidal dispersion of the plasma proteins in the blood (p. 435).

When dispersed-phase particles are larger than those in colloids, if the mixture is left undisturbed the particles will settle out because of the force of gravity. Such mixtures are usually called *suspensions*. The major example of a suspension in the body is the mixture of blood cells suspended in the plasma. The constant movement of blood as it circulates through the blood vessels keeps the blood cells rather evenly dispersed within the plasma. However, if a blood sample is placed in a test tube and treated to prevent clotting, the heavier blood cells gradually settle to the bottom of the tube.

B.6 | Inorganic and Organic Chemicals

Chemicals are commonly classified into two categories: inorganic and organic.

Distinction between inorganic and organic chemicals

The original criterion used for this classification was the origin of the chemicals. Those that came from living or once-living

sources were called *organic*, and those that came from other sources were *inorganic*. Today, the basis for classification is the element carbon. *Organic* chemicals are generally those that contain carbon. All others are classified as *inorganic*. A few carbon-containing chemicals are also classified as inorganic; the most common are pure carbon in the form of diamond and graphite, carbon dioxide (CO₂), carbon monoxide (CO), carbonates such as limestone (CaCO₃), and bicarbonates such as baking soda (NaHCO₃).

The unique ability of carbon atoms to bond to each other and form networks of carbon atoms results in an interesting fact. Even though organic chemicals all contain carbon, scientists have identified millions of these compounds. Some have been isolated from natural plant or animal sources, and many have been synthesized in laboratories. Inorganic chemicals include all the other 108 elements and their compounds. The number of known inorganic chemicals composed of all these other elements is estimated to be about 250 000, compared to millions of organic compounds composed predominantly of carbon.

Monomers and polymers

Another result of carbon's ability to bond to itself is the large size of some organic molecules. Organic molecules range in size from methane (CH₄), a small, simple molecule with one carbon atom, to molecules such as DNA that contain as many as a million carbon atoms. Organic molecules that are essential for life are called *biological molecules*, or *biomolecules* for short. Some biomolecules are rather small organic compounds, including *simple sugars*, *fatty acids*, *amino acids*, and *nucleotides*. These small, single units, known as *monomers* (meaning "single unit"), are building blocks for the synthesis of larger biomolecules, including *complex carbohydrates*, *lipids*, *proteins*, and *nucleic acids*, respectively. These larger organic molecules are called *polymers* (meaning "many units"), reflecting the fact that they are made by the bonding together of a number of smaller monomers. For example, starch is formed by linking many glucose molecules together. Very large organic polymers are often referred to as *macromolecules*, reflecting their large size (*macro* means "large"). Macromolecules include many naturally occurring molecules, such as DNA and structural proteins, as well as many molecules that are synthetically produced, such as synthetic textiles (e.g., nylon) and plastics.

B.7 | Acids, Bases, and Salts

Acids, bases, and salts may be inorganic or organic compounds.

Acids and bases

Acids and bases are chemical opposites, and salts are produced when acids and bases react with each other. In 1887, Swedish chemist Svante Arrhenius proposed a theory defining acids and bases. He said that an *acid* is any substance that will dissociate, or break apart, when dissolved in water and, in the process, release a hydrogen ion (H⁺). Similarly, *bases* are substances that dissociate when dissolved in water and, in the process, release

a hydroxyl ion (OH^-). Hydrogen chloride (HCl) and sodium hydroxide (NaOH) are examples of Arrhenius acids and bases; their dissociations in water are represented in Equations B-11 and B-12, respectively:

Note that the hydrogen ion is a bare proton, the nucleus of a hydrogen atom. Also note that both HCl and NaOH would behave as electrolytes.

Arrhenius did not know that free hydrogen ions cannot exist in water. They covalently bond to water molecules to form hydronium ions, as shown in Equation B-13:

In 1923, Johannes Brønsted in Denmark and Thomas Lowry in England proposed an acid–base theory that took this behaviour into account. They defined an *acid* as any hydrogen-containing substance that donates a proton (hydrogen ion) to another substance (an acid is a *proton donor*) and a *base* as any substance that accepts a proton (a base is a *proton acceptor*). According to these definitions, the acidic behaviour of HCl given in Equation B-11 is rewritten as shown in Equation B-14:

Note that this reaction is reversible, and the hydronium ion is represented as H_3O^+ . In Equation B-14, the HCl acts as an acid in the forward reaction (left to right), whereas water acts as a base. In the reverse reaction (right to left), the hydronium ion gives up a proton and thus is an acid, whereas the chloride ion, Cl^- , accepts the proton and so is a base. It is still a common practice to use equations such as B-11 to simplify the representation of the dissociation of an acid, even though scientists recognize that equations like B-14 are more correct.

Salts and neutralization reactions

At room temperature, *inorganic salts* are crystalline solids that contain the positive ion (cation) of an Arrhenius base such as NaOH and the negative ion (anion) of an acid such as HCl . Salts can be produced by mixing solutions of appropriate acids and bases, allowing a neutralization reaction to occur. In *neutralization reactions*, the acid and base react to form a salt and water. Most salts that form are water soluble and can be recovered by evaporating the water. Equation B-15 is a neutralization reaction:

When acids or bases are used as solutes in solutions, the concentrations can be expressed as normalities just as they were earlier for salts. An equivalent of acid is the amount that gives up 1 mol of H^+ in solution. Thus, 1 mol of HCl is also 1 equivalent, but 1 mol of H_2SO_4 is 2 equivalents. Bases are described in a similar way, but an equivalent is the amount of base that gives 1 mol of OH^- .

See Chapter 14 for a discussion of acid–base balance in the body.

B.8 | Functional Groups of Organic Molecules

Organic molecules consist of carbon and one or more additional elements covalently bonded to one another in “Tinkertoy” fashion. The simplest organic molecules, *hydrocarbons*, such as methane and petroleum products, have only hydrogen atoms attached to a carbon backbone of varying lengths. All biomolecules always have additional elements besides hydrogen added to the carbon backbone. The carbon backbone forms the stable portion of most biomolecules. Other atoms covalently bonded to the carbon backbone, either alone or in clusters, form what is termed *functional groups*. All organic compounds can be classified according to the functional group or groups they contain. *Functional groups* are specific combinations of atoms that generally react in the same way, regardless of the number of carbon atoms in the molecule to which they are attached. For example, all *aldehydes* contain a functional group that contains one carbon atom, one oxygen atom, and one hydrogen atom covalently bonded in a specific way:

The carbon atom in an aldehyde group forms a single covalent bond with the hydrogen atom and a *double bond* (a bond in which two covalent bonds are formed between the same atoms, designated by a double line between the atoms) with the oxygen atom. The aldehyde group is attached to the rest of the molecule by a single covalent bond extending to the left of the carbon atom. Most aldehyde reactions are the same regardless of the size and nature of the rest of the molecule to which the aldehyde group is attached. Reactions of physiological importance often occur between two functional groups or between one functional group and a small molecule such as water.

B.9 | Carbohydrates

Carbohydrates are organic compounds of tremendous biological and commercial importance. They are widely distributed in nature and include such familiar substances as starch, table sugar, and cellulose. Carbohydrates have five important functions in living organisms: they provide energy, serve as a stored form of chemical energy, provide dietary fibre, supply carbon atoms for the synthesis of cell components, and form part of the structural elements of cells.

Chemical composition of carbohydrates

Carbohydrates contain carbon, hydrogen, and oxygen. They acquired their name because most of them contain these three elements in an atomic ratio of one carbon to two hydrogens to

one oxygen. This ratio suggests that the general formula is CH_2O and that the compounds are simply carbon hydrates (“watered” carbons), or carbohydrates. It is now known that they are not hydrates of carbon, but the name persists. All carbohydrates have a large number of functional groups per molecule. The most common functional groups in carbohydrates are *alcohol*, *ketone*, and *aldehyde*:

Types of carbohydrates

The simplest carbohydrates are simple sugars, also called *monosaccharides*. As their name indicates, they consist of single, simple-sugar units called saccharides (*mono* means “one”). The molecular structure of *glucose*, an important monosaccharide, is shown in ▶Figure B-7a. In solution, most glucose molecules assume the ring form shown in ▶Figure B-7b. Other common monosaccharides are *fructose*, *galactose*, and *ribose*—or functional groups formed by reactions between pairs of these three.

Disaccharides are sugars formed by linking two monosaccharide molecules together through a covalent bond (*di* means “two”). Some common examples of disaccharides are *sucrose* (common table sugar) and *lactose* (milk sugar). Sucrose molecules are formed from one glucose and one fructose molecule. Lactose molecules each contain one glucose and one galactose unit.

Because of the many functional groups on carbohydrate molecules, large numbers of simple carbohydrate molecules are able to bond together and form long chains and branched networks. The resultant substances, *polysaccharides*, contain many saccharide units (*poly* means “many”). Three common polysaccharides made up entirely of glucose units are glycogen, starch, and cellulose.

- *Glycogen* is a storage carbohydrate found in animals. It is a highly branched polysaccharide that averages a branch every 8 to 12 glucose units. The structure of glycogen is

© 2016 Cengage

▶ **FIGURE B-8** A simplified representation of glycogen. Each circle represents a glucose molecule.

represented in ▶Figure B-8, where each circle represents one glucose unit.

- *Starch*, a storage carbohydrate of plants, consists of two fractions, amylose and amylopectin. Amylose consists of long, essentially unbranched chains of glucose units. Amylopectin is a highly branched network of glucose units averaging 24 to 30 glucose units per branch. Thus, it is less highly branched than glycogen.
- *Cellulose*, a structural carbohydrate of plants, exists in the form of long, unbranched chains of glucose units. The bonding between the glucose units of cellulose is slightly different from the bonding between the glucose units of glycogen and starch. Humans have digestive enzymes that catalyze the breaking (hydrolysis) of the glucose-to-glucose bonds in starch but lack the necessary enzymes to hydrolyze cellulose glucose-to-glucose bonds. So starch is a form of food for humans, but cellulose is not. Cellulose is the indigestible fibre in our diets.

B.10 | Lipids

Lipids are a diverse group of organic molecules made up of substances with widely different compositions and molecular structures. Unlike carbohydrates, which are classified on the basis of their *molecular structure*, lipids are classified on the basis of their *solubility*. Lipids are insoluble in water but soluble in nonpolar solvents such as alcohol. Thus, lipids are the waxy, greasy, or oily compounds found in plants and animals. Lipids repel water, a useful characteristic of the protective wax coatings found on some plants. Fats and oils are energy rich and have relatively low densities. These properties account for the use of fats and oils as stored energy in plants and animals. Still other lipids occur as structural components, especially in cellular membranes. The oily plasma membrane that surrounds each cell serves as a barrier that separates the intracellular contents from the surrounding extracellular fluid (pp. 5, 29, and 30).

Simple lipids

Simple lipids contain just two types of components: fatty acids and alcohols. *Fatty acid molecules* consist of a hydrocarbon

▶ **FIGURE B-7** Forms of glucose

chain with a *carboxyl* functional group ($-\text{COOH}$) on the end. The hydrocarbon chain can be of variable length, but natural fatty acids always contain an even number of carbon atoms. The hydrocarbon chain can also contain one or more double bonds between carbon atoms. Fatty acids with no double bonds are called *saturated fatty acids*, whereas those with double bonds are called *unsaturated fatty acids*. The more double bonds present, the higher the degree of unsaturation. Saturated fatty acids predominate in dietary animal products (e.g., meat, eggs, and dairy products), whereas unsaturated fatty acids are more prevalent in plant products (e.g., grains, vegetables, and fruits). Consumption of a greater proportion of saturated rather than unsaturated fatty acids is linked with a higher incidence of cardiovascular disease (p. 374).

The most common alcohol found in simple lipids is *glycerol* (glycerin), a three-carbon alcohol that has three alcohol functional groups ($-\text{OH}$).

Simple lipids called fats and oils are formed by a reaction between the carboxyl group of three fatty acids and the three alcohol groups of glycerol. The resulting lipid is an E-shaped molecule called a *triglyceride*. Such lipids are classified as fats or oils on the basis of their melting points. *Fats* are solids at room temperature, whereas *oils* are liquids. Their melting points depend on the degree of unsaturation of the fatty acids of

the triglyceride. The melting point goes down with increasing degree of unsaturation. Therefore, oils contain more unsaturated fatty acids than fats do. Examples of the components of fats and oils and a typical triglyceride molecule are shown in Figure B-9.

When triglycerides form, a molecule of water is released as each fatty acid reacts with glycerol. Adipose tissue in the body contains triglycerides. When the body uses adipose tissue as an energy source, the triglycerides react with water to release free fatty acids into the blood. The fatty acids can be used as an immediate energy source by many organs. In the liver, free fatty acids are converted into compounds called *ketone bodies*. Two of the ketone bodies are acids, and one is the ketone called acetone. Excess ketone bodies are produced during *diabetes mellitus*, a condition in which most cells resort to using fatty acids as an energy source because the cells are unable to take up adequate amounts of glucose in the face of inadequate insulin action (p. 278).

Complex lipids

Complex lipids have more than two types of components. The different complex lipids usually contain three or more of the following components: glycerol, fatty acids, a phosphate group, an alcohol other than glycerol, and a carbohydrate. Those that contain phosphate are called *phospholipids*. ▶Figure B-10 contains representations of a few complex lipids; it emphasizes the components but does not give details of the molecular structures.

Steroids are lipids that have a unique structural feature consisting of a fused carbon ring system containing three six-membered rings and a single five-membered ring (▶Figure B-11). Different steroids possess this characteristic ring structure but have different functional groups and carbon chains attached.

Cholesterol, a steroidal alcohol, is the most abundant steroid in the human body. It is a component of cell membranes and is used by the body to produce other important steroids that include bile salts, male and female sex hormones, and adrenocortical hormones. The structures of cholesterol and cortisol, an important adrenocortical hormone, are shown in ▶Figure B-12.

B.11 | Proteins

The name *protein* is derived from the Greek word *proteios*, which means “of first importance.” It is certainly an appropriate term for these very important biological compounds. Proteins are indispensable components of all living things, where they play

▶ **FIGURE B-9** Triglyceride components and structure

crucial roles in all biological processes. Proteins are the main structural component of cells, and all chemical reactions in the body are catalyzed by enzymes, all of which are proteins.

Chemical composition of proteins

Proteins are macromolecules made up of monomers called *amino acids*. Hundreds of different amino acids, both natural and synthetic, are known, but only 20 are commonly found

in natural proteins. From this limited pool of 20 amino acids, cells build thousands of different types of proteins, each with a distinctly different function, much the same way that composers create a diversity of unique music from a relatively small number of notes. Different proteins are constructed according to variations in the types and numbers of amino acids used and also in the order they are linked together. However, proteins are not formed haphazardly by a random linking of amino acids. Every protein in the body is deliberately and precisely synthesized under the direction of the blueprint laid down in the person's genes. Thus amino acids are assembled in a specific pattern to produce a given protein to accomplish a particular structural or functional task in the body. (More information about protein synthesis can be found in Appendix C.)

Peptide bonds

Each amino acid molecule has three important parts: an amino functional group ($-\text{NH}_2$), a carboxyl functional group ($-\text{COOH}$), and a characteristic side chain or R group. These components are shown in expanded form in ►Figure B-13. Amino acids form long chains as a result of reactions between the amino group of one amino acid and the carboxyl group of another amino acid. This reaction is illustrated in Equation B-16:

Eq. B-16

Notice that after the two molecules react, the ends of the product still have an amino group and a carboxyl group that can react to extend the chain length. The covalent bond formed in the reaction is called a *peptide bond* (Figure B-14).

On a molecular scale, proteins are immense molecules. Their size can be illustrated by comparing a glucose molecule to a molecule of *haemoglobin*, a protein. Glucose has a molecular weight of 180 amu and a molecular formula of $\text{C}_6\text{H}_{12}\text{O}_6$. *Haemoglobin*, a relatively small protein, has a molecular weight of 65 000 amu and a molecular formula of $\text{C}_{2952}\text{H}_{4664}\text{O}_{832}\text{N}_{812}\text{S}_8\text{Fe}_4$.

► **FIGURE B-14 A peptide bond.** In forming a peptide bond, the carboxyl group of one amino acid reacts with the amino group of another amino acid.

Levels of protein structure

The many atoms in a protein are not arranged in a random way. In fact, proteins have a high degree of structural organization that plays an important role in their behaviour in the body.

PRIMARY STRUCTURE

The first level of protein structure is called the *primary structure*. It is simply the order in which amino acids are bonded together to form the protein chain. Amino acids are frequently represented by three-letter abbreviations, such as Gly for glycine and Arg for arginine. When this practice is followed, the primary structure of a protein can be represented as in ► Figure B-15, which shows part of the primary structure of human insulin, or as in ► Figure B-16a, which depicts a portion of the primary structure of haemoglobin.

SECONDARY STRUCTURE

The second level of protein structure, called the *secondary structure*, results when hydrogen bonding occurs between the amino hydrogen of one amino acid and the carboxyl oxygen

of another amino acid in the same chain. As a result of this hydrogen bonding, the involved portion of the chain typically assumes a coiled, helical shape called the alpha (α)

► **FIGURE B-15 A portion of the primary protein structure of human insulin**

helix, which is by far the most common secondary structure found in the body (► Figure B-16b). Other secondary structures such as the beta (β) pleated sheet and random coils can also form, depending on the pattern of hydrogen bonding between amino acids located in different parts of the same chain.

TERTIARY AND QUATERNARY STRUCTURE

The third level of structure in proteins is the *tertiary structure*. It results when functional groups of the side chains of amino acids in the protein chain react with each other. Several different types of interactions are possible, as shown in ► Figure B-17. Tertiary structures can be visualized by letting a length of wire represent the chain of amino acids in the primary structure of a protein. Next imagine that the wire is wound around a pencil to form a helix, which represents the secondary structure. The pencil is removed, and the helical structure is now folded back on itself or carefully wadded into a ball. Such folded or spherical structures represent the tertiary structure of a protein (► Figure B-16c).

All functional proteins exist in at least a tertiary structure. Sometimes, several polypeptides interact with each other to form a fourth level of protein structure, the *quaternary structure*. For example, *haemoglobin* contains four highly folded polypeptide chains (the *globin* portion) (► Figure B-16d). Four iron-containing *heme* groups, one tucked within the interior of each of the folded polypeptide subunits, complete the quaternary structure of *haemoglobin* (see Figure 9-2).

Hydrolysis and denaturation

One of the important functions of proteins is to serve as enzymes that catalyze the many essential chemical reactions of the body. In addition to catalyzing reactions, proteins can undergo reactions themselves. Two of the most important are hydrolysis and denaturation.

HYDROLYSIS

Notice that according to Equation B-16, the formation of peptide bonds releases water molecules. Under appropriate conditions, it is possible to reverse such reactions by adding water to the peptide bonds and breaking them. *Hydrolysis* (breakdown by H_2O) reactions of this type convert large proteins into smaller fragments or even into individual amino acids. Hydrolysis is the means by which digestive enzymes break down ingested food into small units that can be absorbed from the digestive tract lumen into the blood.

DENATURATION

Denaturation of proteins occurs when the bonds holding a protein chain in its characteristic tertiary or secondary conformation are broken. When this happens, the protein chain takes on a random, disorganized conformation. Denaturation can result when proteins are subjected to heating (including when body temperature rises too high; p. 711), to extremes of pH (p. 621), or to treatment with specific chemicals such as alcohol or heavy metal ions. In some instances, denaturation is accompanied by

© 2016 Cengage

FIGURE B-16 Levels of protein structure. Proteins can have four levels of structure. (a) The primary structure is a particular sequence of amino acids bonded in a chain. (b) At the secondary level, hydrogen bonding occurs between various amino acids within the chain, causing the chain to assume a particular shape. The most common secondary protein structure in the body is the alpha helix. (c) The tertiary structure is formed by the folding of the secondary structure into a functional three-dimensional configuration. (d) Many proteins form a fourth level of structure composed of several polypeptides, as exemplified by haemoglobin.

► **FIGURE B-17** Side chain interactions leading to the tertiary protein structure

coagulation or precipitation, as illustrated by the changes that occur in the white of an egg as it is fried.

Nucleic acids

Nucleic acids are high-molecular-weight macromolecules responsible for storing and using genetic information in living cells and passing it on to future generations. These important biomolecules are classified into two categories: *deoxyribonucleic acid (DNA)* and *ribonucleic acid (RNA)*. DNA is found primarily in the cell's nucleus, and RNA is found primarily in the cytoplasm that surrounds the nucleus.

Both types of nucleic acid are made up of units called *nucleotides*, which in turn consist of three simpler components. Each nucleotide contains an organic nitrogenous base, a sugar, and a phosphate group. The three components are chemically bonded together with the sugar molecule lying between the base and the phosphate. In RNA, the sugar is *ribose*, whereas in DNA it is *deoxyribose*. When nucleotides bond together to form nucleic acid chains, the bonding is between the phosphate of one

nucleotide and the sugar of another. The resulting nucleic acids consist of chains of alternating phosphates and sugar molecules, with a base molecule extending out of the chain from each sugar molecule (see ► Figure C-1, Appendix C, p. A-20).

The chains of nucleic acid have structural features somewhat like those found in proteins. DNA takes the form of two chains that mutually coil around one another to form the well-known double helix. Some RNA occurs in essentially straight chains, whereas in other types the chain forms specific loops or helices. See Appendix C for further details.

B.12 High-energy Biomolecules

Not all nucleotides are used to construct nucleic acids. One very important nucleotide—*adenosine triphosphate (ATP)*—is used as the body's primary energy carrier. Certain bonds in ATP temporarily store energy that is harnessed during the metabolism of foods and made available to the parts of the cells where it is needed to do specific cellular work (pp. 24-28). Let's see how ATP functions in this role. Structurally, ATP is a modified RNA (ribose-containing) nucleotide that has adenine as its base and two additional phosphates bonded in sequence to the original nucleotide phosphate. This means adenosine triphosphate, as the name implies, has a total of three phosphates attached in a string to *adenosine*, the composite of ribose and adenine (Figure B-18). Attaching these additional phosphates requires considerable energy input. The high-energy input used to create these *high-energy phosphate bonds* is "stored" in the bonds for later use. Most energy transfers in the body involve ATP's terminal phosphate bond. When energy is needed, the third phosphate is cleaved off by hydrolysis, yielding *adenosine diphosphate (ADP)* and an inorganic phosphate (P_i) and releasing energy in the process (Equation B-17):

Why do cells use ATP as an energy currency that they can cash in by the splitting of high-energy phosphate bonds as needed? Why don't they simply and directly use the energy released during the oxidation of nutrient molecules such as glucose? The answer is that if all the energy stored in glucose were to be released at once, this amount of energy would be more than the cell could immediately use, and so much of it would be squandered. Instead, the energy trapped within the glucose bonds is gradually released and harnessed in the form of the high-energy phosphate bonds of ATP—that is, in cellular "bite-size pieces."

Under the influence of an enzyme, ATP can be converted to a cyclic form of adenosine monophosphate, which contains only one phosphate group, the other two having been cleaved off. The resultant molecule, called *cyclic AMP (cAMP)*, serves as an intracellular messenger, affecting the activities of a number of enzymes involved in important reactions in the body (p. 217).

► **FIGURE B-18** The structure of ATP

Storage, Replication, and Expression of Genetic Information

c.1 | Deoxyribonucleic Acid (DNA) and Chromosomes

The nucleus of the cell houses *deoxyribonucleic acid* (DNA), the genetic blueprint that is unique for each individual.

Functions of DNA

As genetic material, DNA serves two essential functions. First, it contains instructions for assembling the structural and enzymatic proteins of the cell. Cellular enzymes in turn control the formation of other cellular structures and also determine the functional activity of the cell by regulating the rate at which metabolic reactions proceed. The nucleus serves as the cell's control centre by directly or indirectly controlling almost all cell activities; this is accomplished through the role of the cell's DNA in governing protein synthesis. Because cells make up the body, the DNA code determines the structure and the function of the body as a whole. The DNA of an organism not only dictates whether the organism is a human, a toad, or a pea but also determines the unique physical and functional characteristics of that individual, all of which ultimately depend on the proteins produced under DNA control.

Second, by replicating (making copies of itself), DNA perpetuates the genetic blueprint within all new cells formed within the body, and is thereby responsible for passing on genetic information from parents to children.

We will examine the structure of DNA and the coding mechanism it uses, and then turn our attention to the means by which DNA replicates itself and controls protein synthesis.

Structure of DNA

Deoxyribonucleic acid is a huge molecule, composed in humans of millions of nucleotides arranged into two long, paired, strands that spiral around each other to form a double helix. Each *nucleotide* has three components: (1) a *nitrogenous base*, a ring-shaped organic molecule containing nitrogen; (2) a five-carbon ring-shaped sugar molecule, which in DNA is *deoxyribose*; and (3) a phosphate group. Nucleotides are joined end to end by linkages between the sugar of one nucleotide and the phosphate group of the adjacent nucleotide to form a long polynucleotide (many

nucleotide) strand with a sugar–phosphate backbone and bases projecting out one side (►Figure C-1). The four different bases in DNA are the double-ringed bases *adenine* (A) and *guanine* (G) and the single-ringed bases *cytosine* (C) and *thymine* (T). The two polynucleotide strands within a DNA molecule are wrapped around each other so that their bases all project to the interior of the helix. The strands are held together by weak hydrogen bonds formed between the bases of adjoining strands (Appendix B, ►Figure B-6). Base pairing is highly specific: Adenine pairs only with thymine and guanine pairs only with cytosine (►Figure C-2).

Genes

The composition of the repetitive sugar–phosphate backbones that form the “sides” of the DNA “ladder” is identical for every molecule of DNA, but the sequence of the linked bases that form the “rungs” varies among different DNA molecules. The particular sequence of bases in a DNA molecule serves as instructions, or a molecular code, that dictates the assembly of amino acids into a given order for the synthesis of specific *polypeptides* (chains of amino acids linked by peptide bonds; see Appendix B, p. A-14). A *gene* is a stretch of DNA that codes for the synthesis of a particular polypeptide. Polypeptides, in turn, are folded into a three-dimensional configuration to form a functional protein. Not all portions of a DNA molecule code for structural or enzymatic proteins. Some stretches of DNA code for proteins that regulate genes. Other segments appear important in organizing and packaging DNA within the nucleus. Still other regions are known as nonsense base sequences because they have no apparent significance.

Packaging of DNA into chromosomes

The DNA molecules within each human cell, if lined up end to end, would extend more than 2 m (2 000 000 µm), yet these molecules are packed into a nucleus that is only 5 µm in diameter. These molecules are not randomly crammed into the nucleus but are precisely organized into **chromosomes**. Each chromosome consists of a different DNA molecule and contains a unique set of genes.

Somatic (body) *cells* contain 46 chromosomes (the *diploid number*), which can be sorted into 23 pairs on the basis of various distinguishing features. Chromosomes composing a matched

► **FIGURE C-1 Polynucleotide strand.** Sugar-phosphate bonds link adjacent nucleotides together to form a polynucleotide strand with bases projecting to one side. The sugar-phosphate backbone is identical in all polynucleotides, but the sequence of the bases varies.

pair are termed *homologous chromosomes*—one member of each pair having been derived from the individual's maternal parent and the other member from the paternal parent. *Germ* (reproductive) *cells* (i.e., sperm and eggs) contain only one member of each homologous pair for a total of 23 chromosomes (the *haploid number*). Union of a sperm and an egg results in a new diploid cell with 46 chromosomes, consisting of a set of 23 chromosomes from the mother and another set of 23 from the father (p. 727).

DNA molecules are packaged and compressed into discrete chromosomal units in part by nuclear proteins associated with DNA. Two classes of proteins—histone and nonhistone proteins—bind with DNA. *Histones* form bead-shaped bodies that play a key role in packaging DNA into its chromosomal structure. The *nonhistones* are important in gene regulation. The complex formed between the DNA and its associated proteins is known as *chromatin*. The long threads of DNA within a chromosome are wound around histones at regular intervals, thereby compressing a given DNA molecule to about one-sixth its fully extended length. This “beads-on-a-string” structure is further folded and supercoiled into higher and higher levels of organization to further condense DNA into rodlike chromosomes that are readily visible through a light microscope during cell division (►Figure C-3). When the cell is not dividing, the chromosomes partially decondense (i.e., unravel) to a less compact form of chromatin that is indistinct under a light microscope but appears as thin strands and clumps with an electron microscope. The decondensed form of DNA is its working form; this is the form used as a template for protein assembly. Let's turn our attention to this working form of DNA in operation.

c.2 | Complementary Base Pairing, Replication, and Transcription

Complementary base pairing serves as the foundation for both DNA replication and the initial step of protein synthesis. We now examine the mechanism and significance of complementary base pairing in each of these circumstances, starting with DNA replication.

DNA replication

During DNA replication, the two decondensed DNA strands “unzip” as the weak bonds between the paired bases are enzymatically broken. Then *complementary base pairing* takes place: New nucleotides present within the nucleus pair with the exposed bases from each unzipped strand (►Figure C-4). New adenine-bearing nucleotides pair with exposed thymine-bearing nucleotides in an old strand, and new guanine-bearing nucleotides pair with exposed cytosine-bearing nucleotides in an old strand. This complementary base pairing is initiated at one end of the two old strands and proceeds in an orderly fashion to the other end. The new nucleotides attracted to and thus aligned in a prescribed order by the old nucleotides are sequentially joined by sugar-phosphate linkages to form two new strands that are complementary to each of the old strands.

► **FIGURE C-2 Complementary base pairing in DNA.** (a) Two polynucleotide strands held together by weak hydrogen bonds formed between the bases of adjoining strands—adenine always paired with thymine and guanine always paired with cytosine. (b) Arrangement of the two bonded polynucleotide strands of a DNA molecule into a double helix.

This replication process results in two complete double-stranded DNA molecules: one strand within each molecule having come from the original DNA molecule, and one strand having been newly formed by complementary base pairing. These two DNA molecules are both identical to the original DNA molecule; due to the imposed pattern of base pairing, the “missing” strand in each of the original separated strands has been produced anew. This replication process, which occurs only during cell division, is essential for perpetuating the genetic code in both the new daughter cells. The duplicate copies of DNA are separated and evenly distributed to the two halves of the cell before it divides. The topic of cell division is covered in detail in Section C.4.

DNA transcription and messenger RNA

At other times, when it’s not replicating in preparation for cell division, DNA serves as a blueprint for dictating cellular protein synthesis. How is this accomplished when DNA is sequestered within the nucleus and protein synthesis is carried out by ribosomes within the cytoplasm? Several types of another nucleic acid, *ribonucleic acid* (RNA), serve as the go-between.

STRUCTURE OF RIBONUCLEIC ACID

Ribonucleic acid differs structurally from DNA in three regards: (1) The five-carbon sugar in RNA is *ribose* instead of deoxyribose, the only difference between them being the presence in

ribose of a single oxygen atom that is absent in deoxyribose; (2) RNA contains the closely related base *uracil* instead of thymine, with the three other bases being the same as in DNA; and (3) RNA is single-stranded and not self-replicating.

All RNA molecules are produced in the nucleus using DNA as a template, and then exit the nucleus through openings in the nuclear membrane, called *nuclear pores*. These pores are large enough for passage of RNA molecules, but they block the much larger DNA molecules.

The DNA instructions for assembling a particular protein coded in the base sequence of a given gene are transcribed into a molecule of *messenger RNA* (*mRNA*). The segment of the DNA molecule to be copied uncoils, and the base pairs separate to expose the particular sequence of bases in the gene. In any given gene, only one of the DNA strands is used as a template for transcribing RNA. Which strand is copied differs for each gene along the same DNA molecule. The beginning and end of a gene within a DNA strand are designated by particular base sequences that serve as start and stop signals.

TRANSCRIPTION

Transcription is accomplished by complementary base pairing of free RNA nucleotides with their DNA counterparts in the exposed gene (► Figure C-5). The same pairing rules apply except that uracil, the RNA nucleotide substitute for thymine, pairs with adenine in the exposed DNA nucleotides. As soon as the RNA nucleotides pair

FIGURE C-3 Levels of organization of DNA. (a) Double helix of a DNA molecule. (b) DNA molecule wound around histone proteins, forming a “beads-on-a-string” structure. (c) Further folding and supercoiling of the DNA–histone complex. (d) Rodlike chromosomes, the most condensed form of DNA, which are visible in the cell’s nucleus during cell division.

with their DNA counterparts, sugar–phosphate bonds are formed to join the nucleotides together into a single-stranded RNA molecule that is released from DNA once transcription is complete. The original conformation of DNA is then restored. The RNA strand is much shorter than a DNA strand, because only a one-gene segment of DNA is transcribed into a single RNA molecule. The length of the finished RNA transcript varies, depending on the size of the gene. Within its nucleotide base sequence, this RNA transcript contains instructions for assembling a particular protein. Note that the message is coded in a base sequence that is *complementary to, not identical to*, the original DNA code.

Messenger RNA delivers the final coded message to the ribosomes for *translation* into a particular amino acid sequence to form a given protein. Thus, genetic information flows from DNA (which can replicate itself) through RNA to protein. This is accomplished first by *transcription* of the DNA code into a complementary RNA code, followed by *translation* of the RNA code into a specific protein. In the next section, you will learn more

about the steps in translation. The structural and functional characteristics of the cell as determined by its protein composition can be varied, subject to control, depending on which genes are switched on to produce mRNA.

Free nucleotides present in the nucleus cannot be randomly joined together to form either DNA or RNA strands, because the enzymes required to link the sugar and phosphate components of nucleotides are active only when bound to DNA. This ensures that DNA, mRNA, and protein assembly occur only according to genetic plan.

c.3 | Translation and Protein Synthesis

Three forms of RNA participate in protein synthesis. Besides messenger RNA, two other forms of RNA are required for translation of the genetic message into cellular protein: ribosomal RNA and transfer RNA.

► **FIGURE C-4 Complementary base pairing during DNA replication.** During DNA replication, the DNA molecule is unzipped, and each old strand directs the formation of a new strand; the result is two identical double-helix DNA molecules.

- *Messenger RNA* carries the coded message from nuclear DNA to a cytoplasmic ribosome, where it directs the synthesis of a particular protein.
- *Ribosomal RNA* (rRNA) is an essential component of *ribosomes*, the “workbenches” for protein synthesis (p. 23). Ribosomes “read” the base sequence code of mRNA and translate it into the appropriate amino acid sequence during protein synthesis.
- *Transfer RNA* (tRNA) transfers the appropriate amino acids in the cytosol to their designated site in the amino acid sequence of the protein under construction.

► **FIGURE C-5 Complementary base pairing during DNA transcription.** During DNA transcription, a messenger RNA molecule is formed as RNA nucleotides are assembled by complementary base pairing at a given segment of one strand of an unzipped DNA molecule (i.e., a gene).

Triplet code and codon

Twenty different amino acids are used to construct proteins, yet only four different nucleotide bases are used to code for these 20 amino acids. In the “genetic dictionary,” each different amino acid is specified by a *triplet code* that consists of a specific sequence of three bases in the DNA nucleotide chain. For example, the DNA sequence ACA (adenine, cytosine, adenine) specifies the amino acid cysteine, whereas the sequence ATA specifies the amino acid tyrosine. Each DNA triplet code is transcribed into mRNA as a complementary code word, or *codon*, consisting of a sequenced order of the three bases that pair with the DNA triplet. For example, the DNA triplet code ATA is transcribed as UAU (uracil, adenine, uracil) in mRNA.

Sixty-four different DNA triplet combinations (and, accordingly, 64 different mRNA codon combinations) are possible using the four different nucleotide bases (4^3). Of these possible combinations, 61 code for specific amino acids and the remaining 3

serve as “stop signals.” A stop signal is like a period at the end of a sentence. The sentence consists of a series of triplet codes that specify the amino acid sequence in a particular protein. When the stop codon is reached, ribosomal RNA releases the finished polypeptide product. Because 61 triplet codes each specify a particular amino acid and there are 20 different amino acids, a given amino acid may be specified by more than one base-triplet combination. For example, tyrosine is specified by the DNA sequence ATG as well as by ATA. In addition, one DNA triplet code, TAC (mRNA codon sequence AUG) functions as a “start signal” in addition to specifying the amino acid methionine. This code marks the place on mRNA where translation is to begin; this ensures the message is started at the correct end and reads in the right direction. Interestingly, the same genetic dictionary is used universally; a given three-base code stands for the same amino acid in all living things, including microorganisms, plants, and animals.

Ribosomes

A *ribosome* brings together all components that participate in protein synthesis—mRNA, tRNA, and amino acids—and provides the enzymes and energy required for linking the amino acids together. The nature of the protein synthesized by a given ribosome is determined by the mRNA message being translated. Each mRNA serves as a code for only one particular polypeptide.

A ribosome is an rRNA-protein structure organized into two subunits of unequal size. These subunits are brought together only when a protein is being synthesized (▶ Figure C-6, step 1). During assembly of a ribosome, an mRNA molecule attaches to the smaller of the ribosomal subunits by means of a *leader sequence*, a section of mRNA that precedes the start codon. The small subunit with mRNA attached then binds to a large subunit to form a complete, functional ribosome. When the two subunits unite, a groove is formed that accommodates the mRNA molecule as it is being translated.

Transfer RNA and anticodons

Free amino acids in the cytosol cannot recognize and bind directly with their specific codons in mRNA. Transfer RNA must bring the appropriate amino acid to its proper codon. Even though tRNA is single-stranded, as are all RNA molecules, it is folded back onto itself into a T shape with looped ends (▶ Figure C-7). The open-ended stem portion recognizes and binds to a specific amino acid. There are at least 20 varieties of tRNA, each able to bind with only one of the 20 kinds of amino acids. A tRNA is said to be “charged” when it is carrying its passenger amino acid. The loop end of a tRNA opposite the amino acid binding site contains a sequence of three exposed bases, known as the *anticodon*, which is complementary to the mRNA codon that specifies the amino acid being carried. Through complementary base pairing, a tRNA can bind with mRNA and insert its amino acid into the protein under construction only at the site designated by the codon for the amino acid. For example, the tRNA molecule that binds with tyrosine bears the anticodon AUA, which can pair only with the mRNA codon UAU, which specifies tyrosine.

This dual-binding function of tRNA molecules ensures that the correct amino acids are delivered to mRNA for assembly in the order specified by the genetic code. Transfer RNA can bind with mRNA only at a ribosome, so protein assembly does not occur except in the confines of a ribosome.

Steps of protein synthesis

The three steps of protein synthesis are initiation, elongation, and termination.

1. **Initiation.** Protein synthesis is initiated when a charged tRNA molecule bearing the anticodon specific for the start codon binds at this site on mRNA (▶ Figure C-6, step 2).
2. **Elongation.** A second charged tRNA bearing the anticodon specific for the next codon in the mRNA sequence then occupies the site next to the first tRNA (step 3). At any given time, a ribosome can accommodate only two tRNA molecules bound to adjacent codons. Through enzymatic action, a peptide bond is formed between the two amino acids that are linked to the stems of the adjacent tRNA molecules (step 4). The linkage is subsequently broken between the first tRNA and its amino acid passenger, leaving the second tRNA with a chain of two amino acids. The uncharged tRNA molecule (the one minus its amino acid passenger) is released from mRNA (step 5). The ribosome then moves along the mRNA molecule by precisely three bases, a distance of one codon (step 6), so that the tRNA bearing the chain of two amino acids is moved into the number one ribosomal site for tRNA. Then, an incoming charged tRNA with a complementary anticodon for the third codon in the mRNA sequence occupies the number two ribosomal site that was vacated by the second tRNA (step 7). The chain of two amino acids subsequently binds with and is transferred to the third tRNA to form a chain of three amino acids (step 8). Through repetition of this process, amino acids are subsequently added one at a time to a growing polypeptide chain in the order designated by the codon sequence. In this way, the ribosomal translation machinery moves stepwise along the mRNA molecule one codon at a time (step 9). This process is rapid. Up to 10 to 15 amino acids can be added per second.
3. **Termination.** Elongation of the polypeptide chain continues until the ribosome reaches a stop codon in the mRNA molecule, at which time the polypeptide is released. The polypeptide is then folded and modified into a full-fledged protein. The ribosomal subunits dissociate and are free to reassemble into another ribosome for translation of other mRNA molecules.

Energy cost of protein synthesis

Protein synthesis is expensive, in terms of energy. Attachment of each new amino acid to the growing polypeptide chain requires a total investment of splitting four high-energy phosphate bonds:

1 On binding with a messenger RNA (mRNA) molecule, the small ribosomal subunit joins with the large subunit to form a functional ribosome.

2 A transfer RNA (tRNA), charged with its specific amino acid passenger, binds to mRNA by means of a complementary base pairing between the tRNA anticodon and the first mRNA codon positioned in the first ribosomal binding site.

3 Another tRNA molecule attaches to the next codon on mRNA positioned in the second ribosomal binding site.

4 The amino acid from the first tRNA is linked to the amino acid on the second tRNA.

5 The first tRNA detaches.

6 The mRNA molecule shifts forward one codon (a distance of a three-base sequence).

7 Another charged tRNA moves in to attach with the next codon on mRNA, which has now moved into the second ribosomal binding site.

8 The amino acids from the tRNA in the first ribosomal site are linked with the amino acid in the second site.

9 This process continues (i.e., steps 5 through 8 are repeated), with the polypeptide chain continuing to grow, until a stop codon is reached and the polypeptide chain is released.

► **FIGURE C-6** Ribosomal assembly and protein translation

► **FIGURE C-7 Structure of a tRNA molecule.** The open end of a tRNA molecule attaches to free amino acids. The anticodon loop of the tRNA molecule attaches to a complementary mRNA codon.

two to charge tRNA with its amino acid, one to bind tRNA to the ribosomal-mRNA complex, and one to move the ribosome forward one codon.

Polyribosomes

A number of copies of a given protein can be produced from a single mRNA molecule before the latter is chemically degraded. As one ribosome moves forward along the mRNA molecule, a

new ribosome attaches at the starting point on mRNA and also starts translating the message. Attachment of many ribosomes to a single mRNA molecule results in a *polyribosome*. Multiple copies of the identical protein are produced as each ribosome moves along and translates the same message (► Figure C-8). The released proteins are used within the cytosol, except for the few that move into the nucleus through the nuclear pores.

In contrast to the cytosolic polyribosomes, ribosomes directed to bind with the rough endoplasmic reticulum (ER) feed their growing polypeptide chains into the ER lumen. The resultant proteins are subsequently packaged for export out of the cell or for replacement of membrane components within the cell.

Control of gene activity and protein transcription

Because each somatic cell in the body has an identical DNA blueprint, you might assume they would all produce the same proteins. This is not the case, however, because different cell types are able to transcribe different sets of genes and thus synthesize different sets of structural and enzymatic proteins. For example, only red blood cells can synthesize haemoglobin, even though all body cells carry the DNA instructions for haemoglobin synthesis. Only about 7 percent of the DNA sequences in a typical cell are ever transcribed into mRNA for ultimate expression as specific proteins.

Control of gene expression involves gene regulatory proteins that activate (switch on) or repress (switch off) the genes that code for specific proteins within a given cell. Various DNA segments that do not code for structural and enzymatic proteins code for synthesis of these regulatory proteins. The molecular mechanisms by which these regulatory genes in turn are controlled in human cells are only beginning to be understood. In some instances, regulatory proteins are controlled by

► **FIGURE C-8 A polyribosome.** A polyribosome is formed by numerous ribosomes simultaneously translating mRNA.

gene-signalling factors that bring about differential gene activity among various cells to accomplish specialized tasks. The largest group of known gene-signalling factors in humans is the hormones. Some hormones exert their homeostatic effect by selectively altering the transcription rate of the genes that code for enzymes, which are responsible for catalyzing the reaction(s) regulated by the hormone. For example, the hormone cortisol promotes the breakdown of fat stores by stimulating synthesis of the enzyme that catalyzes the conversion of stored fat into its component fatty acids. In other cases, gene action appears to be time specific; that is, certain genes are expressed only at a certain developmental stage in the individual. This is especially important during embryonic development.

C.4 | Cell Division

Most cells in the human body can reproduce themselves—a process important in growth, replacement, and repair of tissues. The rate at which cells divide is highly variable. Cells within the deeper layers of the intestinal lining divide every few days to replace cells that are continually sloughed off the surface of the lining into the digestive tract lumen. In this way, the entire intestinal lining is replaced about every three days (p. 681). At the other extreme are nerve cells, which permanently lose the ability to divide beyond a certain period of fetal growth and development. Consequently, when nerve cells are lost through trauma or disease, they cannot be replaced (p. 5). In between these two extremes are cells that divide infrequently, but do so when needed to replace damaged or destroyed tissue. The factors that control the rate of cell division remain obscure.

Mitosis

Recall that cell division involves two components: nuclear division and cytoplasmic division (*cytokinesis*). Nuclear division in somatic cells is accomplished by *mitosis*, in which a complete set of genetic information (i.e., a diploid number of chromosomes) is distributed to each of two new daughter cells.

A cell capable of dividing alternates between periods of mitosis and periods of nondivision. The interval of time between cell division is known as *interphase*. Because mitosis takes less than an hour to complete, the vast majority of cells in the body at any given time are in interphase.

Replication of DNA and growth of the cell take place during interphase in preparation for mitosis. Although mitosis is a continuous process, it displays four distinct phases: *prophase*, *metaphase*, *anaphase*, and *telophase* (► Figure C-9).

PROPHASE

1. Chromatin condenses and becomes microscopically visible as chromosomes. The condensed duplicate strands of DNA, known as *sister chromatids*, remain joined within the chromosome at a point called the *centromere* (► Figure C-10).
2. Cells contain a pair of centrioles, the short cylindrical structures that form the mitotic spindle during cell division. The

centriole pair divides, and the daughter centrioles move to opposite ends of the cell, where they assemble between them a mitotic spindle made up of microtubules.

3. The membrane surrounding the nucleus starts to break down.

METAPHASE

1. The nuclear membrane completely disappears.
2. The 46 chromosomes, each consisting of a pair of sister chromatids, align themselves at the midline, or equator, of the cell. Each chromosome becomes attached to the spindle by means of several spindle fibres that extend from the centriole to the centromere of the chromosome.

ANAPHASE

1. The centromeres split, converting each pair of sister chromatids into two identical chromosomes, which separate and move toward opposite poles of the spindle. Molecular motors pull the chromosomes along the spindle fibres toward the poles.
2. At the end of anaphase, an identical set of 46 chromosomes is present at each of the poles, for a transient total of 92 chromosomes in the soon-to-be-divided cell.

TELOPHASE

1. The cytoplasm divides through formation and gradual tightening of an actin contractile ring at the midline of the cell, thus forming two separate daughter cells, each with a full diploid set of chromosomes.
2. The spindle fibres disassemble.
3. The chromosomes uncoil to their decondensed chromatin form.
4. A nuclear membrane reforms in each new cell.

Cell division is complete with the end of telophase. Each of the new cells now enters interphase.

Meiosis

Nuclear division in the specialized case of germ cells is accomplished by *meiosis*, in which only half a set of genetic information (i.e., a haploid number of chromosomes) is distributed to each daughter cell. Meiosis differs from mitosis in several important regards (Figure C-9). Specialized diploid germ cells undergo one chromosome replication followed by two nuclear divisions to produce four haploid germ cells.

MEIOSIS I

1. During prophase of the first meiotic division, the members of each homologous pair of chromosomes line up side by side to form a *tetrad*, which is a group of four sister chromatids with two identical chromatids within each member of the pair.
2. The process of crossing over occurs during this period, when the maternal copy and the paternal copy of each

► **FIGURE C-9** A comparison of events in mitosis and meiosis

chromosome are paired. *Crossing over* involves a physical exchange of chromosome material between nonsister chromatids within a tetrad (► Figure C-11). This process yields new chromosome combinations, thus contributing to genetic diversity.

3. During metaphase, the 23 tetrads line up at the equator.
4. At anaphase, homologous chromosomes, each consisting of a pair of sister chromatids joined at the centromere, separate and move toward opposite poles. Maternally and paternally derived chromosomes migrate to opposite poles in random assortments of one member of each chromosome pair without regard for its original derivation. This genetic mixing provides novel new combinations of chromosomes.
5. During the first telophase, the cell divides into two cells. Each cell contains 23 chromosomes consisting of two sister chromatids.

MEIOSIS II

1. Following a brief interphase in which no further replication occurs, the 23 unpaired chromosomes line up at the equator, the centromeres split, and the sister chromatids

separate for the first time into independent chromosomes that move to opposite poles.

2. During cytokinesis, each of the daughter cells derived from the first meiotic division forms two new daughter cells. The end result is four daughter cells, each containing a haploid set of chromosomes.

Union of a haploid sperm and haploid egg results in a zygote (fertilized egg) that contains the diploid number of chromosomes. Development of a new multicellular individual from the zygote is accomplished by mitosis and cell differentiation. Because DNA is normally faithfully replicated in its entirety during each mitotic division, all cells in the body possess an identical aggregate of DNA molecules. Structural and functional variations between different cell types result from differential gene expression.

Mutations

An estimated 10^{16} cell divisions take place in the body during the course of a person's lifetime to accomplish growth, repair, and normal cell turnover. Because more than 3 billion nucleotides must be replicated during each cell division, it's no wonder "copying errors" occasionally occur. Any change in the DNA

From Christine J. Harrison et al., Cytogenetics

FIGURE C-10 A scanning electron micrograph of human chromosomes from a dividing cell. The replicated chromosomes appear as double structures, with identical sister chromatids joined in the middle at a common centromere.

sequence is known as a *point (gene) mutation*. A point mutation arises when a base is inadvertently substituted, added, or deleted during the replication process.

FIGURE C-11 Crossing over. (a) During prophase I of meiosis, each homologous pair of chromosomes lines up side by side to form a tetrad. (b) Physical exchange of chromosome material occurs between nonsister chromatids. (c) As a result of this crossing over, new combinations of genetic material are formed within the chromosomes.

When a base is inserted in the wrong position during DNA replication, the mistake can often be corrected by a built-in “proofreading” system. Repair enzymes remove the newly replicated strand back to the defective segment, at which time normal base pairing resumes to resynthesize a corrected strand. Not all mistakes can be corrected, however.

Mutations can arise spontaneously by chance alone or they can be induced by *mutagens*, which are factors that increase the rate at which mutations take place. Mutagens include various

chemical agents as well as ionizing radiation, such as X-rays and atomic radiation. Mutagens promote mutations either by chemically altering the DNA base code through a variety of mechanisms or by interfering with the repair enzymes so that abnormal base segments cannot be cut out.

Depending on the location and nature of a change in the genetic code, a given mutation may (1) have no noticeable effect if it does not alter a critical region of a cellular protein; (2) adversely alter cell function if it impairs the function of a crucial protein; (3) be incompatible with the life of the cell, in which case the cell dies and the mutation is lost with it; or (4) in rare cases, prove beneficial if a more efficient structural or enzymatic protein results. If a mutation occurs in a body cell (*somatic mutation*), the outcome will be reflected as an alteration in all future copies of the cell in the affected individual, but it will not be perpetuated beyond the life of the individual. If, by contrast, a mutation occurs in a sperm- or egg-producing cell

(*germ cell mutation*), the genetic alteration may be passed on to succeeding generations.

In most instances, *cancer* results from multiple somatic mutations that occur over a course of time within DNA segments known as *proto-oncogenes*. Proto-oncogenes are normal genes whose coded products are important in the regulation of cell growth and division. These genes have the potential of becoming overzealous *oncogenes* (cancer genes), which induce the uncontrolled cell proliferation characteristic of cancer. Proto-oncogenes can become cancer producing as a result of several sequential mutations in the gene itself or by changes in adjacent regions that regulate the proto-oncogenes. Less frequently, tumour viruses become incorporated in the DNA blueprint and act as oncogenes. Alternatively, cancer may arise from mutations that disable *tumour suppressor genes*, which normally restrain cell proliferation in check-and-balance fashion.

Principles of Quantitative Reasoning

By Kim E. Cooper, Midwestern University, and John D. Nagy, Scottsdale Community College

D.1 | Introduction

Historically, as a branch of science matures, it typically becomes more precise and usually more quantitative. This trend is becoming increasingly true of biology and especially of physiology. Most students, however, are uncomfortable with quantitative reasoning. Students are usually quite capable of doing the mechanical manipulations of mathematics but have trouble translating back and forth between words, concepts, and equations. This appendix is meant to help you become more comfortable working with equations.

D.2 | Why Are Equations Useful?

A great deal of what we do in science involves establishing functional relations between variables of interest (e.g., blood pressure and heart rate, transport rate and concentration gradient). Equations are simply a compact and exact way of expressing such relationships. The tools of mathematics then allow us to draw conclusions systematically from these relationships. Mathematics is a very powerful set of tools or, more generally, a very powerful way of thinking. Mathematics allows you to think extremely precisely, and therefore clearly, about complex relationships. Equations and quantitative notions are the keys to that precision. For example, a quantitative comparison of the predictions of a theory against the results of measurement forms the basis of statistics and of much of the hypothesis testing on which science is based. A scientific conclusion without adequate quantification and statistical backing may be little more than an impression or opinion.

It may seem odd to say that mathematics allows you to think more clearly about complex ideas. People unfamiliar with mathematical thinking often complain that even simple relationships produce complicated equations and that complex relationships are mathematically intractable. Certainly, many basic concepts require considerable mathematical expertise to be handled properly, but such concepts are in fact not simple. More commonly, however, many simple equations are seen as complex because many students are poorly trained in how to think about equations.

D.3 | How to Think about an Equation

In this section we take the first, and often overlooked, step in thinking quantitatively. That is, how do we begin to think about some new equation presented to us? We start by becoming comfortable with the “meaning” of an equation. This step is absolutely necessary for you to use an equation properly. As a specific example, consider the Nernst equation (p. 55) for potassium. Various books show this equation in several different forms, but they all say essentially the same thing:

$$E_{K^+} = (RT/zF) \ln \{ [K^+]_{out} / [K^+]_{in} \}$$

$$E_{K^+} = (RT/zF) 2.303 \log \{ [K^+]_{out} / [K^+]_{in} \}$$

$$E_{K^+} = (61\text{mV}/z) \log \{ [K^+]_{out} / [K^+]_{in} \}$$

These equations may seem like meaningless strings of symbols. But what are these equations trying to tell us? What do they represent? The following four steps are intended to help you become comfortable with any new equation. Try them with the Nernst equation.

1. Be sure you can define the symbols and give dimensions and units. Check the equation for dimensional consistency.

One of the first steps is to figure out which symbols represent the variables of interest and which are simple constants. In this case, all the symbols are constants except two.

E_{K^+} is the Nernst (equilibrium) potential for potassium. It represents the concentration gradient (force of diffusion) on a mole of potassium ions. E_{K^+} has the dimensions of a voltage and is usually given in units of mV (millivolts). This dimension is used so that the concentration gradient is expressed in the same dimensions as the other force acting on the ions—that is, the electrical gradient. Using the same dimensions makes it possible to compare the two forces.

$[K^+]$ represents the concentration of potassium. With the subscript *out*, this symbol refers to the concentration of potassium outside the cell. With the subscript *in*, this symbol refers to the concentration of potassium inside the cell. $[K^+]$ has

dimensions of concentration and is usually expressed in units of mM (millimolars; millimoles/litre).

2. Identify the dependent and independent variables. Try to find normal values and ranges for the variables. Before continuing, we need to define *dependent* and *independent variables*.

Recall that equations represent relationships between variables. Whenever you hear the word *relationship*, think of a graph, as in ▶ Figure D-1, for example.

Graphs are often a good way to represent relationships and therefore equations. This graph says the value of variable 2 depends on the value of variable 1. Thus, for any value of variable 1 the corresponding value for variable 2 can be determined from the graph. In other words, variable 1 determines the value of variable 2. Because variable 2 depends on variable 1, we call variable 2 the *dependent variable*. Variable 1, in contrast is independent of variable 2, so we call variable 1 the *independent variable*. There can be any number of dependent and *independent variables*.

How do you determine which variables are dependent and which are independent? The answer usually depends on cause and effect: *Effects* are dependent variables, and *causes* are independent. For example, we know (see Chapter 9, p. 401) that mean arterial pressure (*MAP*) is the product of cardiac output (*CO*) and total peripheral resistance (*TPR*); that is,

$$MAP = CO \times TPR$$

MAP is on the left-hand side of this equation because we think of mean arterial pressure as a result of cardiac output and total peripheral resistance. Or, to put this another way, mean arterial pressure is a function of cardiac output and total peripheral resistance. As a cause–effect relationship, it seems backward to think of mean arterial pressure somehow “causing” cardiac output to be a certain value. Therefore, *MAP* is the effect, the dependent variable, and we place it on the left-hand side of the equality symbol. Conversely, *CO* and *TPR* are the causes, the independent variables, and we put them on the right.

In our Nernst equation example, the independent variables are the concentrations. The dependent variable is the Nernst potential because we think of the potential as being a result of

▶ FIGURE D-1

the ion concentrations. We also know that E_{K^+} is about -90 mV, and $[K^+]_{out}$ and $[K^+]_{in}$ are about 5 mM and 150 mM, respectively.

3. Identify the constants and know their numeric values:

- R is the gas constant. It has dimensions of energy per mole per degree of temperature and the value of 8.31 joules/kelvin $\cdot$ mole. It is also convenient to note that a joules = volt $\times$ coulomb.
- T is temperature, with the dimension of temperature in units of kelvins. Normal body temperature is around 37°C [$= 308$ kelvins (K)].
- z is the valence of the ion. Valence is the charge on an ion, including the sign. For potassium, $z = +1$.
- F is Faraday’s constant, which has dimensions of charge per mole, units of coulombs per mole, and a value of $96\,500$ C/mol.

Refer back to the Nernst equations given on the preceding page. Note that the constants just defined appear in the first two equations, but not the third. In the third equation, the quantity RT/F has already been evaluated for you, as follows:

$$\begin{aligned} RT/F &= [(8.31 \text{ V} \cdot \text{C/K} \cdot \text{mol})(308 \text{ K})]/(96\,500 \text{ C/mol}) \\ &= 26.5 \text{ mV} \end{aligned}$$

We multiply this value by 2.303 to convert the natural logarithm ($\ln$) to the base 10 logarithm. Note that $26.5 \text{ mV} \times 2.303 = 61 \text{ mV}$.

4. State the equation in words. Summarize it in a few sentences so that someone can understand what it is about. Don’t just say the names of the symbols.

Just saying the names of the symbols would be equivalent to saying the following: “The Nernst potential is given by a constant times the logarithm of the ratio of the ion concentrations.” This is certainly true, but does nothing to aid our intuition. A preferable statement would be “The Nernst equation allows us to calculate the force pushing ions into or out of a cell via diffusion.” This is valuable, because we can compare this force to the force moving ions in and out via the membrane voltage and see which is larger and hence in what direction the ions will actually move. The force is expressed in electrical units so we can compare it directly with the membrane voltage. The constants convert from concentration to electrical units.

When you understand what an equation means you will be able to use it to answer questions. The next section gives you some guidance in taking this next step.

D.4 | How to Think with an Equation

Before you can use an equation to help you think, you need to develop a few basic skills, and these skills are not difficult to learn.

1. Be sure you know the algebraic rules for manipulating variables within any function involved (such as $\sqrt{\quad}$, $\exp$, or $\log$).

In the case of the Nernst equation, the tricky function is the logarithm. Consult a university-level algebra book if you need to brush up on the rules of working with logs or any other function. For instance, it is useful to know that

$$\log\{A\} = -\log\{1/A\}$$

and that the log operation is undone by taking it to the power of 10; that is,

$$10^{\log\{A\}} = A$$

2. Be able to solve for any variable in terms of the others.

Given just three variables (E_{K^+} , $[K^+]_{in}$, and $[K^+]_{out}$) only a few types of questions can be asked. Two of the three variables must be given, and you must solve for the third. If the two concentrations are given, then the formula is already set to give you the Nernst potential. If the Nernst potential and one concentration are given, however, you must be able to solve for the other concentration. Try to do this and obtain the two following equations:

$$\begin{aligned} [K^+]_{out} &= [K^+]_{in} 10^{(E_K + 61\text{mV})} \\ [K^+]_{in} &= [K^+]_{out} 10^{(-E_K + 61\text{mV})} \end{aligned}$$

3. Be able to sketch, at least approximately, the dependence of any variable on any other variable.

The ability to do this is exceedingly valuable. Sketching helps you generate insight about equations; it helps you understand what an equation means. Therefore, sketching helps you understand the solution, as well as solve the problem. If you apply this technique consistently, you may find equations far simpler to handle than you previously suspected. In addition, be sure you can relate your sketch to experimental measurements and physiological situations.

For example, we can draw the relationships between the Nernst potential for potassium and the external potassium ion concentration predicted by the equations as in ▶ Figure D-2. This sketch makes clear that the Nernst potential, which can be measured physiologically, should decrease linearly as the $\log [K^+]_{out}$ increases, which can be controlled experimentally. Therefore,

▶ FIGURE D-2

this sketch suggests an experiment: vary $[K^+]_{out}$. If E_{K^+} does not decrease linearly with increasing $\log [K^+]_{out}$, then we would have a flaw in our understanding. The Nernst equation would not describe the real situation, as we think it should. Scientific advances are almost always heralded by such contradictions.

4. Be able to combine several equations to find new relationships.

Combining separate pieces of information is always useful. In fact, some scientists have argued that this activity is all scientists ever do. To integrate knowledge for yourself, you must be able to combine the various relations you learn about into new combinations. This allows you to solve increasingly complex problems. As an example, consider the following relation:

$$I_{K^+} = G_{K^+} \times (V_m - E_{K^+})$$

This equation describes the number of potassium ions flowing across a membrane if both a concentration gradient (E_{K^+}) and an electrical gradient (V_m) are present. This equation can be combined with the Nernst equation for potassium to answer the following question. Suppose V_m , G_{K^+} , and $[K^+]_{in}$ are fixed. What would the external potassium ion concentration have to be such that no net flux of potassium ions occurs across the membrane? No net flux implies that $I_{K^+} = 0$. But if $G_{K^+} > 0$, $I_{K^+} = 0$ only when the membrane voltage equals the Nernst potential ($V_m = E_{K^+}$). To answer the question, then, we set ($E_{K^+} = V_m$) in the Nernst equation and solve it for $[K^+]_{out}$.

5. Know the equation's underlying assumptions and limits of validity.

Every equation comes from some underlying theory or set of observations and, therefore, has some limited range of validity and rests on certain assumptions. Failure to understand this simple point often leads students to apply equations outside their realm of applicability. In that case, even though the math is done correctly, the results will be incorrect.

In the case of the Nernst equation, things are fairly simple. This equation is derived from a very powerful theory known as *equilibrium thermodynamics*, and hence it has very wide applicability. As another example, consider enzyme kinetics. The rate at which an enzyme catalyzes a reaction (v) is related to

▶ FIGURE D-3

FIGURE D-4

the concentration of substrate on which the enzyme works ($[S]$) by an equation called the Michaelis–Menton relationship. The graph of this relationship can be seen in Figure D-3.

However, this relationship between reaction velocity and substrate concentration does not hold true for some real enzymes, such as lactate dehydrogenase. For this enzyme, the relationship between reaction velocity and substrate concentration is depicted in Figure D-4.

At high substrate concentrations, the enzyme actually is inhibited by too much substrate. For such enzymes, the Michaelis–Menton theory, which works well at low $[S]$, is invalid at higher $[S]$.

D.5 | An Approach to Problem Solving

The final step is to apply these skills to solve a problem. As an example, calculate the concentration of potassium that must exist inside a cell if $E_{K^+} = -95\text{mV}$ and the interstitial fluid has a potassium concentration of 4 mM. Try using the following procedure to solve this problem:

1. Get a clear picture of what is being asked. State it out loud or write it down.

The question asks for the concentration of potassium in the cell, that is, $[K^+]_{\text{in}}$.

2. Determine what you need to know to answer the question.

To answer this, you need to know E_{K^+} and $[K^+]_{\text{out}}$.

3. Determine what information is given. Is it sufficient?

Are other relevant facts or relationships not stated in the problem? Specifically, do you need any other equations?

E_{K^+} is given explicitly in the problem, but you have to translate the words to realize that $[K^+]_{\text{out}} = 4\text{mM}$.

4. Manipulate the equation algebraically so that the unknown is on the left-hand side and everything else is on the right-hand side.

We now solve the Nernst equation for $[K^+]_{\text{in}}$. This was done in Section D.4, p. A-33:

$$[K^+]_{\text{in}} = [K^+]_{\text{out}} 10^{(-E_{K^+}/61\text{mV})}$$

Substituting for the values given, we obtain the following:

$$\begin{aligned} [K^+]_{\text{in}} &= 4\text{mM} 10^{(95\text{mV}/61\text{mV})} \\ &= 4\text{mM} 10^{(1.56)} \\ &= 4\text{mM}(36.3) \\ &= 145\text{mM} \end{aligned}$$

5. Is the answer dimensionally correct? Do not skip this step. It will tell you immediately if something went wrong.

Yes, the answer is in mM—the proper dimension and unit.

6. Does the answer make sense?

Yes, the value is not alarmingly low or high. Also, because the potassium ion is positively charged, if the potassium concentration outside the cell is lower than that inside the cell, then the interior of the cell would have to be negative at passive equilibrium, which it is.

Apply the approach to problem solving we have just outlined to the quantitative questions in the chapters. When you start out, apply the approach formally and carefully. For example, go through each step, and write everything out as we have done for the Nernst equation. After a time, you may not need to be so formal. Also, as you progress, you will develop your own style and approach to problem solving. Be prepared to spend some time and patience on some of the problems. Not every answer will be immediately apparent. This situation is normal. If you run into difficulties, relax, return to this appendix for guidance, and work through the problem again carefully. Do not go immediately to the answers if you are having difficulty with a problem. It may ease the frustration, but you will be cheating yourself of a valuable learning experience. Besides, being able to solve challenging problems has its own rewards.

Answers to End-of-Chapter Objective Questions, Quantitative Exercises, Points to Ponder, and Clinical Considerations

Chapter 1 The Foundation of Physiology

Check Your Understanding

1.1 (Questions on p. 8.)

1. Physiology is the study of body functions.
2. Chemical level: Various atoms and molecules make up all body structures. Cellular level: Specific chemicals are organized into living cells, which are the basic units of both structure and function. Tissue level: Groups of cells of similar specialization are organized into tissues. Organ level: An organ is made up of several tissue types that act together as a unit to perform a particular function or functions. Body system level: A body system is a collection of related organs that interact to accomplish a common activity essential for survival of the whole body. Organism level: The body systems are structurally and functionally packaged together into the whole body, which is a single, multicellular organism capable of living independently in the surrounding external environment.
3. Every cell performs basic cell functions essential for its survival, including (1) obtaining food and O₂ from the environment surrounding the cell; (2) performing chemical reactions using food and O₂ to provide energy for the cell; (3) eliminating to the surrounding environment wastes produced by these reactions; (4) synthesizing proteins and other components needed by the cell; (5) largely controlling exchanges between the cell and surrounding environment; (6) moving materials within the cell or, in the case of some cells, moving the cell; (7) being sensitive and responsive to changes in the surrounding environment; and (8) reproducing (except for nerve cells and muscle cells). Many cells in the body have additional functions that are specialized to their purpose. For example, nerve cells are specialized to transmit electrical signals, and muscle cells are specialized to contract.
4. The external environment is the surrounding environment in which an organism lives. The internal environment is the fluid inside the body and outside the cells in which the cells live. The intracellular fluid is the fluid collectively within all body cells. The extracellular fluid is the fluid inside the body and outside the cells and constitutes the internal environment. The extracellular fluid consists of the plasma, the fluid portion of the blood, and interstitial fluid, the fluid that surrounds and bathes the cells.

1.2 (Questions on p. 16.)

1. *Intrinsic controls* are inherent compensatory responses that act locally in an organ; *extrinsic controls* are systemic controls initiated outside an organ by the regulatory systems (nervous or endocrine systems) to alter the organ's activity.
2. In *negative feedback*, the output of a control system drives a controlled variable in the opposite direction of an initial change, thereby

counteracting the change. In *positive feedback*, the output of a control system drives a controlled variable in the same direction as the initial change, thus enhancing the change.

3. See ▶ Figure 1-6a, Negative feedback, p. 15

Objective Questions

(Questions on p. 17.)

1. e 2. b 3. c 4. T 5. F 6. T 7. muscle tissue, nervous tissue, epithelial tissue, connective tissue 8. secretion 9. exocrine, endocrine, hormones 10. intrinsic, extrinsic 11. 1. d, 2. g, 3. a, 4. e, 5. b, 6. j, 7. h, 8. i, 9. c, 10. f

Points to Ponder

(Questions on p. 18.)

1. The respiratory system eliminates internally produced CO₂ to the external environment. A decrease in CO₂ in the internal environment brings about a reduction in respiratory activity (i.e., slower, shallower breathing) so that CO₂ produced within the body is allowed to accumulate, instead of being blown off as rapidly as normal to the external environment. The extra CO₂ retained in the body increases the CO₂ levels in the internal environment to normal.
2. b, c, b
3. b
4. immune defence system
5. When a person is engaged in strenuous exercise, the temperature-regulating centre in the brain brings about the widening of the blood vessels of the skin. The resultant increased blood flow through the skin carries the extra heat generated by the contracting muscles to the body surface, where it can be lost to the surrounding environment.

Clinical Consideration

(Question on p. 18.)

Loss of fluids threatens the maintenance of proper plasma volume and blood pressure. Loss of acidic digestive juices threatens the maintenance of the proper pH in the internal fluid environment. The urinary system helps restore the proper plasma volume and pH by reducing the amount of water and acid eliminated in the urine. The respiratory system helps restore the pH by adjusting the rate of removal of acid-forming CO₂. Adjustments made in the circulatory system help maintain blood pressure despite fluid loss. Increased thirst encourages increased fluid intake to help restore plasma volume. These compensatory changes in the urinary, respiratory, and circulatory systems, as well as the sensation of thirst, are all regulated by the two major regulatory systems, the nervous and endocrine systems. Furthermore, the endocrine system makes internal adjustments to help maintain the concentration of nutrients in the internal environment even though no new nutrients are being absorbed from the digestive system.

Chapter 2 Cell Physiology

Check Your Understanding

2.1 (Questions on p. 22.)

1. See Table 2-1, Principles of the Cell Theory
2. These cells are all about the same size.

2.2 (Questions on p. 29.)

1. In anaerobic conditions 2 molecules of ATP are produced (by glycolysis), and in aerobic conditions 32 molecules of ATP are produced (2 by glycolysis, 2 by the citric acid cycle, and 28 by oxidative phosphorylation) from one glucose molecule.

2.3 (Questions on p. 36.)

1. Under an electron microscope, the plasma membrane has a sandwich appearance, with two dark layers separated by a light middle layer. The two dark layers are the hydrophilic polar regions of the lipid and protein molecules that take up a stain, whereas the light middle layer is the poorly stained hydrophobic core composed of the nonpolar regions of these molecules.
2. desmosome (adhering junction that spot-rivets two adjacent but nontouching cells, anchoring them together in tissues subject to considerable stretching); (2) tight junction (impermeable junction that joins the lateral edges of epithelial cells near their luminal borders, thus preventing movement of materials between the cells); and (3) gap junction (communicating junction made up of small connecting tunnels that permit movement of charge-carrying ions and small molecules between two adjacent cells)
3. See Figure 2-9, Desmosome, p. 35.

2.4 (Questions on p. 46.)

1. See Figure 2-20, Comparison of carrier-mediated transport and simple diffusion down a concentration gradient, p. 43.
2. In facilitated diffusion, the carrier undergoes spontaneous changes in shape as a result of thermal energy. In primary active transport, phosphorylation (binding of the phosphate group derived from the carrier splitting ATP) increases affinity of the carrier for its passenger ion; this binding causes the carrier to change its shape. In secondary active transport, the change in shape of a cotransport carrier that binds both Na^+ and the transported solute is driven by a Na^+ concentration gradient established by a primary active transport mechanism.

2.5 (Questions on p. 59.)

1. When a cell's electrical potential is at the resting membrane potential, the membrane is more permeable to K^+ than Na^+ . Because of this, the resting membrane potential is closer to the K^+ equilibrium potential.
2. See Figure 2-30, Types of changes in membrane potential, p. 58.
3. Voltage-gated channels open or close in response to changes in membrane potential. Chemically gated channels change conformation in response to binding of a specific extracellular chemical messenger to a surface membrane receptor. Mechanically gated channels respond to mechanical deformation such as stretching. Thermally gated channels respond to heat or cold.

2.6 (Questions on p. 64.)

1. Because the resting membrane is 25 to 30 times more permeable to K^+ than to Na^+ , K^+ passes through more readily than Na^+ . The substantially larger movement of K^+ out of the cell influences the resting membrane potential to a much greater extent than the smaller movement of Na^+ into the cell does. As a result, the resting potential (-70 mV) is closer to the equilibrium potential for K^+ (-70 mV) than to the equilibrium potential for Na^+ ($+60$ mV). The resting potential is less than the K^+ equilibrium potential because the limited entry of Na^+ neutralizes some of the potential that would be created by K^+ alone.
2. See Figure 2-37 Permeability changes and ion fluxes during a neuronal action potential, p. 63

2.7 (Questions on p. 69.)

1. During the absolute refractory period, all the Na^+ channels are in the inactivated state. However, during the relative refractory period, some Na^+ channels are starting to move from inactive to closed. A stimulus at

this time can cause these closed Na^+ channels to move to the open state and, depending on how many open, fire an action potential. By the end of the relative refractory period, all the Na^+ channels are in the closed state.

2. During the absolute refractory period, no matter how strong the stimulus, an action potential cannot be fired. Therefore, the length of the absolute refractory period defines the maximum rate that a neuron can fire.

2.8 (Questions on p. 79.)

1. At excitatory synapses, neurotransmitters cause the opening of nonspecific cation channels that allow cations (+ charges) to move into the cell. This charge movement depolarizes the membrane potential, making the membrane more excitable because the membrane potential is closer to threshold. In contrast, at inhibitory synapses, different neurotransmitters open certain Cl^- or K^+ channels that cause the membrane to hyperpolarize and make the membrane less excitable.
2. Summation refers to the cumulative effects of EPSPs and IPSPs on a postsynaptic cell. In temporal summation, repetitive EPSPs from the same presynaptic neuron can sum together and potentially reach threshold. Spatial summation refers to the additive effects of several excitatory presynaptic inputs that sum to potentially reach threshold.

Objective Questions

(Questions on pp. 85–86.)

1. plasma membrane 2. deoxyribonucleic acid (DNA), nucleus 3. organelles, cytosol, cytoskeleton 4. adenosine triphosphate (ATP) 5. F 6. T 7. F 8. 1. b, 2. c, 3. c, 4. a, 5. b, 6. c, 7. a, 8. c 9. 1. b, 2. a, 3. b, 4. a, 5. c, 6. b, 7. a, 8. b 10. 1. a, 2. a, 3. b, 4. a, 5. b, 6. a, 7. b 11. 1. c, 2. b, 3. a, 4. a, 5. c, 6. b, 7. c, 8. a, 9. b 12. F 13. T 14. F 15. F 16. refractory period 17. axon hillock 18. synapse 19. temporal summation 20. 1. b, 2. a, 3. a, 4. b, 5. b, 6. a

Quantitative Exercises

(Questions on pp. 86–87.)

1. b
2. $24 \text{ mol O}_2/\text{day} \times 6 \text{ mol ATP/mol O}_2 = 144 \text{ mol ATP/day}$
 $144 \text{ mol ATP/day} \times 507 \text{ g ATP/mol} \times 73\,000 \text{ g ATP/day}$
 $1000 \text{ g}/2.2 \text{ lb} = 73\,000 \text{ g}/x \text{ lb}$
 $1000x = 73\,000 \times 2.2$
 $x = \text{approximately } 160 \text{ lb, or } 73 \text{ kg}$
3. $144 \text{ mol/day} (7300 \text{ cal/mol}) = 1\,051\,200 \text{ cal/day} (1051 \text{ kilocal/day})$
4. About two-thirds of the water in the body is intracellular. Because a person's mass is about 60 percent water, for a 68 kg person

$$68 \text{ kg}(0.6)(2/3) = 27.2 \text{ kg}$$

is the mass of water. Assume that 1 mL of body water weighs 1 g. The total volume in the person's cells then is about 27.2L. The volume of an average cell is

$$\frac{4}{3}\pi(1 \times 10^{-3} \text{ cm})^3 \approx 4.2 \times 10^{-9} \text{ cm}^3$$
$$= 4.2 \times 10^{-9} \text{ mL}$$

So, the number of cells in a 68 kg person is about

$$27.2 \text{ litres} \left(\frac{1000 \text{ mL}}{1 \text{ litre}} \right) \left(\frac{1 \text{ cell}}{4.2 \times 10^{-9} \text{ mL}} \right)$$
$$= 6.476 \times 10^{12} \text{ cells}$$

5. $150 \text{ mg} \left(\frac{1 \text{ mL}}{0.015 \text{ mg}} \right) = 10\,000 \text{ mL}(10 \text{ L})$
6. $E = \frac{61 \text{ mV}}{z} \log \frac{C_o}{C_i}$
 - a. $\frac{61 \text{ mV}}{2} \log \frac{1 \times 10^{-3}}{100 \times 10^{-9}} = +122 \text{ mV}$
 - b. $\frac{61 \text{ mV}}{-1} \log \frac{110 \times 10^{-3}}{10 \times 10^{-3}} = -63.5 \text{ mV}$

7. $I_x = G_x(V_m - E_x)$
 $E_{Na^+} = 61 \text{ mV} \log \frac{145 \text{ mM}}{15 \text{ mM}} = 60.1 \text{ mV}$
 a. $= \ln(-70 \text{ mV} - 60.1 \text{ mV})$
 $= \ln(-130 \text{ mV})$
 $= -130 \text{ pA}$ ($A = \text{amperes}$)
 b. entering
 c. with concentration gradient
 d. with electrical gradient
8. $V_m = \frac{G_{Na^+}}{G_r} E_{Na^+} + \frac{G_{K^+}}{G_r} E_{K^+}$
 a. $G_r = 1 \text{ nS} + 5.3 \text{ nS} = 6.3 \text{ nS}$;
 $V_m = \frac{1}{6.3} 59.1 \text{ mV} + \frac{5.3}{6.3} (-94.4 \text{ mV})$
 $= 9.4 \text{ mV} - 79.4 \text{ mV} = -70 \text{ mV}$
 b. $E_{K^+} = 0 \text{ mV}$; $V_m = 9.4 \text{ mV}$; that is, large depolarization

Points to Ponder

(Questions on pp. 87–88.)

- With cyanide poisoning, the cellular activities that depend on ATP expenditure could not continue, such as synthesis of new chemical compounds, membrane transport, and mechanical work. The resultant inability of the heart to pump blood and failure of the respiratory muscles to accomplish breathing would lead to imminent death.
- ATP is required for muscle contraction. Muscles are able to store limited supplies of nutrient fuel for use in the generation of ATP. During anaerobic exercise, muscles generate ATP from these nutrient stores by means of glycolysis, which yields two molecules of ATP per glucose molecule processed. During aerobic exercise, muscles can generate ATP by means of oxidative phosphorylation, which yields 36 molecules of ATP per glucose molecule processed. Because glycolysis inefficiently generates ATP from nutrient fuels, it rapidly depletes the muscle's limited stores of fuel, and ATP can no longer be produced to sustain the muscle's contractile activity. Aerobic exercise, in contrast, can be sustained for prolonged periods. Not only does oxidative phosphorylation use far less nutrient fuel to generate ATP, but it can be supported by nutrients delivered to the muscle by means of the blood instead of relying on stored fuel in the muscle. Intense anaerobic exercise outpaces the ability to deliver supplies to the muscle by the blood, so the muscle must rely on stored fuel and inefficient glycolysis, thus limiting anaerobic exercise to brief periods of time before energy sources are depleted.
- d. active transport. Levelling off of the curve designates saturation of a carrier molecule, so carrier-mediated transport is involved. The graph indicates that active transport is being used instead of facilitated diffusion, because the concentration of the substance in the intracellular fluid is greater than the concentration in the extracellular fluid at all points until after the transport maximum is reached. Thus, the substance is being moved *against* a concentration gradient, so active transport must be the method of transport being used.
- vesicular transport. The maternal antibodies in the infant's digestive tract lumen are taken up by the intestinal cells by pinocytosis and are extruded on the opposite side of the cell into the interstitial fluid by exocytosis. The antibodies are picked up from the intestinal interstitial fluid by the blood supply to the region.
- c. The action potentials would stop as they met in the middle. As the two action potentials moving toward each other both reached the middle of the axon, the two adjacent patches of membrane in the middle would be in a refractory period, so further propagation of either action potential would be impossible.
- A subthreshold stimulus would transiently depolarize the membrane but not sufficiently to bring the membrane to threshold, so no action potential would occur. Because a threshold stimulus would bring the membrane to threshold, an action potential would occur. An action potential of the same magnitude and duration would occur in response to a suprathreshold stimulus as to a threshold stimulus. Because of the all-or-none law, a stimulus larger than that necessary to bring the membrane to threshold would not produce a larger action potential. (The magnitude of the stimulus is coded in the *frequency* of action potentials generated in the neuron, not the *size* of the action potentials.)
- The hand could be pulled away from the hot stove by flexion of the elbow accomplished by summation of EPSPs at the cell bodies of the neurons controlling the biceps muscle, thus bringing these neurons to threshold. The subsequent action potentials generated in these neurons would stimulate contraction of the biceps. Simultaneous contraction of the triceps muscle, which would oppose the desired flexion of the elbow, could be prevented by generation of IPSPs at the cell bodies of the neurons controlling this muscle. These IPSPs would keep the triceps neurons from reaching threshold and firing so that the triceps would not be stimulated to contract. The arm could deliberately be extended despite a painful finger prick by voluntarily generating EPSPs to override the reflex IPSPs at the neuronal cell bodies controlling the triceps while simultaneously generating IPSPs to override the reflex EPSPs at the neuronal cell bodies controlling the biceps.
- An EPSP, being a graded potential, spreads decrementally from its site of initiation in the postsynaptic neuron. If presynaptic neuron A (near the axon hillock of the postsynaptic cell) and presynaptic neuron B (on the opposite side of the postsynaptic cell body) both initiate EPSPs of the same magnitude and frequency, the EPSPs from A will be of greater strength when they reach the axon hillock than will the EPSPs from B. An EPSP from B will decrease more in magnitude as it travels farther before reaching the axon hillock, the region of lowest threshold and thus the site of action potential initiation. Temporal summation of the larger EPSPs from A may bring the axon hillock to threshold and initiate an action potential in the postsynaptic neuron, whereas temporal summation of the weaker EPSPs from B at the axon hillock may not be sufficient to bring this region to threshold. Therefore, the proximity of a presynaptic neuron to the axon hillock can bias its influence on the postsynaptic cell.

Clinical Consideration

(Question on p. 88.)

As Cl^- is secreted by the intestinal cells into the intestinal tract lumen, Na^+ follows passively along the established electrical gradient. Water passively accompanies this salt (Na^+ and Cl^-) secretion by osmosis. The toxin produced by the cholera pathogen prevents the normal inactivation of cAMP in intestinal cells, so cAMP levels rise. An increase in cAMP opens the Cl^- channels in the luminal membranes of these cells. Increased secretion of Cl^- and the subsequent passively induced secretion of Na^+ and water are responsible for the severe diarrhoea that characterizes cholera.

Chapter 3 The Central Nervous System

Check Your Understanding

3.1 (Questions on p. 98.)

- See ▶ Figure 3-1, Organization of the nervous system, p. 92.
- An *afferent neuron* has a sensory receptor at its peripheral ending, a long peripheral axon (afferent fibre), a cell body devoid of presynaptic inputs located adjacent to the spinal cord, and a short central axon that terminates in the spinal cord. Afferent neurons relay signals from the periphery to the CNS. The cell body of an *efferent neuron* lies in the CNS and has many presynaptic inputs converging on it. Its long peripheral axon (efferent fibre) branches into axon terminals at the effector organ. Efferent neurons carry instructions from the CNS to effector organs. In contrast to afferent and

efferent neurons, which lie primarily in the PNS, *interneurons* lie entirely in the CNS. The cell body of an interneuron receives converging input from afferent neurons and other interneurons, and its diverging output terminates on efferent neurons or other interneurons. Interneurons are important in integrating afferent information, formulating an efferent response, and accomplishing all higher mental functions associated with the human mind.

Atrocytes are the most abundant glial cell and have a starlike shape. They function to hold neurons together, support the blood–brain barrier, help in repair of brain injuries and neural scar formation, as well as helping to regulate the extracellular environment by removing excess K^+ and neurotransmitters. Oligodendrocytes have elongated projections that wrap around axons to form myelin. Microglia are the immune cells of the CNS. Structurally, they have many branches. At rest, they are found in the ECF, where they secrete growth factors until they are activated, at which time they move to the affected area to perform their immune function.

3.2 (Questions on p. 101.)

1. dura mater, arachnoid mater, and pia mater
2. Tight junctions anatomically prevent transport between the cells that form the walls of brain capillaries, and highly selective membrane-bound carriers physiologically restrict transport through these cells. Together, these mechanisms constitute the blood–brain barrier.

3.3 (Questions on p. 109.)

1. See > Figure 3-9, Spinal cord in cross-section, p. 104.
2. A tract is a bundle of nerve fibres (axons of long interneurons) with similar function that travel up (ascending tract) or down (descending tract) in the white matter of the spinal cord. A ganglion is a collection of neuronal cell bodies located outside the CNS. A centre, or nucleus, is a functional collection of neuronal cell bodies located within the CNS. A nerve is a bundle of peripheral axons (both afferent and efferent fibres), enclosed by a connective-tissue covering and following the same pathway.

3.4 (Questions on p. 113.)

1. All sensory input on its way to the higher cortex synapses in the thalamus, which screens out insignificant signals and routes the important signals to appropriate areas of the cortex. In this way the thalamus serves as a relay station for preliminary processing of sensory input.
2. hypothalamus

3.5 (Questions on p. 121.)

1. See > Figure 3-24, Functional areas of the cerebral cortex, p. 117.
2. the ability of the brain to change or be functionally remodelled in response to the demands placed on it

3.6 (Questions on p. 126.)

1. emotions, basic survival and sociosexual behavioural patterns, motivation, and learning
2. amygdala

3.7 (Questions on p. 132.)

1. the process of transferring and fixing short-term memory traces into long-term memory stores
2. Short-term memory involves transient modifications in the function of pre-existing synapses, such as increased neurotransmitter release from a presynaptic neuron or increased responsiveness of a postsynaptic neuron to neurotransmitter. Long-term memory involves gene activation and protein synthesis that leads to relatively permanent structural or functional changes, such as formation of new synapses.
3. The hippocampus is important for declarative memories, the “what” memories of specific people, places, objects, facts, and events that often result after only one experience. The cerebellum plays an essential role in the “how to” procedural memories involving motor skills gained through repetitive training. The prefrontal association cortex is the major orchestrator of working memory, which temporarily holds currently relevant data—both new information and knowledge retrieved from memory stores—and manipulates and relates them to accomplish complex reasoning functions.

3.8 (Questions on p. 136.)

1. refers to subjective awareness of the external world and self
2. (1) an arousal system, which is regulated by a group of neurons in the hypothalamus and involves the reticular activating system in the brain stem; (2) a slow-wave sleep centre in the hypothalamus that contains neurons that induce slow-wave sleep; and (3) a paradoxical sleep centre in the brain stem, which houses REM neurons that switch from slow-wave to REM sleep

Objective Questions

(Questions on p. 138.)

1. F 2. F 3. T 4. F 5. F 6. habituation 7. consolidation 8. dorsal, ventral
9. 1. a, 2. c, 3. a and b, 4. b, 5. a, 6. c, 7. c 10. 1. d, 2. c, 3. f, 4. e, 5. a, 6. b

Points to Ponder

(Questions on p. 139.)

1. Only the left hemisphere has language ability. When sharing of information between the two hemispheres is prevented as a result of severance of the corpus callosum, visual information presented only to the right hemisphere cannot be verbally identified by the left hemisphere, because the left hemisphere is unaware of the information. However, the information can be recognized by nonverbal means, of which the right hemisphere is capable.
2. c. visual disturbances. A severe blow to the back of the head is most likely to traumatize the visual cortex in the occipital lobe.
3. Salivation when seeing or smelling food, striking the appropriate letter on the keyboard when typing, and many of the actions involved in driving a car are conditioned reflexes. You undoubtedly will have many other examples.
4. Insulin excess is going to cause a lowering of blood-borne glucose concentrations. Consequently, this means there is less glucose available for maintaining brain cell function. When glucose concentrations drop enough, neurons will start to die, resulting in brain damage.

Clinical Consideration

(Question on p. 139.)

The deficits following the stroke—numbness and partial paralysis on the upper right side of the body and inability to speak—are indicative of damage to the left somatosensory cortex and left primary motor cortex in the regions devoted to the upper part of the body, plus Broca's area.

Chapter 4 The Peripheral Nervous System: Sensory, Autonomic, Somatic

Check Your Understanding

4.1 (Questions on p. 149.)

1. A stimulus is a change detectable by the body. A receptor potential is a graded potential change in a receptor in response to a stimulus. A labelled line is a committed, incoming neural pathway that carries information regarding a particular sensory modality detected by a specialized receptor type at a specific site in the periphery, and delivers it to a defined area in the somatosensory cortex. Perception is the conscious interpretation of the external world as created by the brain from the sensory input it receives.
2. See > Figure 4-4, Tonic and phasic receptors, p. 146.
3. The receptive field size for a sensory neuron on your tongue is smaller than it is for a sensory neuron on your back; this is because your tongue has greater discriminative ability than your back does.

4.2 (Questions on p. 152.)

1. See > Table 4-2, Characteristics of Pain Nerve Fibres
2. A-delta fibres constitute a fast pain pathway that carries signals arising from mechanical and thermal nociceptors. C fibres constitute a slow pain pathway that carries impulses from polymodal nociceptors.
3. Endogenous opioids serve as endogenous analgesics by binding with opiate receptors at the synaptic knob of afferent pain fibres where they inhibit release of the pain neurotransmitter, substance P, thereby blocking further transmission of the pain signal.

4.3 (Questions on p. 169.)

1. See > Figure 4-15a, Emmetropia, myopia, and hyperopia, p. 159.
2. When a photopigment absorbs light, retinal changes to the all-trans form, activating the photopigment. The activated photopigment activates the G protein transducin, which then activates the intracellular enzyme phosphodiesterase. In the dark, the second messenger cGMP had been keeping chemically gated Na^+ channels open, resulting in a passive,

inward, depolarizing Na^+ leak (dark current). Activated phosphodiesterase degrades cGMP, permitting these chemically gated Na^+ channels to close, thereby stopping the depolarizing Na^+ leak and causing hyperpolarization of the photoreceptor (the receptor potential).

3. See Table 4-3, Properties of Rod Vision and Cone Vision.

4.4 (Questions on p. 181.)

1. The middle ear amplifies the tympanic membrane vibrations and converts them into wavelike movements in the inner ear fluid at the same frequency as the original sound waves.
2. Pitch discrimination depends on which region of the basilar membrane naturally vibrates maximally with a given sound frequency. Loudness discrimination depends on the amplitude of the vibrations. Timbre discrimination depends on overtones of varying frequencies, which cause many points along the basilar membrane to vibrate simultaneously, but less intensely than the fundamental tone.
3. See Figure 4-33, Vestibular apparatus, p. 179.

4.5 (Questions on p. 187.)

1. salty (stimulated by chemical salts); sour (caused by free H^+ in acids); sweet (evoked by the particular configuration of glucose or by artificial sweeteners, which are organic molecules similar in structure to glucose but have no calories); bitter (elicited by alkaloids and poisonous substances, thus discouraging ingestion of potentially dangerous compounds); umami (triggered by amino acids, especially glutamate, as in meat)
2. An odourant is broken down into various components, and each olfactory receptor responds to a particular odour component that multiple scents may have in common. Each glomerulus in the olfactory bulb receives signals only from receptors that detect a particular odour component. Odour discrimination is based on different patterns of glomeruli (the “smell files”) activated by various scents.

4.6 (Questions on p. 194.)

1. See Figure 4-41, Autonomic nervous system, p. 189.
2. The sympathetic nervous system dominates in emergency or stressful (fight-or-flight) situations and promotes responses that prepare the body for strenuous physical activity. The parasympathetic nervous system dominates in quiet, relaxed (rest-and-digest) situations and promotes “general housekeeping” activities such as digestion.
3. The adrenal medulla is a modified sympathetic ganglion that does not give rise to postganglionic fibres but instead, on stimulation by the pre-ganglionic fibre, secretes the hormones epinephrine and norepinephrine into the blood.

4.7 (Questions on p. 197.)

1. The autonomic nervous system innervates cardiac muscle, smooth muscle, most exocrine glands, some endocrine glands, and adipose tissue. The somatic nervous system innervates skeletal muscles.
2. Motor neurons are considered the final common pathway because the only way any other parts of the nervous system can influence skeletal muscle activity is by acting, in common, on these motor neurons.

4.8 (Questions on p. 201.)

1. Acetylcholine (ACh) is the neuromuscular junction neurotransmitter. When it is released from the motor-neuron terminal button in response to an action potential, it binds with and opens nonspecific cation-receptor channels in the motor end plate of the muscle fibre. The resultant ion movement leads to an end-plate potential, which initiates a contraction-inducing action potential that is propagated throughout the muscle fibre. Acetylcholinesterase (AChE), an enzyme in the membrane of the motor end plate, inactivates ACh. By removing ACh, AChE permits the choice between allowing relaxation to take place (no more ACh released) or keeping the contraction going (more ACh released), depending on the body’s momentary needs.
2. An EPP is larger than an EPSP. Because of its magnitude, an EPP is normally large enough to promote sufficient local current flow to bring the muscle membrane adjacent to the motor end plate to threshold, thereby initiating an action potential. Thus, one-to-one transmission of action potentials occurs between a motor neuron and a muscle fibre at a neuromuscular junction. By contrast, one EPSP does not have sufficient magnitude to bring the postsynaptic neuron to threshold. Summation of EPSPs arising from multiple presynaptic action potentials is needed to initiate an action potential in the postsynaptic neuron.

Objective Questions

(Questions on pp. 204–205)

1. transduction 2. adequate stimulus 3. F 4. T 5. T 6. T 7. F 8. T 9. F 10. F 11. 1. f, 2. h, 3. l, 4. d, 5. i, 6. e, 7. b, 8. j, 9. a, 10. g, 11. c, 12. k 12. 1. a, 2. b, 3. c, 4. c, 5. c, 6. a, 7. b, 8. b 13. T 14. F 15. c 16. c 17. sympathetic, parasympathetic 18. adrenal medulla 19. 1. a, 2. b, 3. a, 4. b, 5. a, 6. a, 7. b 20. 1. b, 2. b, 3. a, 4. a, 5. b, 6. b, 7. a

Quantitative Exercises

(Questions on pp. 205–206)

1. The slow pain pathway takes about $(1.3 \text{ m})(1 \text{ sec}/12 \text{ m}) = 0.1083 \text{ sec}$. The fast pathway takes $(1.3 \text{ m})(1 \text{ sec}/30 \text{ m}) = 0.0433 \text{ sec}$. The difference is $0.1083 \text{ sec} - 0.0433 \text{ sec} = 0.065 \text{ sec} = 65 \text{ msec}$.
2. a. The amount of light entering the eye is proportional, approximately, to the area of the open pupil. Recall that the area of a circle is πr^2 . Let r be the pupil radius and A_1 be the original pupil area. Halving the diameter also halves the radius, so the new pupil area is

$$\pi \left(\frac{1}{2} r^2 \right) = \frac{1}{4} \pi r^2 = \frac{1}{4} A_1$$

- b. Therefore, the amount of light allowed into the eye is a quarter of what it was originally.
The area of a rectangle is hw , where h is the height and w the width. Halving either dimension halves the area and hence the amount of light allowed into the eye.
- c. The cat’s pupil can be considered more precise. Think about the coarse and fine adjustments on a microscope. Fine adjustment translates rotations of the knob into much smaller movement of the microscope’s stage than does coarse adjustment.
3. a. Solve the following for I :
 $\beta = (10 \text{ dB}) \log_{10}(I/I_0)$
 $I = I_0 10^{\beta/10} \text{ W/m}^2$
Therefore,
 $I_1 = 10^{-12} (10^{20/10}) = 10^{-12} (10^2) = 10^{-10} \text{ W/m}^2$
 $I_2 = 10^{-12} (10^{70/10}) = 10^{-12} (10^7) = 10^{-5} \text{ W/m}^2$
 $I_3 = 10^{-12} (10^{120/10}) = 10^{-12} (10^{12}) = 1 \text{ W/m}^2$
 $I_4 = 10^{-12} (10^{170/10}) = 10^{-12} (10^{17}) = 10^{-5} \text{ W/m}^2$
b. Because of the logarithm in the definition of decibel, the sound intensity increases exponentially with respect to sound level. This fact should be clear from the definition of dB solved for I . This result implies that the human ear performs well throughout an enormous range of sound intensities.

$$4. t = \frac{x^2}{2D} = \frac{(200 \text{ nm})^2}{2 \times 10^{-5} \text{ cm}^2/\text{sec}} = \frac{4 \times 10^{-14} \text{ m}^2 \cdot \text{sec}}{2 \times 10^{-5} \text{ cm}^2} = \left(\frac{10^4 \text{ cm}^2}{\text{m}^2} \right) = 20 \mu\text{sec}$$

Points to Ponder

(Questions on p. 206.)

1. Pain is a conscious warning that tissue damage is occurring or about to occur. A patient unable to feel pain because of a nerve disorder does not consciously take measures to withdraw from painful stimuli and thus prevent more serious tissue damage.
2. Pupillary dilation (mydriasis) can be deliberately induced by ophthalmic instillation of either an adrenergic drug (such as epinephrine or related compound) or a cholinergic-blocking drug (such as atropine or related compounds). Adrenergic drugs produce mydriasis by causing contraction of the sympathetically supplied radial (dilator) muscle of the iris. Cholinergic blocking drugs cause pupillary dilation by blocking parasympathetic activity to the circular (constrictor) muscle of the iris so that action of the adrenergically controlled radial muscle of the iris is unopposed.
3. The defect would be in the left optic tract or optic radiation.
4. Fluid accumulation in the middle ear in accompaniment with middle ear infections impedes the normal movement of the tympanic membrane, ossicles, and oval window in response to sound. All these structures vibrate less vigorously in the presence of fluid, causing temporary hearing

impairment. Chronic fluid accumulation in the middle ear is sometimes relieved by surgical implantation of drainage tubes in the eardrum. Hearing is restored to normal as the fluid drains to the exterior. Usually, the tube “falls out” as the eardrum heals and pushes out the foreign object.

5. The sense of smell is reduced when you have a cold because odourants do not reach the receptor cells as readily when the mucous membranes lining the nasal passageways are swollen, and excess mucus is present.
6. By promoting arteriolar constriction, epinephrine administered in conjunction with local anaesthetics reduces blood flow to the region; this helps the anaesthetic stay in the region instead of being carried away by the blood.
7. No. Atropine blocks the effect of acetylcholine at muscarinic receptors but does not affect nicotinic receptors. Nicotinic receptors are present on the motor end plates of skeletal muscle fibres.
8. The voluntarily controlled external urethral sphincter is composed of skeletal muscle and supplied by the somatic nervous system.
9. By interfering with normal acetylcholine activity at the neuromuscular junction, α -bungarotoxin leads to skeletal muscle paralysis, with death ultimately occurring as a result of an inability to contract the diaphragm and breathe.
10. If the motor neurons that control the respiratory muscles, especially the diaphragm, are destroyed by poliovirus or amyotrophic lateral sclerosis, the person is unable to breathe and dies (unless breathing is assisted by artificial means).

Clinical Consideration

(Question on p. 206.)

Syncope most frequently occurs as a result of inadequate delivery of blood carrying sufficient oxygen and glucose supplies to the brain. Possible causes include circulatory disorders, such as impaired pumping of the heart or low blood pressure; respiratory disorders, resulting in poorly oxygenated blood; anaemia, in which the oxygen-carrying capacity of the blood is reduced; or low blood glucose, due to improper endocrine management of blood glucose levels. Vertigo, in contrast, typically results from a dysfunction of the vestibular apparatus, arising, for example, from viral infection or trauma, or abnormal neural processing of vestibular information, as, for example, with a brain tumour.

Chapter 5 Principles of Endocrinology: The Central Endocrine Glands

Check Your Understanding

5.1 (Questions on p. 218.)

1. In general, peptide hormones are synthesized and stored within vesicles. Upon the appropriate stimulation, the vesicles undergo exocytosis to release the peptide hormones into the blood. Peptide hormones are usually hydrophilic so they do not require a transport protein in the blood to reach their target. In contrast, because steroid hormones are lipophilic, once they are synthesized they are not stored, but will leave the cell. In the plasma, they are generally bound to transport proteins to help them reach their targets.
2. Different cells have different proteins available for phosphorylation by protein kinase A. The particular cellular action of cAMP depends on what these proteins do once they are phosphorylated.

5.2 (Questions on p. 222.)

1. (1) Negative feedback maintains the plasma concentration of a hormone at a given set level because the output of the hormonal control system counteracts a change in the input. For example, when the concentration of a hormone falls, the control system triggers increased secretion of the hormone, which feeds back to shut off the stimulatory response when the set level is achieved. (2) Neuroendocrine reflexes produce a sudden increase in hormone secretion (that is, “turn up the thermostat setting”) in

response to a specific stimulus, which is often external to the body.

(3) Diurnal (circadian) rhythms are rhythmic fluctuations up and down in the secretion rate of many hormones as a function of the time of day.

2. Down regulation is a reduction in the number of target-cell receptors in the face of a prolonged increase in a hormone. Permissiveness refers to the need for one hormone to be present in adequate amounts to permit another hormone to fully exert its effects. Synergism results when the combined effect of two hormones is greater than the sum of their separate effects. Antagonism takes place when one hormone decreases the effectiveness of another hormone.
3. See > Figure 5-8, Activation of genes by lipophilic hormones, p. 221.

5.3 (Questions on p. 231.)

1. See > Figure 5-12, Hierarchic chain of command and negative feedback in endocrine control, p. 230.
2. (a) Posterior pituitary hormones—vasopressin (antidiuretic hormone, ADH) and oxytocin. (b) Anterior pituitary hormones—growth hormone (GH, somatotropin), thyroid-stimulating hormone (TSH, thyrotropin), adrenocorticotrophic hormone (ACTH, corticotropin), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and prolactin (PRL). (c) Hypophysiotropic hormones—thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), gonadotropin-releasing hormone (GnRH), growth hormone-releasing hormone (GHRH), somatostatin (growth hormone-inhibiting hormone, GHIH), prolactin-releasing peptide (PrRP), and dopamine (prolactin-inhibiting hormone, PIH)
3. The hypothalamus controls hormonal output from the posterior pituitary by a neural connection and controls hormonal output from the anterior pituitary by a vascular connection. The posterior pituitary is a neural extension of the hypothalamus. Neuronal cell bodies in the hypothalamus produce vasopressin and oxytocin, which are transported down the axons that pass through the connecting stalk to the posterior pituitary, where these hormones are stored in the neuronal terminals. When stimulated by the hypothalamus, these hormones are independently released into the systemic blood. The hypothalamus secretes hypophysiotropic hormones into the hypothalamic-hypophyseal portal system, a capillary-to-capillary vascular link that transports them through the connecting stalk to the anterior pituitary, where they control the secretion of hormones produced by the anterior pituitary into the systemic blood.

5.4 (Questions on p. 240.)

1. GH directly increases fatty acid levels in the blood by enhancing the breakdown of triglyceride stores in adipose tissue and increases blood-glucose levels by decreasing glucose uptake by muscles and increasing glucose output by the liver, thus mobilizing fat stores as a major energy source for muscle, while conserving glucose for the glucose-dependent brain. GH also directly and indirectly (via insulin-like growth factor-I [IGF-I]) brings about protein synthesis, decreasing blood amino acids in the process.
2. GH does not act directly to bring about most of its growth-producing actions (increased cell division, enhanced protein synthesis, and bone growth). Instead, GH stimulates the liver to release IGF-I, which directly mediates these growth-promoting actions. GH's only direct growth-promoting action is to stimulate protein synthesis, which it does in conjunction with IGF-I.
3. Growth hormone has a well-characterized diurnal rhythm for secretion. It is primarily under the control of growth hormone-releasing hormone and growth hormone-inhibiting hormone. However, its secretion can be increased by exercise, stress, and low blood glucose.

Objective Questions

(Questions on p. 244.)

1. T 2. T 3. F 4. T 5. T 6. T 7. tropic 8. down regulation 9. epiphyseal plate 10. suprachiasmatic nucleus 11. 1. c, 2. b, 3. b, 4. a, 5. a, 6. c, 7. c

Points to Ponder

(Questions on p. 244.)

1. The concentration of hypothalamic releasing and inhibiting hormones would be considerably lower (in fact, almost nonexistent) in a systemic venous blood sample compared to the concentration of these hormones

in a sample of hypothalamic–hypophyseal portal blood. These hormones are secreted into the portal blood for local delivery between the hypothalamus and anterior pituitary. Any portion of these hormones is picked up by the systemic blood at the anterior pituitary capillary level is greatly diluted by the much larger total volume of systemic blood, compared to the extremely small volume of blood within the portal vessel.

2. Above normal. Without sufficient iodine, the thyroid gland is unable to synthesize enough thyroid hormone. The resultant reduction in negative-feedback activity by the reduced level of thyroid hormone would lead to increased TSH secretion. Despite the elevated TSH, however, the thyroid gland still could not secrete adequate thyroid hormone because of the iodine deficiency.
3. If CRH and/or ACTH is elevated in accompaniment with the excess cortisol secretion, the condition is secondary to a defect at the hypothalamic/anterior pituitary level. If CRH and ACTH levels are below normal in accompaniment with the excess cortisol secretion, the condition is due to a primary defect at the adrenal cortex level, with the excess cortisol inhibiting the hypothalamus and anterior pituitary in negative-feedback fashion.
4. Males with testicular feminization syndrome would be unusually tall because of the inability of testosterone to promote closure of the epiphyseal plates of the long bones in the absence of testosterone receptors.
5. Full-grown athletes sometimes illegally take supplemental doses of growth hormone because it promotes increased skeletal muscle mass through its protein anabolic effect. However, excessive growth hormone can have detrimental side effects, such as possibly causing diabetes or high blood pressure.

Clinical Consideration

(Question on p. 245.)

Hormonal replacement therapy following pituitary gland removal should include thyroid hormone (the thyroid gland will not produce sufficient thyroid hormone in the absence of TSH) and glucocorticoid (because of the absence of ACTH), especially in stress situations. If indicated, male or female sex hormones can be replaced, even though these hormones are not essential for survival. For example, testosterone in males plays an important role in libido. Growth hormone and prolactin need not be replaced because their absence will produce no serious consequences in this individual. Vasopressin may have to be replaced if insufficient quantities of this hormone are picked up by the blood at the hypothalamus in the absence of the posterior pituitary.

Chapter 6 The Endocrine Glands

Check Your Understanding

6.1 (Questions on p. 254.)

1. A thyroid follicle, the functional unit of the thyroid gland, is a hollow sphere consisting of a single layer of follicular cells enclosing an inner lumen filled with colloid, which serves as an extracellular storage site for thyroid hormone. Colloid is filled with thyroglobulin, a large glycoprotein within which are incorporated the thyroid hormones in their various stages of synthesis. During synthesis, attachment of one iodide to tyrosine yields MIT (monoiodotyrosine), and attachment of two iodides to tyrosine yields DIT (di-iodotyrosine). Coupling of one MIT and one DIT yields T3 (tri-iodothyronine), and coupling of two DITs yields T4 (tetraiodothyronine or thyroxine). T3 and T4 are collectively referred to as thyroid hormone.
2. See Figure 6-3, Regulation of thyroid hormone secretion, p. 251.
3. See Table 6.1, Types of Thyroid Dysfunctions

6.2 (Questions on p. 263.)

1. (a) Mineralocorticoids—aldosterone (promotes Na^+ retention and K^+ elimination during urine formation). (b) Glucocorticoids—cortisol (increases blood glucose at the expense of protein and fat stores and helps the body adapt to stress). (c) Sex hormones—dehydroepiandrosterone

(governs androgen-dependent processes in the female, such as growth of pubic and axillary hair, enhancing pubertal growth spurt, and maintaining the sex drive)

2. ACTH stimulates the adrenal cortex to secrete cortisol but has no effect on aldosterone.
3. epinephrine and norepinephrine, which are stored in chromaffin granules, from which they are secreted into the blood by exocytosis on stimulation by preganglionic sympathetic fibres.

6.3 (Questions on p. 282.)

1. Glycogenesis is the conversion of glucose to glycogen, glycogenolysis is the conversion of glycogen to glucose, and gluconeogenesis is the conversion of amino acids to glucose.
2. Insulin $\downarrow$ blood glucose and promotes carbohydrate storage by facilitating glucose transport into most cells via transporter recruitment and by stimulating glycogenesis and inhibiting glycogenolysis and gluconeogenesis. It $\downarrow$ blood fatty acids and promotes triglyceride storage by increasing the entry of fatty acids and glucose into adipose cells, thereby promoting triglyceride synthesis and inhibiting lipolysis. It $\downarrow$ blood amino acids and enhances protein synthesis by promoting active transport of amino acids into muscles, stimulating protein synthesis, and inhibiting protein degradation. Glucagon $\uparrow$ blood glucose and reduces carbohydrate stores by increasing hepatic glucose production via decreasing glycogenesis and by promoting glycogenolysis and gluconeogenesis. It $\uparrow$ blood fatty acids and reduces fat stores by promoting lipolysis and inhibiting triglyceride synthesis. It $\uparrow$ blood ketone levels by enhancing conversion of fatty acids to ketone bodies by the liver. Glucagon inhibits protein synthesis and promotes protein degradation in the liver but not in muscle, the body's major protein store, so it does not have any significant effect on blood amino acid levels.
3. Increased blood glucose stimulates the pancreatic β cells, thus increasing insulin secretion, and inhibits the pancreatic α cells, thus decreasing glucagon secretion.

6.4 (Questions on p. 292.)

1. Following is the distribution of body Ca^{2+} : 99 percent in the skeleton and teeth, 0.9 percent in the cells, and 0.1 percent in the ECF. Of the Ca^{2+} in the ECF, half is bound in complexes and not available to participate in chemical reactions, and the other half is free Ca^{2+} , which is biologically active. This free ECF Ca^{2+} plays a vital role in neuromuscular excitability, excitation–contraction coupling in cardiac and smooth muscle, stimulus–secretion coupling, excitation–secretion coupling, maintenance of tight junctions, and blood clotting.
2. PTH acts on bone, kidneys, and the intestine to increase plasma Ca^{2+} as follows: PTH stimulates a fast exchange of Ca^{2+} from the small labile pool of Ca^{2+} in the bone fluid into the plasma by activating Ca^{2+} pumps in the osteocytic–osteoblastic bone membrane. It induces a slow exchange of Ca^{2+} from the stable pool of Ca^{2+} in the bone minerals of the bone itself into the plasma by stimulating osteoclasts to dissolve bone. PTH acts on the kidneys to conserve Ca^{2+} and eliminate PO_4^{3-} during urine formation and to activate vitamin D. PTH indirectly increases Ca^{2+} and PO_4^{3-} absorption from the small intestine via its role in activating vitamin D, which directly promotes the intestinal absorption of these ingested electrolytes.
3. Vitamin D is essential for the absorption of Ca^{2+} from the intestine. Without adequate vitamin D, the body will activate the process to mobilize Ca^{2+} from internal stores, such as the bones.

Objective Questions

(Questions on p. 294.)

1. F 2. T 3. T 4. T 5. T 6. F 7. F 8. F 9. colloid, thyroglobulin
10. pro-opiomelanocortin 11. glycogenesis, glycogenolysis, gluconeogenesis
12. brain, working muscles, liver 13. bone, kidneys, digestive tract 14. c
15. a, b, c, g, i, j 16. 1. glucose, 2. glycogen, 3. free fatty acids, 4. triglycerides, 5. amino acids, 6. body proteins

Points to Ponder

(Questions on p. 295.)

1. The midwestern United States is no longer an endemic goitre belt even though the soil is still iodine poor, because individuals living in this

region obtain iodine from iodine-supplemented nutrients, such as iodinated salt, and from seafood and other naturally iodine-rich foods shipped from coastal regions.

2. Anaphylactic shock is an extremely serious allergic reaction brought about by massive release of chemical mediators in response to exposure to a specific allergen—such as one associated with a bee sting—to which the individual has been highly sensitized. These chemical mediators bring about circulatory shock (severe hypotension) through a twofold effect: (1) by relaxing arteriolar smooth muscle, thus causing widespread arteriolar vasodilation and a resultant fall in total peripheral resistance and arterial blood pressure; and (2) by causing a generalized increase in capillary permeability, resulting in a shift of fluid from the plasma into the interstitial fluid. This shift decreases the effective circulating volume, further reducing arterial blood pressure. Additionally, these chemical mediators bring about pronounced bronchoconstriction, making it impossible for the victim to move sufficient air through the narrowed airways. Because these responses take place rapidly and can be fatal, people allergic to bee stings are advised to keep injectable epinephrine in their possession. By promoting arteriolar vasoconstriction through its action on α_1 receptors in arteriolar smooth muscle and by promoting bronchodilation through its action on β_2 receptors in bronchiolar smooth muscle (see Table 6-2), epinephrine counteracts the life-threatening effects of the anaphylactic reaction to the bee sting.
3. An infection elicits the stress response, which brings about increased secretion of cortisol and epinephrine, both of which increase the blood glucose level. This becomes a problem for diabetic patients who have to bring down the elevated blood glucose by injecting additional insulin or, preferably, by reducing carbohydrate intake and/or exercising to use up some of the extra blood glucose. In a normal individual, the check-and-balance system between insulin and the other hormones that oppose insulin's actions helps maintain the blood glucose within reasonable limits during the stress response.
4. The presence of Chvostek's sign is due to increased neuromuscular excitability caused by moderate hyposecretion of parathyroid hormone.
5. If malignancy-associated hypercalcaemia arose from metastatic tumour cells that invaded and destroyed bone, both hypercalcaemia and hyperphosphataemia would result as calcium phosphate salts were released from the destructed bone. The fact that hypophosphataemia, not hyperphosphataemia, often accompanies malignancy-associated hypercalcaemia led investigators to rule out bone destruction as the cause of the hypercalcaemia. Instead, they suspected that the tumours produced a substance that mimics the actions of PTH in promoting concurrent hypercalcaemia and hypophosphataemia.

Clinical Consideration

(Question on p. 295.)

"Diabetes of bearded ladies" is descriptive of both excess cortisol and excess adrenal androgen secretion. Excess cortisol secretion causes hyperglycaemia and glucosuria. Glucosuria promotes osmotic diuresis, which leads to dehydration and a compensatory increased sensation of thirst. All these symptoms—hyperglycaemia, glucosuria, polyuria, and polydipsia—mimic diabetes mellitus. Excess adrenal androgen secretion in females promotes masculinizing characteristics, such as beard growth. Simultaneous hypersecretion of both cortisol and adrenal androgen most likely occurs secondary to excess CRH/ACTH secretion, because ACTH stimulates both cortisol and androgen production by the adrenal cortex.

Chapter 7 Muscle Physiology

Check Your Understanding

7.1 (Questions on p. 302.)

1. A *muscle fibre* is composed of *myofibrils* that extend the entire length of the muscle fibre; in general, the larger-diameter *muscle fibres* have a greater number of myofibrils. A whole muscle is composed of muscle

fibres that extend the entire length of the muscle; in general, the larger-diameter muscles have more muscle fibres.

2. The regulatory protein, troponin, binds to both actin and tropomyosin. In the relaxed state, troponin assumes a conformation that causes tropomyosin to cover the myosin cross-bridge binding sites on the actin molecules.

7.2 (Questions on p. 309.)

1. See Figure 7-7, Changes in banding pattern during shortening, p. 303.
2. The dihydropyridine receptors serve as voltage-gated sensors that are activated by an action potential as it propagates along the T tubule. The activated dihydropyridine receptors trigger the opening of Ca^{2+} -release channels (ryanodine receptors) in the adjacent lateral sacs of the sarcoplasmic reticulum, thereby permitting Ca^{2+} release from the lateral sacs. This released Ca^{2+} repositions the troponin–tropomyosin complex so that actin and the myosin cross bridges can interact to accomplish contraction.
3. See the cross-bridge cycle in Figure 7-12. ATP binds to the myosin head and causes the head to detach from the actin molecule. During the cocking of the myosin head, ATP is hydrolyzed to ADP and P_i . When the myosin head binds to actin, P_i is released from the head during the power stroke. ADP is released from the myosin head after the power stroke.

7.3 (Questions on p. 314.)

1. Greater strength of contraction can be achieved through motor unit recruitment, twitch summation, positioning the muscle at its optimal length, the absence of fatigue, and hypertrophy of a muscle (strength training).
2. In twitch summation, the level of cytosolic Ca^{2+} is increased by repeated release of Ca^{2+} from the lateral sacs. In addition, with repeated excitation of a skeletal muscle cell, insufficient time is available between action potentials for the sarcoplasmic reticulum to pump all the released Ca^{2+} back into the lateral sacs. The sustained, elevated cytosolic Ca^{2+} leads to prolonged exposure of myosin cross-bridge binding sites for interaction with actin and thus greater power stroke opportunities.
3. When skeletal muscle is stretched beyond its optimal length, fewer actin sites are available for cross-bridge cycling, which reduces tension generation.

7.4 (Questions on p. 322.)

1. The leg (drumstick) muscles of a turkey consist primarily of red muscle fibres, which have a large number of mitochondria, high levels of myoglobin, low glycogen content, and relatively few glycolytic enzymes. The turkey's leg muscles are built for endurance, not for speed or power. In contrast, the turkey's breast muscles, composed primarily of white muscle fibres, have relatively few mitochondria, low levels of myoglobin, high glycogen content, and an abundance of glycolytic enzymes. The breast muscles are built for speed and power, but lack endurance (for example, turkeys can fly only a very short distance).
2. ATP comes from all of these sources during the course of the race, but oxidative phosphorylation is responsible for generating the largest amount of ATP expended in this event.

Objective Questions

(Questions on pp. 336–337.)

1. F 2. F 3. F 4. T 5. F 6. T 7. concentric, eccentric 8. alpha, gamma 9. denervation atrophy, disuse atrophy 10. a, b, e 11. b 12. 1. f, 2. d, 3. c, 4. e, 5. b, 6. g, 7. a 13. 1. a, 2. a, 3. a, 4. b, 5. b, 6. b

Quantitative Exercises

(Questions on p. 337.)

1. a. For the weekend athlete, the lever ratio is 70 cm/9 cm. So the velocity at the end of the arm is $2.6 \text{ m/sec } (70/9) = 20.2 \text{ m/sec}$ (about 72 km/h).
b. For the professional ballplayer, the lever ratio is 90 cm/9 cm. So

$$10x = 137 \text{ km/h}$$

$$x = 13 \cdot 7 \text{ km/h } (1 \text{ hr}/36000 \text{ sec})$$

$$= 3 \cdot 8 \text{ m/sec}$$

2. The force–velocity curve is as follows:

- The shape of the curve indicates that it takes time to develop force and that the greater the force developed, the more time is needed.
- The maximum velocity does not change when F_0 is increased, but the muscle can lift heavier loads or generate more force. The maximum load does not increase when the cross-bridge cycling rate increases, but the muscle can lift lighter loads faster. If the muscle increases in size, b increases, and the entire curve shifts up with respect to the v axis.

Points to Ponder

(Questions on pp. 337–338.)

- By placing increased demands on the heart to sustain increased delivery of O_2 and nutrients to working skeletal muscles, regular aerobic exercise induces changes in cardiac muscle that enable it to use O_2 more efficiently, such as increasing the number of capillaries supplying blood to the heart muscle. Intense exercise of short duration, such as weight training, in contrast, does not induce cardiac efficiency. Because this type of exercise relies on anaerobic glycolysis for ATP formation, no demands are placed on the heart for increased delivery of blood to the working muscles.
- The power arm of the lever is 4 cm, and the load arm is 28 cm for a lever ratio of 1:7 (4 cm:28 cm). Thus, to lift an 8 kg stack of books with one hand, the child must generate an upward applied force in the biceps muscle of 56 kg. (With a lever ratio of 1:7, the muscle must exert seven times the force of the load; $7 \times 8 \text{ kg} = 56 \text{ kg}$.)
- The length of the thin filaments is represented by the distance between a Z line and the edge of the adjacent H zone. This distance remains the same in a relaxed and contracted myofibril, which leads to the conclusion that the thin filaments do not change in length during muscle contraction.
- Regular bouts of anaerobic, short-duration, high-intensity resistance training would be recommended for competitive downhill skiing. By promoting hypertrophy of the fast glycolytic fibres, such exercise better adapts the muscles to activities that require intense strength for brief periods, such as a swift, powerful descent downhill. In contrast, regular aerobic exercise would be more beneficial for competitive cross-country skiers. Aerobic exercise induces metabolic changes within the oxidative fibres that enable the muscles to use O_2 more efficiently. These changes, which include an increase in mitochondria and capillaries within the oxidative fibres, adapt the muscles to better endure the prolonged activity of cross-country skiing without fatiguing.
- Because the site of voluntary control to overcome the micturition reflex is at the external urethral sphincter and not the bladder, the external urethral sphincter must be skeletal muscle, which is innervated by the voluntarily controlled somatic nervous system, and the bladder must be smooth muscle, which is innervated by the involuntarily controlled autonomic nervous system. The only other type of involuntarily controlled muscle besides smooth muscle is cardiac muscle, which is found only in the heart. Therefore, the bladder must be smooth, not cardiac, muscle.

Clinical Consideration

(Question on p. 338.)

The muscles in the immobilized leg have undergone disuse atrophy. The physician or physical therapist can prescribe regular resistance-type exercises that specifically use the atrophied muscles to help restore them to their normal size.

Chapter 8 Cardiac Physiology

Check Your Understanding

8.1 (Questions on p. 351.)

- See ▶ Figure 8-1, Pulmonary and systemic circulations in relation to the heart, p. 346.
- The *right* and *left atrioventricular (AV valves)* let blood flow from the atria to the ventricles during ventricular filling, but prevent backflow of blood from the ventricles into the atria during ventricular emptying. The *aortic* and *pulmonary semilunar valves* let blood flow from the ventricles into the aorta and pulmonary arteries during ventricular emptying, but prevent backflow of blood from these major arteries into the ventricles during ventricular filling.
- The endocardium is the thin inner layer. The middle myocardium mainly consists of the cardiac muscle cells. The epicardium is the thin outer layer.

8.2 (Questions on p. 361.)

- See ▶ Figure 8-7, Pacemaker activity of cardiac autorhythmic cells, p. 352 and ▶ Figure 8-10, Action potential of cardiac contractile muscle cells, p. 355.
- SA node* (70–80 action potentials/min), *AV node* (40–60 action potentials/min), and *Bundle of His and Purkinje fibres* (20–40 action potentials/min)
- The electrical activity associated with atrial repolarization occurs simultaneously with ventricular depolarization and is masked by the QRS complex on a normal ECG.

8.3 (Questions on p. 365.)

- Systole* is the period of contraction and emptying, and *diastole* is the period of relaxation and filling during the cardiac cycle.
- (1) aortic pressure > atrial pressure > ventricular pressure, (2) aortic pressure > ventricular pressure > atrial pressure, (3) ventricular pressure > aortic pressure > atrial pressure, (4) aortic pressure > ventricular pressure > atrial pressure
- The first heart sound is associated with the closure of the AV valves; this occurs at the beginning of isovolumetric ventricular contraction. The second heart sound is the semilunar valves; this occurs at the beginning of isovolumetric ventricular relaxation.

8.4 (Questions on p. 373.)

- Parasympathetic stimulation* decreases heart rate and has no effect on stroke volume. *Sympathetic stimulation* increases heart rate and increases stroke volume by increasing the contractile strength of the heart.
- See ▶ Figure 8-20, Intrinsic control of stroke volume (Frank-Starling curve), p. 368.

Quantitative Exercises

(Questions on pp. 381–382.)

- $CO = HR \times SV$
 $40 \text{ L/min} = HR \times 0.07 \text{ L}$
 $HR = (40 \text{ L/min}) / (0.07 \text{ L}) = 571 \text{ beats/min}$
This rate is not physiologically possible.

$$\begin{aligned}
 2. \quad \text{ESV} &= \text{EDV} - \text{SV} \\
 &= 125\text{mL} - 85\text{mL} \\
 &= 40\text{mL}
 \end{aligned}$$

Points to Ponder

(Questions on p. 382.)

1. Because, at a given heart rate, the interval between a premature beat and the next normal beat is longer than the interval between two normal beats, the heart fills for a longer period of time following a premature beat before the next period of contraction and emptying begins. Because of the longer filling time, the end-diastolic volume is larger, and, according to the Frank-Starling law of the heart, the subsequent stroke volume will be correspondingly larger.
2. The heart of a trained athlete is stronger and can pump blood more efficiently, so the resting stroke volume is larger than in an untrained person. For example, if the resting stroke volume of a strong-hearted athlete is 100 mL, a resting heart rate of only 50 beats/minute produces a normal resting cardiac output of 5000 mL/minute. An untrained person with a resting stroke volume of 70 mL, in contrast, must have a heart rate of about 70 beats/minute to produce a comparable resting cardiac output.
3. The direction of flow through a patent ductus arteriosus is the reverse of the flow that occurs through this vascular connection during fetal life. With a patent ductus arteriosus, some of the blood present in the aorta is shunted into the pulmonary artery because, after birth, the aortic pressure is greater than the pulmonary artery pressure. This abnormal blood flow produces a “machinery murmur,” which lasts throughout the cardiac cycle but is more intense during systole and less intense during diastole. Thus, the murmur waxes and wanes with each beat of the heart, sounding somewhat like a washing machine as the agitator rotates back and forth. The murmur is present throughout the cardiac cycle because a pressure differential between the aorta and pulmonary artery is present during both systole and diastole. The murmur is more intense during systole because more blood is diverted through the patent ductus arteriosus as a result of the greater pressure differential between the aorta and pulmonary artery during ventricular systole than during ventricular diastole. Typically, the systolic aortic pressure is 120 mmHg, and the systolic pulmonary arterial pressure is 24 mmHg, for a pressure differential of 96 mmHg. By contrast, the diastolic aortic pressure is normally 80 mmHg, and the diastolic pulmonary arterial pressure is 8 mmHg, for a pressure differential of 72 mmHg.
4. A transplanted heart that does not have any innervation adjusts the cardiac output to meet the body’s changing needs by means of both intrinsic control (the Frank-Starling mechanism) and extrinsic hormonal influences, such as the effect of epinephrine on the rate and strength of cardiac contraction.
5. In left bundle-branch block, the right ventricle becomes completely depolarized more rapidly than the left ventricle. As a result, the right ventricle contracts before the left ventricle, and the right AV valve is forced closed prior to closure of the left AV valve. Because the two AV valves do not close in unison, the first heart sound is “split”; that is, two distinct sounds in close succession can be detected as closure of the left valve lags behind closure of the right valve.

Clinical Consideration

(Question on p. 382.)

The most likely diagnosis is atrial fibrillation. This condition is characterized by rapid, irregular, uncoordinated depolarizations of the atria. Many of these depolarizations reach the AV node at a time when it is not in its refractory period, thereby bringing about frequent ventricular depolarizations and a rapid heartbeat. However, because impulses reach the AV node erratically, the ventricular rhythm and thus the heartbeat are also very irregular as well as being rapid.

Ventricular filling is only slightly reduced despite the fact that the fibrillating atria are unable to pump blood because most ventricular filling occurs during diastole prior to atrial contraction. Because of the erratic heartbeat, variable lengths of time are available between ventricular beats for ventricular filling. However, the majority of ventricular filling occurs early in ventricular diastole after the AV valves first open, so even though

the filling period may be shortened, the extent of filling may be near normal. Only when the ventricular filling period is very short is ventricular filling substantially reduced.

Cardiac output, which depends on stroke volume and heart rate, usually is not seriously impaired with atrial fibrillation. Because ventricular filling is only slightly reduced during most cardiac cycles, stroke volume, as determined by the Frank-Starling mechanism, is likewise only slightly reduced. Only when the ventricular filling period is very short and the cardiac muscle fibres are operating on the lower end of their length-tension curve is the resultant ventricular contraction weak. When the ventricular contraction becomes too weak, the ventricles eject a small or no stroke volume. During most cardiac cycles, however, the slight reduction in stroke volume is often offset by the increased heart rate so that cardiac output is usually near normal. Furthermore, if the mean arterial blood pressure falls because the cardiac output does decrease, increased sympathetic stimulation of the heart brought about by the baroreceptor reflex helps restore cardiac output to normal by shifting the Frank-Starling curve to the left.

On those cycles when ventricular contractions are too weak to eject enough blood to produce a palpable wrist pulse, if the heart rate is determined directly, either by the apex beat or via the ECG, and the pulse rate is taken concurrently at the wrist, the heart rate will exceed the pulse rate, producing a pulse deficit.

Chapter 9 Vascular Physiology

Check Your Understanding

9.1 (Questions on p. 389.)

1. At rest, blood flow is widely distributed and includes the digestive system and the kidneys. During exercise, blood flow is diverted to organs such as skeletal muscles for increase oxygen delivery and the skin to help remove excess heat. Blood flow to the digestive system and kidneys will be reduced as they are not important at this time.
2. digestive tract, kidneys, and skin
3. $F = \Delta P/R$
 $R \propto 1/r^4$

9.2 (Questions on p. 394.)

1. See ■ Table 9-1, Features of Blood Vessels
2. Arteries have an abundance of elastin fibres that allow them to stretch to accommodate the extra volume of blood pumped into them during systole, and then to recoil and drive the extra blood forward into the remaining vasculature during diastole
3. See ► Figure 9-7a, Arterial blood pressure, p. 392.

Objective Questions

(Questions on pp. 429–430.)

10. 1. b, 2. a, 3. b, 4. a, 5. a, 6. a, 7. b, 8. a, 9. b, 10. a, 11. b, 12. a, 13. a

Quantitative Exercises

(Questions on pp. 430–431.)

1. $(120\text{mmHg})/(30\text{L/min}) = 4\text{PRU}$
2. a. $90\text{mmHg} + (180\text{mmHg} - 90\text{mmHg})/3 = 120\text{mmHg}$
b. Because the other forces acting across the capillary wall, such as plasma colloid osmotic pressure, typically do not change with age, one would suspect fluid loss from the capillaries into the tissues would occur as a result of the increase in capillary blood pressure.
3. systemic: $(95\text{mmHg})/(19\text{PRU})$
 $= 95\text{mmHg}/(19\text{mmHg/L/min}) = 5\text{L/min}$
pulmonary: $(20\text{mmHg})/(4\text{PRU}) = 5\text{L/min}$
4. a. 125 mmHg
b. 77 mmHg
c. $48\text{mmHg}(125\text{mmHg} - 77\text{mmHg}) = 48\text{mmHg}$
d. $93\text{mmHg}\left[77 + \frac{1}{3}(48) = 77 + 16 = 93\text{mmHg}\right]$

- e. No; no blood would be able to get through the brachial artery, so no sound would be heard.
- f. Yes; blood would flow through the brachial artery when the arterial pressure was between 118 and 125 mmHg and would not flow through when the arterial pressure fell below 118 mmHg. The turbulence created by this intermittent blood flow would produce sounds.
- g. No; blood would flow continuously through the brachial artery in smooth, laminar fashion, so no sound would be heard.

Points to Ponder

(Questions on p. 431.)

1. An elastic support stocking increases external pressure on the remaining veins in the limb to produce a favourable pressure gradient that promotes venous return to the heart and minimizes swelling that would result from fluid retention in the extremity.
2. The classmate has apparently fainted because of insufficient blood flow to the brain as a result of pooling of blood in the lower extremities brought about by standing still for a prolonged time. When the person faints and assumes a horizontal position, the pooled blood will quickly return to the heart, improving cardiac output and blood flow to his brain. Trying to get the person up would be counterproductive, so the classmate trying to get him up should be advised to let him remain lying down until he recovers on his own.
3. The drug is apparently causing the arteriolar smooth muscle to relax by causing the release of a local vasoactive chemical mediator from the endothelial cells that induces relaxation of the underlying smooth muscle.
4.
 - a. Because activation of α_1 -adrenergic receptors in vascular smooth muscle brings about vasoconstriction, blockage of α_1 -adrenergic receptors reduces vasoconstrictor activity, thereby lowering the total peripheral resistance and arterial blood pressure.
 - b. Because activation of β_1 -adrenergic receptors, which are found primarily in the heart, increases the rate and strength of cardiac contraction, drugs that block β_1 -adrenergic receptors reduce cardiac output and thus arterial blood pressure by decreasing the rate and strength of the heartbeat.
 - c. Drugs that directly relax arteriolar smooth muscle lower arterial blood pressure by promoting arteriolar vasodilation and reducing total peripheral resistance.
 - d. Diuretic drugs reduce the plasma volume, thereby lowering arterial blood pressure, by increasing urinary output. Salt and water that normally would have been retained in the plasma are excreted in the urine.
 - e. Because sympathetic activity promotes generalized arteriolar vasoconstriction, thereby increasing total peripheral resistance and arterial blood pressure, drugs that block the release of norepinephrine from sympathetic endings lower blood pressure by preventing this vasoconstrictor effect.
 - f. Similarly, drugs that act on the brain to reduce sympathetic output lower blood pressure by preventing the effect of sympathetic activity on promoting arteriolar vasoconstriction and the resultant increase in total peripheral resistance and arterial blood pressure.
 - g. Drugs that block Ca^{2+} channels reduce the entry of Ca^{2+} into the vascular smooth muscle cells from the ECF in response to excitatory input. Because the level of contractile activity in vascular smooth muscle cells depends on their cytosolic Ca^{2+} concentration, drugs that block Ca^{2+} channels reduce the contractile activity of these cells by reducing Ca^{2+} entry and lowering their cytosolic Ca^{2+} concentration. Total peripheral resistance and, accordingly, arterial blood pressure are decreased as a result of reduced arteriolar contractile activity.
 - h. Drugs that interfere with the production of angiotensin II block activation of the hormonal pathway that promotes salt and water conservation (the renin-angiotensin-aldosterone system). As a result, more salt and water are lost in the urine, and less fluid is retained in the plasma. The resultant reduction in plasma volume lowers the arterial blood pressure.

Clinical Consideration

(Question on p. 431.)

The abnormally elevated levels of epinephrine found with a pheochromocytoma bring about secondary hypertension by (1) increasing the heart rate;

- (2) increasing cardiac contractility, which increases stroke volume;
- (3) causing venous vasoconstriction, which increases venous return and subsequently stroke volume by means of the Frank-Starling mechanism; and
- (4) causing arteriolar vasoconstriction, which increases total peripheral resistance. Increased heart rate and stroke volume both lead to increased cardiac output. Increased cardiac output and increased total peripheral resistance both lead to increased arterial blood pressure.

Chapter 10 The Blood

Check Your Understanding

10.1 (Questions on p. 436.)

1. See ▶ Figure 10-1, Haematocrit and types of blood cells, p. 435.
2. Plasma proteins (1) exert an osmotic effect important in the distribution of ECF between the vascular and interstitial compartments, (2) buffer pH changes, (3) transport many substances that are poorly soluble in plasma, (4) include clotting factors, (5) include inactive precursor molecules, and (6) include antibodies.

10.2 (Questions on p. 444.)

1. Four anatomic features of erythrocytes contribute to the efficiency with which they transport O_2 . (1) Most importantly, they are completely full of O_2 -carrying haemoglobin, and 98.5 percent of the O_2 in the blood is bound to haemoglobin. (2) Their unique biconcave shape provides a larger surface area for diffusion of O_2 across the membrane than would a spherical cell of the same volume. (3) Their thinness enables O_2 to diffuse rapidly from the exterior to the innermost regions of the cell. (4) Their membrane flexibility enables them to deform so that they can squeeze through capillaries less than half their diameter on their O_2 -delivery route.
2. O_2 , CO_2 , H^+ , CO, and NO
3. *Erythropoietin*, which the kidneys secrete into the blood in response to reduced O_2 delivery, stimulates increased erythrocyte production by the red bone marrow.

10.3 (Questions on p. 447.)

1. See ▶ Figure 10-8, Peripheral blood smear, p. 445.
2. Neutrophils are phagocytic specialists, act like suicide bombers by releasing neutrophil extracellular traps (NETs) during a unique type of programmed cell death, are the first defenders on the scene of bacterial invasion, and are important in inflammatory responses. Eosinophils are important in allergic reactions and attack parasitic worms. Basophils release histamine that is important in allergic reactions and heparin that speeds up removal of fat particles from the blood. Monocytes leave the blood and set up residence in tissues throughout the body, where they mature into large tissue phagocytes known as macrophages. B lymphocytes produce antibodies. T lymphocytes accomplish cell-mediated immunity by releasing chemicals that punch holes in virally invaded body cells and in cancer cells.

10.4 (Questions on p. 454.)

1. The plasma protein von Willebrand factor (vWF) adheres to exposed collagen at a vessel defect. Circulating platelets attach to binding sites on vWF. Collagen activates the bound platelets, which release ADP that causes passing-by platelets to become sticky and pile on top of the growing *platelet plug* at the defect site in a positive-feedback fashion.
2. See ▶ Figure 10-14, Clot pathways, p. 451.

Objective Questions

Quantitative Exercises

(Questions on p. 456.)

1.
 - a. $(15 \text{ g})/(100 \text{ mL}) = (150 \text{ g/L})$
 $(150 \text{ g/L}) \times (1 \text{ mol}/66 \times 10^3 \text{ g}) = 2.27 \text{ mM}$
 - b. $(2.27 \text{ mM}) \times (4 \text{ O}_2/\text{Hb}) = 9.09 \text{ mM}$

- c. $(9.09 \times 10^{-3} \text{ mol O}_2/\text{L blood}) \times (22.4 \text{ L O}_2/\text{mol O}_2) = 204 \text{ mL O}_2/\text{L blood}$
2. Normal blood contains $5 \times 10^9 \text{ RBCs/mL}$.
Normal blood volume is 5 L.
Thus, a normal person has $(5 \times 10^9 \text{ RBCs/mL}) \times (5000 \text{ mL}) = 25 \times 10^{12} \text{ RBCs}$.
The normal haematocrit (Ht) is 45 percent, whereas the anaemic has a Ht of 30 percent. This represents a loss of 1/3 of the RBCs, that is, $8.3 \times 10^{12} \text{ RBCs}$.
If RBCs are produced at a rate of $3 \times 10^6 \text{ RBCs/sec}$, then the time to re-establish the Ht is $8.3 \times 10^{12} \text{ RBCs} / (3 \times 10^6 \text{ RBCs/sec}) = 2.77310^6 \text{ sec} = 32 \text{ days}$.
Thus, it takes about a month to replace a haemorrhagic loss of RBCs of this magnitude.
3. $v = 1.5 \times \exp(2h)$; calculate v for $h = 0.4$ and $h = 0.7$.
When $h = 0.4$, $v = 1.5 \times \exp(0.8) = 3.3$.
When $h = 0.7$, $v = 1.5 \times \exp(1.4) = 6.1$.
 $6.1/3.3 = 1.85$, that is, an 85 percent increase in viscosity. Because resistance is directly proportional to viscosity, the resistance will also increase by 85 percent.

Points to Ponder

(Questions on p. 456.)

- No, you cannot conclude that a person with a haematocrit of 62 definitely has polycythaemia. With 62 percent of the whole-blood sample consisting of erythrocytes (normal being 45%), the number of erythrocytes compared to the plasma volume is definitely elevated. However, the person *may* have polycythaemia, in which the number of erythrocytes is abnormally high, or may be dehydrated, in which case a normal number of erythrocytes is concentrated in a smaller-than-normal plasma volume.
- If the genes that direct fetal haemoglobin-F synthesis could be reactivated in a patient with sickle cell anaemia, a portion of the abnormal haemoglobin S that causes the erythrocytes to warp into defective sickle-shaped cells would be replaced by “healthy” haemoglobin F, thus sparing a portion of the RBCs from premature rupture. Haemoglobin F would not completely replace haemoglobin S because the gene for synthesis of haemoglobin S would still be active.
- Most heart attack deaths are attributable to the formation of abnormal clots that prevent normal blood flow. The sought-after chemicals in the “saliva” of bloodsucking creatures are particular agents that break up or prevent the formation of these abnormal clots.

Although genetically engineered tissue-plasminogen activator (tPA) is already being used as a clot-busting drug, this agent brings about degradation of fibrinogen as well as fibrin. Thus, even though the life-threatening clot in the coronary circulation is dissolved, the fibrinogen supplies in the blood are depleted for up to 24 hours until new fibrinogen is synthesized by the liver. If the patient sustains a ruptured vessel in the interim, insufficient fibrinogen might be available to form a blood-staunching clot. For example, many patients treated with tPA suffer haemorrhagic strokes within 24 hours of treatment due to incomplete sealing of a ruptured cerebral vessel. Therefore, scientists are searching for better alternatives to combat abnormal clot formation by examining the naturally occurring chemicals produced by bloodsucking creatures that permit them to suck a victim's blood without the blood clotting.

- When considering the symptoms of porphyria, one could imagine how tales of vampires—blood-craving, hairy, fanged, monstrous-looking creatures who roamed in the dark and were warded off by garlic—might easily have evolved from people's encounters with victims of this condition. This possibility is especially likely when considering how stories are embellished and distorted as they get passed along by word of mouth.

Clinical Consideration

(Question on p. 456.)

Because the white blood cell count is within the normal range, the patient's pneumonia is most likely not caused by a bacterial infection. Bacterial infections are typically accompanied by an elevated total white blood cell count

and an increase in percentage of neutrophils. Therefore, the pneumonia is probably caused by a virus. Because antibiotics are more useful in combating bacterial than viral infections, antibiotics are not likely to be useful in combating this patient's pneumonia.

Chapter 11 Body Defences

Check Your Understanding

11.1 (Questions on p. 464.)

- The skin consists of an outer *epidermis* and inner *dermis*. The epidermis has an inner layer of living cube-shaped cells and an outer keratinized layer of dead, flattened cells. The epidermis has no direct blood supply, instead it gets its nourishment from the underlying dermis, a connective tissue layer that has an abundance of blood vessels. The skin is anchored to muscle or bone by the *hypodermis*: a layer of loose connective tissue that often contains an abundance of fat cells, in which case it is called *adipose tissue*.
- (1) *Melanocytes* produce the pigment melanin, which is responsible for different skin colours. (2) *Keratinocytes* produce keratin, which gives rise to the outer, protective, keratinized layer of the epidermis. (3) *Langerhans cells* present antigen to helper T cells. (4) *Granstein cells* are immune-suppressive cells.

11.2 (Questions on p. 466.)

- Immunity* is the body's ability to resist or eliminate potentially harmful foreign materials or abnormal cells.
- Innate immune responses* are inherent defense mechanisms that nonselectively defend against foreign or abnormal material of any type, even on initial exposure to it. *Adaptive immune responses* are selectively targeted against a particular foreign material to which the body has already been exposed and had an opportunity to prepare for an attack aimed discriminately at the enemy.

11.3 (Questions on p. 473.)

- (1) *Inflammation* is a nonspecific response to foreign invasion or tissue damage mediated largely by phagocytes and macrophages that destroy or incapacitate the invaders, remove debris, and prepare for subsequent healing and repair. (2) *Interferon* is released by virally invaded cells and, nonspecifically, transiently interferes with the replication of the same or unrelated viruses in other host cells. (3) *Natural killer cells* nonspecifically destroy virally invaded cells and cancer cells by releasing chemicals that directly lyse these cells on first exposure to them. (4) The *complement system* is a group of inactive plasma proteins that, when sequentially activated, destroy foreign cells by forming holes in their plasma membranes.
- The gross manifestations of inflammation are redness, heat, swelling, and pain. Redness and heat are due to the increased blood flow. Fluids accumulate, and this causes the swelling. Pain is caused by chemicals that activate pain receptors.
- Cytokines* refer to all the chemicals, other than antibodies, secreted by leukocytes. Cytokines help enhance the function of other immune cells as well as many other immune functions.

11.4 (Questions on p. 475.)

- Antibody mediated immunity* is accomplished by B lymphocytes, and *cell-mediated immunity* is accomplished by T lymphocytes.
- An *antigen* is a large, foreign, unique molecule that triggers a specific immune response against itself.

11.5 (Questions on p. 481.)

- An *antibody* is Y-shaped. The *Fab* regions on the tip of each arm are variable among antibodies and determine with which specific antigen the antibody can bind in a lock-and-key fashion. The *Fc* tail region, which is constant for a given antibody class, binds with a particular antibody mediator, thereby determining what the antibody does once it binds with antigen.
- neutralization of bacterial toxins, agglutination, activation of the complement system, enhancement of phagocytosis by acting as opsonins, and stimulation of natural killer cells
- See > Figure 11-13, Clonal selection theory, p. 479.

11.6 (Questions on p. 491.)

1. *Cytotoxic*, or *killer*, *T cells* destroy virus-invaded host cells and cancer cells by secreting (1) perforin, which forms hole-punching complexes in the victim cell; or (2) granzymes, which trigger the victim cell to self-destruct through apoptosis. *Helper T cells* secrete cytokines that amplify the activities of other immune cells. *Regulatory T cells* suppress immune responses; they inhibit both innate and adaptive immune responses in check-and-balance fashion to minimize harmful immune pathology.
2. *Antigen-presenting cells* process and present antigen, complexed with MHC molecules (self-antigens), on their surface to T cells. T cells cannot interact with antigen without this “formal introduction.”
3. In the process of *immune surveillance*, natural killer cells, cytotoxic T cells, macrophages, and the interferon they collectively secrete normally eradicate newly arisen cancer cells before they have a chance to multiply and spread.

11.7 (Questions on p. 494.)

1. See Table 11-3, Immediate versus Delayed Hypersensitivity Reactions.
2. In contrast to *IgG antibodies*, which freely circulate and immediately amplify innate defense mechanisms on binding with their specific antigen, *IgE antibodies* specific for different antigens attach by their tail portions to mast cells and basophils in the absence of antigen. The binding of an appropriate antigen triggers the rupture of the cell's granules, which contain histamine and other inflammatory chemical mediators that spew forth into the surrounding tissue, where they cause the allergic response.

Objective Questions

(Questions on pp. 496–497.)

1. F 2. F 3. F 4. F 5. T 6. toll-like receptors 7. membrane-attack complex

14. 1. a, 2. a, 3. b, 4. b, 5. c, 6. c, 7. b, 8. a, 9. b, 10. b, 11. a, 12. b 15. 1. b, 2. a, 3. a,
4. b, 5. a, 6. a, 7. a, 8. b

Quantitative Exercise

(Question on p. 497.)

1. $NEP = \text{net outward pressure} - \text{net inward pressure}$
 $NEP = (P_C + \pi_{IF}) - (P_{IF} + \pi_P)$
Note for this problem, $(P_{IF} + \pi_P) = (25 \text{ mmHg} + 1 \text{ mmHg}) = 26 \text{ mmHg}$,
is constant for all cases.

Points to Ponder

(Questions on p. 497.)

1. Against bacteria, defences begin with the innate immune mechanism of inflammation. Resident macrophages engulf invading bacteria, while histamine-induced vascular responses increase blood flow. This increased blood flow brings additional immune-effector cells such as neutrophils and monocytes to help engulf and destroy foreign invaders and debris. These innate immune mechanisms are coupled with adaptive immune mechanisms. Plasma cells secrete customized antibodies, which specifically bind to invading bacteria, further leading to the bacteria's destruction.
2. A vaccine against a particular microbe can be effective only if it induces formation of antibodies and/or activated T cells against a stable antigen that is present on all microbes of this type. It has not been possible to produce a vaccine against HIV because it frequently mutates. Specific immune responses induced by vaccination against one form of HIV may prove to be ineffective against a slightly modified version of the virus.
3. Failure of the thymus to develop would lead to an absence of T lymphocytes and no cell-mediated immunity after birth. This outcome would seriously compromise the individual's ability to defend against viral invasion and cancer.
4. Researchers are working on ways to “teach” the immune system to view foreign tissue as “self” as a means to prevent the immune system of an organ-transplant patient from rejecting the foreign tissue, while leaving the patient's capacity for immune defence fully intact. The immunosuppressive drugs now used to prevent transplant rejection cripple the recipients' immune defence systems and leave the patients more vulnerable to microbial invasion.
5. The skin cells visible on the body's surface are all dead.

Clinical Consideration

(Questions on p. 497.)

1. The spleen primarily acts as a blood filter. It is responsible for the removal of old blood cells and platelets, the storage of red blood cells, and the production, storage, and release of lymphocytes and macrophages.
2. Patients who have had their spleen—an important element of the immune system—removed can develop infections much quicker than a person with a spleen. The severity of infections also tends to be worse, such that infections that would normally be considered mild can become life threatening.
3. Christine's platelet count will increase. Because the spleen normally removes old platelets from the blood, her platelet count can increase above normal and increase the risk of blood clots.

Chapter 12 The Respiratory System

Check Your Understanding

12.1 (Questions on p. 503.)

1. See Figure 12-3, Schematic of airways, p. 503.
2. Only 0.5 μm separates the air in the alveoli from the blood in the pulmonary capillaries, and the alveolar air-blood interface presents a tremendous surface area (75 m^2) for exchange. The thinness and extensive surface area of the alveolar membrane facilitate gas exchange because the rate of diffusion is inversely proportional to the thickness and directly proportional to the surface area of this interface.
3. *Type I alveolar cells* form the walls of the alveoli.

12.2 (Questions on p. 505.)

1. The three factors are the pressure gradient, resistance to flow, and the inertia of the system. Of these, the first two are most important.

12.3 (Questions on p. 508.)

1. At residual volume, the deflating actions of the lungs do not oppose the inflating actions of the chest wall, so the pressure reflects the passive inflation of the chest wall. At functional residual capacity, the pressure of the lungs to deflate is equal to the pressure of the chest wall to inflate, so the net pressure is 0. At total lung capacity, both the lungs and the chest wall exert pressure to deflate.
2. At functional residual capacity, the need to generate pressure is minimized, which decreases the amount of work (energy) needed to breathe.

12.4 (Questions on p. 510.)

1. The forces that keep the alveoli open are the transmural pressure gradient and pulmonary surfactant (which opposes alveolar surface tension), and the forces that promote alveolar collapse are elastic recoil and alveolar surface tension.

12.5 (Questions on p. 514.)

1. Alveolar pressure must decrease to below atmospheric pressure.
2. During inspiration pleural pressure decreases, transpulmonary pressure decreases, whereas alveolar pressure initially decreases and then increases to 0 again. During expiration, pleural pressure increases, transpulmonary pressure increases, and alveolar pressure first increases then decreases to 0.

12.6 (Questions on p. 520.)

1. In the case of obstructive disease, lung volume is greater and peak flow is achieved earlier, but it is less than for a normal person, and forced vital capacity is less than expected. In the case of restrictive lung disease, lung volume is smaller and peak flow is reduced.
2. With an exacerbation of obstructive lung disease, a person cannot breathe out due to airway collapse. This results in trapping gas and increasing lung volume.

12.7 (Questions on p. 523.)

1. To increase alveolar ventilation during exercise you need to breathe faster and generate a higher tidal volume. However, this capability is limited by the delivery of oxygen to the respiratory muscles; without enough oxygen delivery, fatigue will occur.

12.8 (Questions on p. 525.)

1. See ■ Table 12.6, Partial Pressures of Gases in Different Parts of the Respiratory System.

12.9 (Questions on p. 529.)

1. See ■ Table 12-7, Factors that Influence the Rate of Gas Transfer across the Alveolar-Capillary Membrane.

12.10 (Questions on p. 530.)

1. If ventilation to a region is not sufficient, there will be a regional decrease in P_{O_2} . This will cause a constriction of the vascular smooth muscle, thereby increasing vascular resistance and decreasing blood flow, which allows a rise in P_{O_2} . If P_{CO_2} is high, it will cause a dilation of the regional airways to increase regional ventilation to decrease P_{CO_2} .

12.11 (Questions on p. 539.)

1. Oxygen can be transported both as dissolved gas (1–2%) and bound to haemoglobin (98–99%). Carbon dioxide can be transported as dissolved gas (5–10%), bound to haemoglobin (5–10%), or as bicarbonate (80–90%).

12.12 (Questions on p. 541.)

1. See ► Figure 12-37, Effects of hyperventilation and hypoventilation on arterial P_{O_2} and P_{CO_2} , p. 540.

12.13 (Questions on p. 543.)

1. The discharge of motor neurons that innervate pump muscles change with inspiration and expiration. In contrast, the discharge patterns for motor neurons that innervate muscles controlling the diameter of the upper airway are relatively constant.
2. When the chemical drive to breathing is increased, motor neurons innervating muscles of the upper airway are recruited, and their discharge pattern resembles those for the pump neurons.

12.14 (Questions on p. 549.)

1. Potential factors are P_{O_2} , P_{CO_2} , arterial H^+ . P_{CO_2} is likely the most important due to its actions on the central chemoreceptors of the respiratory centre.

Objective Questions

(Questions on p. 552.)

1. F 2. F 3. T 4. F 5. F 6. F 7. Quantitative Exercises

(Questions on p. 553.)

For general reference for questions 1 and 2:

$$P_{A_{O_2}} = P_{I_{O_2}} - (\dot{V}_{O_2}/\dot{V}_A) \times 863 \text{ mmHg}$$

$$P_{A_{CO_2}} = (\dot{V}_{CO_2}/\dot{V}_A) \times 863 \text{ mmHg}$$

1. $\dot{V}_A = 3 \text{ L/min}$
 $\dot{V}_{O_2} = 0.3 \text{ L/min}$, $R = 1$, therefore $\dot{V}_{CO_2} = 0.3 \text{ L/min}$
 $P_{A_{CO_2}} = (0.3 \text{ L/min}/3 \text{ L/min}) \times 863 \text{ mmHg} = 86.3 \text{ mmHg}$
2. a. $380 \text{ mmHg} \times 0.21 = 79.8 \text{ mmHg}$
b. $P_{A_{O_2}} = 79.8 \text{ mmHg} - (0.06) \times 431.5 \text{ mmHg}$
 $= 79.8 \text{ mmHg} - 25.8 \text{ mmHg}$
 $= 57 \text{ mmHg}$
c. $P_{A_{CO_2}} = (0.2 \text{ L/min}/4.2 \text{ L/min}) \times 431.5 \text{ mmHg}$
 $= 20.5 \text{ mmHg}$
3. $V_T = 350 \text{ mL}$, $f = 12/\text{min}$, $\dot{V}_A = 0.8 \times \dot{V}_E$, $V_D = ?$
 $\dot{V}_A = f \times (V_T - V_D)$
 $\dot{V}_E = f \times V_T$
 $0.8 = \dot{V}_A/\dot{V}_E = f \times [(V_T - V_D)]/(f \times V_T)$
 $= 1 - (V_D/V_T)$
 $0.8 = 1 - V_D/350 \text{ mL}$
 $V_D/350 \text{ mL} = 0.2$
 $V_D = 0.2(350 \text{ mL}) = 70 \text{ mL}$

Points to Ponder

(Questions on p. 554.)

1. Total atmospheric pressure decreases with increasing altitude, yet the percentage of O_2 in the air remains the same. At an altitude of 9144 m (30 000 feet), the atmospheric pressure is only 226 mmHg. Because 21 percent of atmospheric air consists of O_2 , the P_{O_2} of inspired air at 9144 m is only 47.5 mmHg, and alveolar P_{O_2} is even lower, at about 20 mmHg. At this low P_{O_2} , haemoglobin is only about 30 percent saturated with O_2 ; this is much too low to sustain tissue needs for O_2 .

The P_{O_2} of inspired air can be increased by two means when flying at high altitude. First, by pressurizing the plane's interior to a pressure comparable to that of atmospheric pressure at sea level, the P_{O_2} of inspired air within the plane is 21 percent of 760 mmHg, or the normal 160 mmHg. Accordingly, alveolar and arterial P_{O_2} and percentage of Hb saturation are likewise normal. In the emergency situation of failure to maintain internal cabin pressure, breathing pure O_2 can raise the P_{O_2} considerably above that accomplished by breathing normal air. When a person is breathing pure O_2 , the entire pressure of inspired air is attributable to O_2 . For example, with a total atmospheric pressure of 226 mmHg at an altitude of 9144 m, the P_{O_2} of inspired pure O_2 is 226 mmHg, which is more than adequate to maintain normal arterial Hb saturation.

2. a. Hypercapnia would not accompany the hypoxia associated with cyanide poisoning. In fact, CO_2 levels decline, because oxidative metabolism is blocked by the tissue poisons so that CO_2 is not being produced.
b. Hypercapnia could but may not accompany the hypoxia associated with pulmonary oedema. Pulmonary diffusing capacity is reduced in pulmonary oedema, but O_2 transfer suffers more than CO_2 transfer because the diffusion coefficient for CO_2 is 20 times that for O_2 . As a result, hypoxia occurs much more readily than hypercapnia in these circumstances. Hypercapnia does occur, however, when pulmonary diffusing capacity is severely impaired.
c. Hypercapnia would accompany the hypoxia associated with restrictive lung disease because ventilation is inadequate to meet the metabolic needs for both O_2 delivery and CO_2 removal. Both O_2 and CO_2 exchange between the lungs and atmosphere are equally affected.
d. Hypercapnia would not accompany the hypoxia associated with high altitude. In fact, arterial P_{CO_2} levels actually decrease. One of the compensatory responses in acclimatization to high altitudes is reflex stimulation of ventilation as a result of the reduction in arterial P_{O_2} . This compensatory hyperventilation to obtain more O_2 blows off too much CO_2 in the process, so arterial P_{CO_2} levels decline below normal.
e. Hypercapnia would not accompany the hypoxia associated with severe anaemia. Reduced O_2 -carrying capacity of the blood has no influence on blood CO_2 content, so arterial P_{CO_2} levels are normal.
f. Hypercapnia would accompany the circulatory hypoxia associated with congestive heart failure. Just as the diminished blood flow fails to deliver adequate O_2 to the tissues, it also fails to remove sufficient CO_2 .
g. Hypercapnia would accompany the hypoxia associated with obstructive lung disease, because ventilation would be inadequate to meet the metabolic needs for both O_2 delivery and CO_2 removal. Both O_2 and CO_2 exchange between the lungs and atmosphere would be equally affected.
3. $P_{CO_2} = 122 \text{ mmHg}$
 $0.21(\text{atmospheric pressure} - \text{partial pressure of } H_2O)$
 $= 0.21(630 \text{ mmHg} - 47 \text{ mmHg})$
 $= 0.21(583 \text{ mmHg}) = 122 \text{ mmHg}$
4. Voluntarily hyperventilating before going underwater lowers the arterial P_{CO_2} but does not increase the O_2 content in the blood. Because the P_{CO_2} is below normal, the swimmers can hold their breath longer than usual before the arterial P_{O_2} increases to the point that they are driven to surface for a breath. Therefore, a swimmer can stay underwater longer. The risk, however, is that the O_2 content of the blood, which was normal, not increased, before going underwater, continues to fall. Therefore, the O_2 level in the

blood can fall dangerously low before the CO_2 level builds to the point of driving the swimmer to take a breath. Low arterial P_{O_2} does not stimulate respiratory activity until it has fallen to 60 mmHg. Meanwhile, the person may lose consciousness (known as shallow water blackout) and drown due to inadequate O_2 delivery to the brain. If the person does not hyperventilate so that both the arterial P_{CO_2} and O_2 content are normal before going underwater, the buildup of CO_2 will drive the person to the surface for a breath before the O_2 levels fall to a dangerous point.

5. c. The arterial P_{O_2} will be less than the alveolar P_{CO_2} , and the arterial will be greater than the alveolar P_{CO_2} . Because pulmonary diffusing capacity is reduced, arterial P_{CO_2} and P_{O_2} do not equilibrate with alveolar P_{CO_2} and P_{O_2} .

If the person is administered 100 percent O_2 , the alveolar P_{O_2} will increase, and the arterial P_{O_2} will increase accordingly. Even though P_{O_2} arterial will not equilibrate with alveolar P_{O_2} , it will be higher than when the person is breathing atmospheric air.

The arterial P_{CO_2} will remain the same whether the person is administered 100 percent O_2 or is breathing atmospheric air. The alveolar and thus the blood-to-alveolar P_{CO_2} gradient are not changed by breathing 100 percent O_2 because the P_{CO_2} in atmospheric air and 100 percent O_2 are both essentially zero (P_{CO_2} in atmospheric air 0.3 mmHg).

Clinical Consideration

(Question on p. 554.)

Emphysema is characterized by a collapse of the smaller respiratory airways and a breakdown of alveolar walls. Because of the collapse of smaller airways, airway resistance is increased with emphysema. As with other chronic obstructive pulmonary diseases, expiration is impaired to a greater extent than inspiration because airways are naturally dilated slightly more during inspiration than expiration as a result of the greater transmural pressure gradient during inspiration. Because airway resistance is increased, a patient with emphysema must produce larger-than-normal intra-alveolar pressure changes to accomplish a normal tidal volume. Unlike quiet breathing in a normal person, the accessory inspiratory muscles (neck muscles) and the muscles of active expiration (abdominal muscles and internal intercostal muscles) must be brought into play to inspire and expire a normal tidal volume of air.

The spirogram would be characteristic of chronic obstructive pulmonary disease. Because the patient experiences more difficulty emptying the lungs than filling them, the total lung capacity would be essentially normal, but the functional residual capacity and the residual volume would be elevated as a result of the additional air trapped in the lungs following expiration. Because the residual volume is increased, the inspiratory capacity and vital capacity will be reduced. Also, the FEV_1 will be markedly reduced because the expiratory flow is decreased by the airway obstruction. The FEV_1 -to-vital capacity ratio will be much lower than the normal 80 percent.

Because of the reduced surface area for exchange as a result of a breakdown of alveolar walls, gas exchange would be impaired. Therefore, arterial P_{CO_2} would be elevated and arterial P_{O_2} reduced compared to normal.

Paradoxically, administering O_2 to this patient to relieve his hypoxic condition would markedly depress his drive to breathe by elevating the arterial P_{O_2} and removing the primary driving stimulus for respiration. In addition, changes that occur in the distribution of ventilation and perfusion impair gas exchange. Because of this danger, O_2 therapy should either not be administered or administered extremely cautiously.

inner part of the cortex next to the medulla. The loops of Henle of cortical nephrons dip only slightly into the medulla, but the juxtamedullary nephrons have long loops of Henle that plunge deep into the medulla. The juxtamedullary nephrons' peritubular capillaries form hairpin loops known as vasa recta. See ▶ Figure 13-5, Comparison of juxtamedullary and cortical nephrons, p. 563.

3. At rest there is more than adequate renal blood flow to supply O_2 to the kidneys. However, during exercise, other organs, such as skeletal muscle, have a higher requirement for blood flow, and the temporary shunting of blood flow to those regions does not greatly impact the kidneys. As well, decreased renal blood flow decreases urine production.

13.2 (Questions on p. 573.)

1. See ▶ Table 13-1, Forces Involved in Glomerular Filtration.
2. Extrinsic control of the GFR is accomplished by sympathetic nervous system input to the afferent arterioles aimed at regulating arterial blood pressure. When arterial blood pressure falls, sympathetically induced afferent arteriolar vasoconstriction decreases glomerular capillary blood pressure, causing a decrease in GFR. The resultant reduction in urine volume conserves fluid and salt that would have been lost from the body in urine. This saved fluid helps restore plasma volume and blood pressure to normal in the long term. The opposite compensatory effect takes place when arterial blood pressure is too high.

13.3 (Questions on p. 582.)

1. See ▶ Figure 13-14, Steps of transepithelial transport, p. 574.
2. The kidneys secrete the enzymatic hormone renin in response to reduced NaCl , ECF volume, and arterial blood pressure. Renin activates angiotensinogen, a plasma protein produced by the liver, into angiotensin I, which is converted into angiotensin II by angiotensin-converting enzyme produced in the lungs. Angiotensin II stimulates the adrenal cortex to secrete the hormone aldosterone, which stimulates Na^+ reabsorption by the kidneys. The resulting retention of Na^+ exerts an osmotic effect that holds more H_2O in the ECF. Together, the conserved Na^+ and H_2O help correct the original stimuli that activated this hormonal system.
3. For phosphate, the T_m is fixed at its normal plasma concentration, whereas for glucose the T_m is greater than the normal plasma concentration. Any excess phosphate in the plasma is immediately secreted. However, with slight increases in plasma glucose concentrations, there is no increase in glucose excretion until the T_m is reached.

13.4 (Questions on p. 585.)

1. Secretion of H^+ , K^+ , and organic anions and cations
2. The removal of foreign organic compounds from the body is hastened via secretion by the organic ion secretory systems in the proximal tubule. The liver helps rid the body of foreign compounds that are not ionic in their original form by converting them into an anionic form.

13.5 (Questions on p. 597.)

1. (1) clearance rate = GFR, (2) clearance rate, GFR, (3) clearance rate. GFR
2. The loop of Henle establishes the gradient by reabsorbing Na and Cl , the vasa recta preserve the gradient by countercurrent exchange, and the collecting ducts use the gradient to concentrate urine.
3. *Vasopressin*, which is secreted into the blood by the posterior pituitary in response to a H_2O deficit, increases the permeability of the distal and collecting tubules to H_2O . *Vasopressin* activates the cAMP pathway within the principal cells lining these tubules when it binds with V_2 receptors specific for it at the basolateral membrane of these cells. cAMP increases the opposite luminal membrane's permeability to H_2O by promoting the insertion of aquaporin water channels into the membrane. Water enters the cell from the tubular lumen through the inserted water channels and exits the cell through different, permanently positioned water channels at the basolateral border to enter the blood, in this way being reabsorbed to correct the H_2O deficit.

Chapter 13 The Urinary System

Check Your Understanding

13.1 (Questions on p. 566.)

1. See ▶ Figure 13-6, Basic renal processes, p. 564.
2. *Cortical nephrons* are the most abundant type of nephron. The *juxtamedullary nephrons* are important in establishing the medullary vertical osmotic gradient. The glomeruli of cortical nephrons lie in the outer cortex, whereas the glomeruli of juxtamedullary nephrons lie in the

Objective Questions

(Questions on pp. 602–603.)

1. F 2. F 3. T 4. T 5. T 6. nephron 7. potassium 8. 500 9. 1. b, 2. a, 3. b, 4. b, 5. a, 6. b, 7. b, 8. b, 9. b 10. e 11. b 12. b, e, a, d, c 13. c, e, d, a, b, f 14. g, c, d, a, f, b, e 15. 1. a, 2. a, 3. c, 4. b, 5. d

Quantitative Exercises

(Questions on p. 603)

	Patient 1	Patient 2
a. GFR	125 mL/min	124 mL/min
RPF	620 mL/min	400 mL/min
b. RBF	1127 mL/min	727 mL/min
c. FF	0.20	0.31

d. All of patient 1's values are within the normal range. Patient 2's GFR is normal, but he has a low renal plasma flow and a high filtration fraction. Therefore, his GFR is too high for that RPF. This might imply enlarged filtration slits or a leaky glomerulus, in general. The low RPF may imply low renal blood pressure, perhaps from a partially blocked renal artery.

2. filtered load = GFR $\times$ plasma concentration

$$= (0.125 \text{ litre/min}) \times (145 \text{ mmol/litre})$$

$$= 8.125 \text{ mmol/min}$$

3. $GFR = (U \times [I]_U) / [I]_B$

$$U = (GFR \times [I]_B) / [I]_U = (125 \text{ mL/min})(3 \text{ mg/L}) / (300 \text{ mg/L})$$

$$= 1.25 \text{ mL/min}$$

$$\text{Clearance rate of a substance} = \frac{\text{urine concentration of a substance} \times \text{urine flow rate}}{\text{plasma concentration of the substance}}$$

$$4. = \frac{7.5 \text{ mg/mg} \times 2 \text{ mL/min}}{0.2 \text{ mg/mL}}$$

$$= 75 \text{ mL/min}$$

Because a clearance rate of 75 mL/min is less than the average GFR of 125 mL/min, the substance is being reabsorbed.

Points to Ponder

(Questions on p. 604.)

- The longer loops of Henle in desert rats (known as *kangaroo rats*) permit a greater magnitude of countercurrent multiplication and thus a larger medullary vertical osmotic gradient. As a result, these rodents can produce urine that is concentrated up to an osmolarity of almost 6000 mOsm/L, which is five times more concentrated than maximally concentrated human urine at 1200 mOsm/L. Because of this tremendous concentrating ability, kangaroo rats never have to drink; the H₂O produced metabolically within their cells during oxidation of foodstuff (food + O₂ $\rightarrow$ CO₂ + H₂O + energy) is sufficient for their needs.
- a. 250 mg/min filtered
filtered load of substance = plasma concentration of substance $\times$ GFR
filtered load of substance = 200 mg/100 mL $\times$ 125 mL/min
= 250 mg/min
b. 200 mg/min reabsorbed; a T_m's worth of the substance will be reabsorbed
c. 50 mg/min excreted amount of substance excreted = amount of substance filtered – amount of substance reabsorbed = 250 mg/min – 200 mg/min = 50 mg/min
- Aldosterone stimulates Na⁺ reabsorption and K⁺ secretion by the renal tubules. Therefore, the most prominent features of Conn's syndrome (hypersecretion of aldosterone) are hypernatraemia (elevated Na⁺ levels in the blood) caused by excessive Na⁺ reabsorption, hypokalemia (below-normal K⁺ levels in the blood) caused by excessive K⁺ secretion, and hypertension (elevated blood pressure) caused by excessive salt and water retention.
- e. 300/300. If the ascending limb were permeable to water, it would not be possible to establish a vertical osmotic gradient in the interstitial fluid of the renal medulla, nor would the ascending-limb fluid become hypotonic before entering the distal tubule. As the ascending limb pumped NaCl into the interstitial fluid, water would osmotically follow, so both the interstitial fluid and the ascending limb would remain isotonic at

300 mOsm/L. With the tubular fluid entering the distal tubule being 300 mOsm/L, instead of the normal 100 mOsm/L, it would not be possible to produce urine with an osmolarity less than 300 mOsm/L. Likewise, in the absence of the medullary vertical osmotic gradient, it would not be possible to produce urine more concentrated than 300 mOsm/L, no matter how much vasopressin was present.

- Because the descending pathways between the brain and the motor neurons that supply the external urethral sphincter and pelvic diaphragm are no longer intact, the accident victim can no longer voluntarily control micturition. Therefore, bladder emptying in this individual is governed entirely by the micturition reflex.

Clinical Consideration

(Question on p. 604.)

prostate enlargement

Chapter 14 Fluid and Acid-Base Balance

Check Your Understanding

14.1 (Questions on p. 609.)

- inputs* = ingestion or metabolic production; *outputs* = excretion or metabolic consumption
- Stable balance*: when total body input of a substance equals its total body output. *Positive balance*: when the gains via input for a substance exceed its losses via output. *Negative balance*: when losses for a substance exceed its gains

14.2 (Questions on p. 619.)

- See Table 14-1, Classification of Body Fluid
- ECF volume* is regulated by maintaining salt balance and is important in maintaining blood pressure. *ECF osmolarity* is regulated by maintaining free water balance and is important for preventing the swelling or shrinking of cells.
- When the ECF is hypertonic, water osmotically leaves the cells, causing them to shrink. When the ECF is hypotonic, water osmotically enters the cells, causing them to swell.

14.3 (Questions on p. 637.)

- Only a narrow pH range is compatible with life because even small changes in [H⁺] have dramatic effects on normal cell function. Changes in [H⁺] (1) lead to changes in excitability of nerve and muscle cells, which can cause death due to either severe acidosis by depressing the CNS or severe alkalosis by causing spasm of the respiratory muscles; (2) alter enzyme activity, thus disturbing life-supporting metabolic activity catalyzed by these enzymes; and (3) influence [K⁺], which can lead to fatal cardiac abnormalities.
- metabolic acidosis. To compensate, the ECF buffers take up extra H⁺, the lungs blow off additional H⁺-generating CO₂, and the kidneys excrete more H⁺ and conserve more HCO₃⁻

Objective Questions

(Questions on p. 638.)

1. T 2. F 3. F 4. T 5. T 6. intracellular fluid 7. H₂CO₃, HCO₃⁻ 8. d 9. b 10. a, d, e 11. b, e 12. c 13. 1. metabolic acidosis, 2. diabetes mellitus, 3. pH = 7.1, 4. respiratory alkalosis, 5. anxiety, 6. pH = 7.7, 7. respiratory acidosis, 8. pneumonia, 9. pH = 7.1, 10. metabolic alkalosis, 11. vomiting, 12. pH = 7.7

Quantitative Exercises

(Questions on p. 639.)

$$1. \text{ pH} = 6.1 + \log[\text{HCO}_3^-] / (0.03 \text{ mM/mmHg} \times 40 \text{ mmHg})$$

$$7.4 = 6.1 + \log[\text{HCO}_3^-] / 1.2 \text{ mM}$$

$$\log[\text{HCO}_3^-] / 1.2 \text{ mM} = 7.4 - 6.1 = 1.3$$

$$[\text{HCO}_3^-] = 1.2 \text{ mM} \times (10^{1.3}) = 24 \text{ mM}$$

Ingested Fluid	Compartment	Size of Compartment before Ingestion (litres)	Size of Compartment after Ingestion (litres)	Percent Increase in Size of Compartment after Ingestion
Distilled Water	TBW	42	43	2
	ICF (2/3 TBW)	28	28.667	2
	ECF (1/3 TBW)	14	14.333	2
	plasma (20% ECF)	2.8	2.866	2
	ISF (80% ECF)	11.2	11.466	2
Saline	TBW	42	43	2
	ICF	28	28	0
	ECF	14	15	7
	plasma	2.8	3	7
	ISF	11.2	12	7

- $\text{pH} = -\log[\text{H}^+]$, $[\text{H}^+] = 10^{-\text{pH}}$
 $[\text{H}^+] = 10^{-6.8} = 158 \text{ nM}$ for $\text{pH} = 6.8$
 $[\text{H}^+] = 10^{-8.0} = 10 \text{ nM}$ for $\text{pH} = 8.0$
- Note that distilled water is permeable across all barriers, so it distributes equally among all compartments. However, the saline does not enter cells, so it stays in the ECF. The resultant distributions are summarized in the chart below. Clearly, saline is better at expanding the plasma volume.

Points to Ponder

(Questions on p. 639.)

- The rate of urine formation increases when alcohol inhibits vasopressin secretion and the kidneys are unable to reabsorb water from the distal and collecting tubules. Because extra free water that normally would have been reabsorbed from the distal parts of the tubule is lost from the body in the urine, the body becomes dehydrated, and the ECF osmolarity increases following alcohol consumption. That is, more fluid is lost in the urine than is consumed in the alcoholic beverage as a result of alcohol's action on vasopressin. Thus, the imbibing person experiences a water deficit and still feels thirsty, despite the recent fluid consumption.
- If a person loses 1500 mL of salt-rich sweat and drinks 1000 mL of water without replacing the salt during the same time period, there will still be a volume deficit of 500 mL, and the body fluids will have become hypotonic (the remaining salt in the body will be diluted by the ingestion of 1000 mL of free water). As a result, the hypothalamic osmoreceptors (the dominant input) will signal the vasopressin-secreting cells to *decrease* vasopressin secretion and thus increase urinary excretion of the extra free water that is making the body fluids too dilute. Simultaneously, the left atrial volume receptors will signal the vasopressin-secreting cells to *increase* vasopressin secretion to conserve water during urine formation and thus help relieve the volume deficit. These two conflicting inputs to the vasopressin-secreting cells are counterproductive. For this reason, it is important to replace both water and salt following heavy sweating or abnormal loss of other salt-rich fluids. If salt is replaced along with water intake, the ECF osmolarity remains close to normal and the vasopressin-secreting cells receive signals only to increase vasopressin secretion to help restore the ECF volume to normal.
- When a dextrose solution equal in concentration to that of normal body fluids is injected intravenously, the ECF volume is expanded, but the ECF and ICF are still osmotically equal. Therefore, no net movement of water occurs between the ECF and ICF. When the dextrose enters the cell and is metabolized, however, the ECF becomes hypotonic as this solute leaves the plasma. If the excess free water is not excreted in the urine rapidly enough, water will move into the cells by osmosis.
- Because baking soda (NaHCO_3) is readily absorbed from the digestive tract, treatment of gastric hyperacidity with baking soda can lead to

metabolic alkalosis as too much (HCO_3^-) is absorbed. Treatment with antacids that are poorly absorbed is safer because these products remain in the digestive tract and do not produce an acid-base imbalance.

- c. The haemoglobin buffer system buffers carbonic acid-generated hydrogen ion. In the case of respiratory acidosis accompanying severe pneumonia, the $\text{H}^+ + \text{Hb} \rightarrow \text{HHb}$ reaction shifts toward the HHb side, thus removing some of the extra free H^+ from the blood.

Clinical Consideration

(Question on p. 639.)

The resultant prolonged diarrhoea leads to dehydration and metabolic acidosis due, respectively, to excessive loss in the feces of fluid and NaHCO_3 that normally would have been absorbed into the blood.

Compensatory measures for dehydration have included increased vasopressin secretion, resulting in increased water reabsorption by the distal and collecting tubules and a subsequent reduction in urine output. Simultaneously, fluid intake has been encouraged by increased thirst. The metabolic acidosis has been combated by removal of excess H^+ from the ECF by the $[\text{HCO}_3^-]$ member of the H_2CO_3 : $[\text{HCO}_3^-]$ buffer system, by increased ventilation to reduce the amount of acid-forming CO_2 in the body fluids, and by the kidneys excreting extra H^+ and conserving $[\text{HCO}_3^-]$.

Chapter 15 The Digestive System

Check Your Understanding

15.1 (Questions on p. 652.)

- See ► Figure 15-2, Layers of the digestive tract wall, p. 650.
- Pacemaker cells called interstitial cells of Cajal (ICC) generate slow-wave potentials that cyclically bring the membrane closer to or farther from threshold potential. Slow-wave potentials spread via gap junctions from ICCs to the surrounding smooth muscle cells, which themselves are interconnected by gap junctions into functional syncytia. If the slow waves reach threshold at the peaks of depolarization, a volley of action potentials is triggered at each peak, resulting in rhythmic cycles of contraction in the sheet of smooth muscle cells driven by the pacemaker. The slow-wave frequency varies regionally in the digestive tract. Contractions within the tract occur at the rate of slow-wave frequency within a given section of tract.
- The sympathetic nervous system tends to slow the digestive tract and secretion. The parasympathetic nervous system increases smooth muscle motility and secretion of digestive enzymes.

15.2 (Questions on p. 654.)

1. *mucus*: facilitates swallowing by moistening food particles to hold them together and by providing lubrication; *amylase*: begins digestion of dietary starches; *lysosome*: exerts antibacterial actions by lysing bacteria, binding IgA antibodies, secreting lactoferrin that binds iron needed for bacterial multiplication, and rinsing away material that may serve as a food source for bacteria
2. *Parasympathetic stimulation* induces production of a large volume of watery saliva that is rich in enzymes. *Sympathetic stimulation* produces a small volume of thick saliva that is rich in mucus.

15.3 (Questions on p. 656.)

1. During swallowing, respiration is temporarily inhibited while the entrance to the trachea is closed off to prevent food from entering the respiratory airways. Contraction of the laryngeal muscles tightly aligns the vocal folds across the glottis. For further protection, the epiglottis folds downward over the closed glottis.
2. The *pharyngoesophageal sphincter* at the upper end of the esophagus separates the pharynx from the esophagus and prevents air from entering the esophagus and stomach during breathing. This sphincter remains tonically contracted except during a swallow, when it opens. The *gastroesophageal sphincter* at the lower end of the esophagus separates the esophagus from the stomach and prevents reflux of gastric contents into the esophagus. It relaxes during a swallow.

15.4 (Questions on p. 667.)

1. A strong peristaltic contraction in the stomach antrum pushes the luminal contents downward toward a slightly open pyloric sphincter. A small portion of the chyme is forced through the sphincter before the peristaltic wave reaches the sphincter and closes it tightly. When food that is moving forward hits the closed sphincter, it is tossed backward, only to be propelled forward again by the next peristaltic wave. This *retropulsion* (cycles of food being moved forward and backward in the antrum) shears and grinds the food into smaller pieces and thoroughly mixes it with gastric secretions, converting it into chyme before emptying.
2. The cephalic phase of gastric secretion occurs in response to food-related stimuli such as thinking about, tasting, smelling, seeing, chewing, and swallowing food. The response is mediated by vagal activation of the chief and parietal secretory cells (which secrete HCl and pepsinogen, respectively) and the endocrine G cells (which secrete the hormone gastrin that further stimulates the chief and parietal cells).
3. The following components of the gastric mucosal barrier enable the stomach to contain potent HCl without injuring itself: (1) The luminal membranes of the gastric mucosal cells are impermeable to H^+ , so HCl cannot penetrate into the cells; (2) tight junctions join the cells and prevent HCl from penetrating between them; (3) the surface mucous cells secrete mucus, which serves as a physical barrier to acid penetration; and (4) HCO_3^- secreted with the mucus serves as a chemical barrier that neutralizes acid in the vicinity of the mucosa. Finally, the entire stomach lining undergoes significant turnover, with the cells being replaced every three days.

15.5 (Questions on p. 676.)

1. The pancreas produces proteolytic enzymes for digesting food proteins, but these enzymes could also digest the proteins of the cells that produce them if they were not stored in inactive form until they are secreted. These inactive enzymes are stored in secretory zymogen granules in the pancreatic acinar cells until appropriate stimuli induce their secretion. They are activated to protein-digesting enzymes (trypsin, chymotrypsin, and carboxypeptidase) only when they reach the duodenal lumen, where they act on food, not the pancreatic cells.
2. Bile salts contribute to dietary fat digestion by their detergent action (fat emulsification) in the small intestine. Intestinal mixing movements break up large fat globules into smaller droplets. The droplets do not recombine into the large globule because bile salts adsorb on the surface of the smaller droplets, creating a *lipid emulsion* consisting of many small fat droplets suspended in the watery chyme. This action increases the surface area of fat available for attack by pancreatic lipase.

15.6 (Questions on p. 688.)

1. Three major structural features increase the surface area of the small intestine available for absorption: (1) Large *circular folds* on the small-intestine luminal surface increase the surface area threefold; (2) microscopic finger-like projections, known as *villi*, that sit atop the circular folds increase the surface area another tenfold; and (3) a multitude of hairlike protrusions, referred to as *microvilli* or the *brush border* on each villus surface, collectively increase the surface area another twentyfold. Together these three adaptations increase the absorptive surface area of the small intestine approximately 600 times greater than compared to a completely smooth tube of the same length and diameter.
2. Absorption of most dietary carbohydrate and protein is accomplished by secondary active transport that involves the cotransport of N^+ and the nutrient molecule into the absorptive cell. Although the cotransporter does not use ATP directly, the Na^+-K^+ pump (which directly uses energy) establishes a N^+ concentration gradient that drives the cotransporter to move Na^+ downhill and move the nutrient molecule uphill into the cell across the luminal membrane. The nutrient molecules move out of the cell into the blood across the basal membrane by facilitated diffusion, completing the absorptive process.

15.7 (Questions on p. 692.)

1. Large-intestine *haustral contractions* are very similar to small intestine *segmentation contractions* in that both are rhythmic, autonomous, oscillating ringlike contractions initiated by pacemaker cells, but haustral contractions occur much less frequently (once every 30 minutes) than segmentation contractions (9 to 12 per minute). Haustral contractions, which are nonpropulsive, shuffle the colonic content back and forth, facilitating salt and water absorption, which compact the content and form a firm fecal mass. In contrast, segmentation in the small intestine is both a slowly propulsive and mixing movement.
2. The $NaHCO_3$ produced by the *large intestine* mainly serves to protect the large intestine from acid produced during colonic fermentation by the intestinal bacteria. The primary role of pancreatic $NaHCO_3$ secreted into the duodenal lumen is to neutralize the acidic chyme that empties from the stomach, thereby protecting the small intestine from acid damage in addition to creating an alkaline environment that optimizes pancreatic digestive enzyme activity.

15.8 (Questions on p. 693.)

1. *Trophic hormones* induce growth of their target tissues. For example, gastrin is trophic to the gastric mucosa, in addition to stimulating secretion by the parietal and chief cells. The significance is that the hormone helps maintain the gastric mucosa, despite harsh conditions, thereby maintaining the secretory capabilities of this stomach lining.
2. *secretin*: stomach smooth muscle and parietal cells (acts as an enterogastrone to inhibit gastric motility and acid secretion), pancreatic duct cells (stimulates $NaHCO_3$ secretion); *CCK*: stomach smooth muscle and parietal cells (acts as an enterogastrone), pancreatic acinar cells (stimulates secretion of pancreatic digestive enzymes), gallbladder (causes contraction), sphincter of Oddi (causes relaxation), and brain (signals satiety)

Objective Questions

(Questions on pp. 695–696.)

1. F 2. T 3. T 4. F 5. F 6. F 7. long, short 8. chyme 9. three 10. vitamin B₁₂, bile salts 11. bile salts 12. b 13. 1. c, 2. e, 3. b, 4. a, 5. f, 6. d 14. 1. c, 2. c, 3. d, 4. a, 5. e, 6. c, 7. a, 8. b, 9. c, 10. b, 11. b

Quantitative Exercise

(Question on p. 696.)

1. a. $r = 0.5 \text{ cm}$, $\text{area} = 4\pi(0.25) = \pi \text{ cm}^2$

$$\text{volume} = \left(\frac{4}{3}\pi\right)(0.5)^3 = 0.5236 \text{ cm}^3$$

$$\text{area/volume} = 6$$

- b. Each new droplet's volume is $5.236 \times 10^{-3} \text{ cm}^3$, so the average radius is therefore 0.1077 cm. The area of a sphere with that radius is $4\pi(0.1077 \text{ cm})^2 = 0.1458 \text{ cm}^2$
area/volume = 27.8
- c. Area emulsified/area droplet = $(100)(0.1458 \text{ cm}^2)/\pi \text{ cm}^2 = 4.64$. Thus, the total surface area of all 100 emulsified droplets is 4.64 times the area of the original larger lipid droplet.
- d. Volume emulsified/volume droplet = $(100)(5.236 \times 10^{-3} \text{ cm}^3)/0.5236 \text{ cm}^3 = 1.0$.
Therefore, the total volume did not change as a result of emulsification, as would be expected, because the total volume of the lipid is conserved during emulsification. The volume originally present in the large droplet is divided up among the 100 emulsified droplets.

Points to Ponder

(Questions on pp. 696–697.)

1. Patients who have had their stomachs removed must eat small quantities of food frequently instead of consuming the typical three meals a day because they have lost the ability to store food in the stomach and meter it into the small intestine at an optimal rate. If a person without a stomach consumed a large meal that entered the small intestine all at once, the luminal contents would quickly become too hypertonic as digestion of the large nutrient molecules into a multitude of small, osmotically active, absorbable units outpaced the more slowly acting process of absorption of these units. As a consequence of this increased luminal osmolarity, water would enter the small intestine lumen from the plasma by osmosis, resulting in circulatory disturbances as well as intestinal distension. To prevent this “dumping syndrome” from occurring, the patient must “feed” the small intestine only small amounts of food at a time so that absorption of the digested end products can keep pace with their rate of production. The person has to consciously take over metering the delivery of food into the small intestine because the stomach is no longer present to assume this responsibility.
2. The gut-associated lymphoid tissue launches an immune attack against any pathogenic (disease-causing) microorganisms that enter the readily accessible digestive tract and escape destruction by salivary lysozyme or gastric HCl. This action defends against entry of these potential pathogens into the body proper. The large number of immune cells in the gut-associated lymphoid tissue is adaptive as a first line of defence against foreign invasion, considering that the surface area of the digestive tract lining represents the largest interface between the body proper and the external environment.
3. Defecation would be accomplished entirely by the defecation reflex in a patient paralyzed from the waist down because of lower spinal cord injury. Voluntary control of the external anal sphincter would be impossible because of interruption in the descending pathway between the primary motor cortex and the motor neuron supplying this sphincter.
4. When insufficient glucuronyl transferase is available in the neonate to conjugate all the bilirubin produced during erythrocyte degradation with glucuronic acid, the extra unconjugated bilirubin cannot be excreted into the bile. Therefore, this extra bilirubin remains in the body, giving rise to mild jaundice in the newborn.
5. Removal of the stomach leads to pernicious anaemia because of the resultant lack of intrinsic factor, which is necessary for absorption of vitamin B₁₂. Removal of the terminal ileum leads to pernicious anaemia because this is the only site where vitamin B₁₂ can be absorbed.

Clinical Consideration

(Question on p. 697.)

A person whose bile duct is blocked by a gallstone experiences a painful gallbladder attack after eating a high-fat meal because the ingested fat triggers the release of cholecystokinin, which stimulates gallbladder contraction. As the gallbladder contracts and bile is squeezed into the blocked bile duct, the duct becomes distended prior to the blockage. This distension is painful.

The feces are greyish white because no bilirubin-containing bile enters the digestive tract when the bile duct is blocked. Bilirubin, when acted on by bacterial enzymes, is responsible for the brown colour of feces, which are greyish white in its absence.

Chapter 16 Energy Balance and Temperature Regulation

Check Your Understanding

16.1 (Questions on p. 710.)

1. *External work* is the energy expended by skeletal muscles to move external objects or to move the body in relation to the environment. *Internal work* constitutes all biological energy expenditure that does not accomplish mechanical work outside the body; it includes skeletal muscle activity associated with postural maintenance and shivering and all energy-expending activities essential for sustaining life, such as pumping blood or breathing. *Metabolic rate* is the rate at which energy is expended during both external and internal work: metabolic rate = energy expenditure/unit of time. *Appetite signals* give the sensation of hunger, driving us to eat. *Satiety signals* give the sensation of being full, suppressing the desire to eat. *Adiposity signals* are indicative of the size of fat stores in adipose tissue and are important in the long-term control of body weight. *Adipokines* refer to hormones secreted by adipocytes. *Visceral fat* is the deep, “bad” fat that surrounds the abdominal organs and is likely to be chronically inflamed and secrete harmful adipokines. *Subcutaneous fat* is deposited under the skin (it is the fat you can pinch) and is less harmful than visceral fat.
2. The basal metabolic rate can be determined indirectly by measuring a person's O₂ uptake per unit of time and multiplying this value by the energy equivalent of O₂, which is 4.8 kcal of energy liberated per litre of O₂ consumed. This technique is based on the fact that a direct relationship exists between the volume of O₂ used and the quantity of heat produced as follows: Food + O₂ → CO₂ + H₂O + energy (mostly transformed into heat).
3. Neuropeptide Y, from the arcuate nucleus of hypothalamus, increases appetite.
Melanocortins, from the arcuate nucleus of hypothalamus, decreases appetite.
Leptin, from adipose tissue, decreases appetite.
Insulin, from the pancreas, decreases appetite.
Orexins, from the lateral hypothalamus, increase appetite.
Corticotrophin-releasing hormone, from the paraventricular nucleus of hypothalamus, decreases appetite.
Ghrelin, from the stomach, increases appetite.
PPY, from the small and large intestines, decreases appetite.
CCK, from the small intestine, decreases appetite.
Stomach distension, from the stomach, decreases appetite.

16.2 (Questions on p. 719.)

1. *radiation*: transfer of heat energy from a warmer object to a cooler object in the form of heat waves that travel through space; *conduction*: transfer of heat between objects of differing temperatures that are in direct contact with each other; *convection*: transfer of heat energy by air currents; *evaporation*: conversion of a liquid such as sweat to a gaseous vapour, a process that requires heat, which is absorbed from the skin
2. See ■ Table 16-4, Coordinated Adjustments in Response to Heat or Cold Exposure.

Objective Questions

(Questions on p. 720.)

1. F 2. F 3. F 4. F 5. T 6. T 7. T 8. T 9. arcuate nucleus 10. shivering 11. non-shivering thermogenesis 12. sweating 13. b 14. e 15. 1. b, 2. a, 3. c, 4. a, 5. d, 6. c, 7. b, 8. d, 9. c, 10. b

Quantitative Exercise

(Question on pp. 720–721.)

- From physics we know that $\Delta T(^{\circ}\text{C}) = \Delta U/(m \times C)$.

Also note that $\Delta U/t = \text{BMR}$; that is, the rate of using energy is the basal metabolic rate. m represents the mass of body fluid; for a typical person, this is 42 L.

$$(42 \text{ L}) \times (1 \text{ kg/L}) = 42 \text{ kg}$$

$$C = 1.0 \text{ kcal}/(\text{kg}^{\circ}\text{C})$$

Given that water boils at 100°C and normal body temperature is 37°C , we need to change the temperature by 63°C . Thus,

$$t = (\Delta T \times C \times m)/\text{BMR} = (63^{\circ}\text{C})[1.0 \text{ kcal}/(\text{kg}^{\circ}\text{C})](42 \text{ kg})/(75 \text{ kcal/h}) = 35 \text{ h}$$

At the higher metabolic rate during exercise,

$$t = (63^{\circ}\text{C})[1.0 \text{ kcal}/(\text{kg}^{\circ}\text{C})](42 \text{ kg})/(1000 \text{ kcal/h}) = 2.6 \text{ h}$$

Points to Ponder

(Questions on p. 721.)

- Evidence suggests that CCK serves as a satiety signal. It is believed to serve as a signal to stop eating when enough food has been consumed to meet the body's energy needs, even though the food is still in the digestive tract. Therefore, when drugs that inhibit CCK release are administered to experimental animals, the animals overeat because this satiety signal is not released.
- Don't go on a "crash diet." Be sure to eat a nutritionally balanced diet that provides all essential nutrients, but reduce total caloric intake, especially by cutting down on high-fat foods. Spread out consumption of the food throughout the day instead of just eating several large meals. Avoid bedtime snacks. Burn more calories through a regular exercise program.
- Engaging in heavy exercise on a hot day is dangerous because of problems arising from trying to eliminate the extra heat generated by the exercising muscles. First, there are conflicting demands for distribution of the cardiac output—temperature-regulating mechanisms trigger skin vasodilation to promote heat loss from the skin surface, whereas metabolic changes within the exercising muscles induce local vasodilation in the muscles to match the increased metabolic needs with increased blood flow. Further exacerbating the problem of conflicting demands for blood flow is the loss of effective circulating plasma volume resulting from the loss of a large volume of fluid through another important cooling mechanism: sweating. Therefore, it is difficult to maintain an effective plasma volume and blood pressure and simultaneously keep the body from overheating when engaging in heavy exercise in the heat, so heat exhaustion is likely to ensue.
- When a person is soaking in a hot bath, loss of heat by radiation, conduction, convection, and evaporation is limited to the small surface area of the body exposed to the cooler air. Heat is being gained by conduction at the larger skin surface area exposed to the hotter water.

- The thermoconforming fish would not run a fever when it has a systemic infection because it has no mechanisms for regulating internal heat production or for controlling heat exchange with its environment. The body temperature of fish varies capriciously with the external environment, no matter whether the fish has a systemic infection or not. It is not able to maintain body temperature either at some normal set point or at an elevated set point (i.e., a fever).

Clinical Consideration

(Question on p. 721.)

Cooled tissues need less nourishment than tissues at normal body temperature because of their pronounced reduction in metabolic activity. The lower O_2 need of cooled tissues accounts for the occasional survival of drowning victims who have been submerged in icy water considerably longer than one could normally survive without O_2 .

Chapter 17 The Reproductive System

Check Your Understanding

17.1 (Questions on p. 731.)

- testes* in males and *ovaries* in females. In both sexes, these primary reproductive organs perform the dual function of producing gametes (sperm in males and ova in females) and secreting sex hormones (testosterone in males and estrogen and progesterone in females).
- See table below.

17.2 (Questions on p. 741.)

- See Table 17-1, Effects of Testosterone.
- The *seminiferous tubules* are the highly coiled tubular component of the testes where spermatogenesis takes place. The *Leydig cells*, which lie in the interstitial spaces between the seminiferous tubules, secrete testosterone. *Sertoli cells* are epithelial cells that lie in close association with and protect, nurse, and enhance the developing sperm cells throughout their development in the seminiferous tubules. Sertoli cells also secrete inhibin and are the site of action for control of *spermatogenesis* by both testosterone and FSH. *Spermatogenesis* is the sequence of steps by which relatively undifferentiated primordial germ cells proliferate and are converted into extremely specialized, motile spermatozoa. *Spermiogenesis* refers to the remodelling or packaging of the haploid spermatids into spermatozoa. *Spermiation* is the final release of a mature spermatozoon from the Sertoli cell to which it has been attached throughout development. *Spermatogonia* are the undifferentiated primordial germ cells that have a diploid number of single-strand chromosomes. Two mitotic divisions of a spermatogonium yield four *primary spermatocytes*, each with a diploid number of double-strand chromosomes. The first meiotic division of these primary spermatocytes yields eight *secondary spermatocytes*, each with a haploid number of

Embryonic Structure	Reproductive Structure Derived from this Embryonic Structure in Males	Reproductive Structure Derived from this Embryonic Structure in Females
Gonadal Ridge	Testes	Ovaries
Genital Tubercle	Penis	Clitoris
Urethral Folds	Cord of erectile tissue that surrounds the urethra in the penis	Labia minora
Genital Swellings	Scrotum and prepuce	Labia majora
Wolffian Ducts	Epididymis, ductus deferens, ejaculatory duct, and seminal vesicles	Nothing; ducts degenerate
Müllerian Ducts	Nothing; ducts degenerate	Oviducts, uterus, cervix, and upper vagina
Urogenital Sinus	Prostate gland, bulbourethral gland	Lower vagina

double-strand chromosomes. The second meiotic division of these secondary spermatocytes yields 16 spermatids, each with a haploid number of single-strand chromosomes. The *spermatids* are packaged into highly specialized *spermatozoa*, each with a haploid number of single-strand chromosomes.

17.3 (Questions on p. 744.)

1. (1) *excitement phase* (erection and heightened sexual awareness); (2) *plateau phase* (intensification of sexual responses and systemic responses, such as increased heart rate, blood pressure, respiratory rate, and muscle tension); (3) *orgasmic phase* (ejaculation in males, orgasm in both sexes); and (4) *resolution phase* (return to prearousal state)
2. The male sex act includes erection and ejaculation. *Erection*, hardening of the normally flaccid penis to permit its entry into the vagina, is accomplished by engorgement of the penis erectile tissue with blood as a result of marked parasympathetically induced vasodilation of the penile arterioles and mechanical compression of the veins. *Ejaculation* occurs in two phases: The *emission phase*, emptying of sperm and accessory sex gland secretions (semen) into the urethra, is accomplished by sympathetically induced contraction of smooth muscle in the walls of the reproductive ducts and accessory sex glands. The *expulsion phase*, the forceful expulsion of semen from the penis, is accomplished by motor neuron-induced contraction of the skeletal muscles at the base of the penis.

17.4 (Questions on p. 774.)

1. The ovarian *follicle* secretes estrogen; the corpus luteum secretes progesterone (most) and estrogen. *Estrogen* stimulates growth of the endometrium and myometrium and induces synthesis of progesterone receptors in the endometrium. *Progesterone* acts on the estrogen-primed endometrium to convert it into a hospitable and nutritious lining (with loose, edematous connective tissue, glycogen stores, and increased blood supply) suitable for implantation. The *menstrual phase* of the uterine cycle takes place during the first half of the ovarian follicular phase, after the end of the last cycle when the estrogen and progesterone supply was withdrawn upon degeneration of the corpus luteum. The highly developed uterine lining sloughs (menstruation) simultaneously with the beginning of a new follicular phase, which is under the influence of rising FSH and LH upon withdrawal of the inhibitory actions of estrogen and progesterone. The *proliferative phase* of the uterine cycle occurs during the last half of the ovarian follicular phase, as the endometrium stops sloughing and starts to repair itself and proliferate under the influence of rising levels of estrogen from the newly recruited, rapidly growing antral follicles. Peak estrogen secretion causes the LH surge, which triggers ovulation, ending both the ovarian follicular phase and the uterine proliferative phase. The *secretory, or progesterational, phase* of the uterine cycle begins concurrent with the ovarian luteal phase, as progesterone from the corpus luteum converts the thickened, estrogen-primed endometrium to a lush environment capable of supporting an early embryo, should the released egg be fertilized and implant.
2. The *zygote* is the fertilized ovum, following union of the male and female chromosomes. The *blastocyst* is a single-layer hollow ball of about 50 cells resulting from mitotic cell divisions of the *zygote*; the blastocyst is the developmental stage that implants in the endometrium. The *inner cell mass* is a dense mass on one side of the blastocyst that is destined to become the fetus. The *trophoblast* is the thin outermost layer of the blastocyst that accomplishes implantation, after which it develops into the fetal part of the placenta. The *decidua* is the endometrial tissue that's modified at the implantation site to enhance its ability to support the implanting embryo. The *chorion* is the thickened trophoblastic layer after implantation is complete. The *placenta* is the specialized organ of exchange between the maternal and fetal blood that is derived from both trophoblastic embryonic tissue and decidual maternal tissue and that secretes peptide and steroid hormones essential for maintaining

pregnancy. The *embryo* is the product of fertilization during the first two months of intrauterine development, when tissue differentiation is taking place. The *fetus* is the product of fertilization during the last seven months of gestation, after differentiation is complete and tremendous tissue growth and maturation occur.

3. During *parturition*, a positive-feedback loop involving oxytocin, a powerful uterine muscle stimulant, is responsible for the progression of labour. Oxytocin promotes uterine muscle contractions that force the fetus against the cervix, dilating it and triggering a neuroendocrine reflex that results in secretion of even more oxytocin, which stimulates even stronger contractions, and so on as labour progresses until the cervix is dilated sufficiently for the baby to be pushed out. During *breastfeeding*, oxytocin causes milk ejection (milk letdown) by stimulating contraction of the myoepithelial cells surrounding the milk-secreting alveoli.

Objective Questions

(Questions on pp. 779–777.)

1. T 2. T 3. T 4. F 5. T 6. F 7. T 8. seminiferous tubules, FSH, testosterone 9. thecal, LH, granulosa, FSH 10. corpus luteum of pregnancy 11. human chorionic gonadotropin 12. c 13. b 14. 1. c, 2. a, 3. b, 4. c, 5. a, 6. a, 7. c, 8. b, 9. e 15. 1. a, 2. c, 3. b, 4. a, 5. a, 6. b

Points to Ponder

(Questions on p. 778.)

1. The anterior pituitary responds only to the normal pulsatile pattern of GnRH and does not secrete gonadotropins in response to continuous exposure to GnRH. In the absence of FSH and LH secretion, ovulation and other events of the ovarian cycle do not ensue, so continuous GnRH administration may find use as a contraceptive technique.
2. Testosterone hypersecretion in a young boy causes premature closure of the epiphyseal plates so that he stops growing before he reaches his genetic potential for height. The child would also display signs of precocious pseudopuberty, characterized by premature development of secondary sexual characteristics, such as deep voice, beard, enlarged penis, and sex drive.
3. A potentially troublesome side effect of drugs that inhibit sympathetic nervous system activity as part of the treatment for high blood pressure is males' inability to carry out sexual activity. Both divisions of the autonomic nervous system are required for the male sexual activity. Parasympathetic activity is essential for accomplishing erection, and sympathetic activity is important for ejaculation.
4. Posterior pituitary extract contains an abundance of stored oxytocin, which can be administered to induce or facilitate labour by increasing uterine contractility. Exogenous oxytocin is most successful in inducing labour if the woman is near term, presumably because of the increasing concentration of myometrial oxytocin receptors at that time.
5. GnRH or FSH and LH are not effective in treating the symptoms of menopause because the ovaries are no longer responsive to the gonadotropins. Thus, treatment with these hormones would not cause estrogen and progesterone secretion. In fact, GnRH, FSH, and LH levels are already elevated in postmenopausal women because of lack of negative feedback by the ovarian hormones.

Clinical Consideration

(Question on p. 778.)

The first warning of a tubal pregnancy is pain caused by stretching of the oviduct by the growing embryo. A tubal pregnancy must be surgically terminated because the oviduct cannot expand as the uterus does to accommodate the growing embryo. If not removed, the enlarging embryo will rupture the oviduct, causing possibly lethal haemorrhage.

Reference Values for Commonly Measured Variables in Blood and Commonly Measured Cardiorespiratory Variables

Blood Gases	Normal values
P_{O_2} (arterial)	11–13 kPa (kilopascals)
P_{CO_2} (arterial)	4.7–5.9 kPa
Electrolytes	
Ca^{2+} (total)	2.2–2.6 mmol/L
Cl^-	97–110 mmol/L
K^+	3.5–5.0 mmol/L
Na^+	135–146 mmol/L
Hormones	
Aldosterone	83–277 pmol/L
Cortisol	
8:00 a.m.	140–690 nmol/L
4:00 p.m.	40–330 nmol/L
Estradiol	
Women (early follicular phase)	73–367 pmol/L
Women (midcycle peak)	551–2753 pmol/L
Men	37–184 pmol/L
Insulin (fasted)	43–186 pmol/L
Insulin-like growth factor I	
16–24 years old	182–780 μ g/L
25–50 years old	114–492 μ g/L
Parathyroid hormone	10–75 ng/L
Progesterone	
Women (luteal phase)	6–81 nmol/L
Women (pregnancy)	15–770 nmol/L
Men	0.6–4.3 nmol/L
Testosterone	
Women	<3.5 nmol/L
Men	9–35 nmol/L
Thyroid-stimulating hormone	0.3–4.0 mIU/L
Thyroxine (adults)	64–140 nmol/L

Blood Gases	Normal values
Nutrients (fasting)	
Glucose	4–6 mmol/L
Free fatty acids	0.3–1.0 mmol/L
Triglycerides	<1.8 mmol/L
Proteins	
Albumin	35–55 g/L
Globulins	20–35 g/L
Fibrinogens	2–4 g/L
Red and White Blood Cells	
Red blood cell count	$4.1\text{--}5.4 \times 10^{12}/L$
Haematocrit	
Male	0.42–0.52
Female	0.37–0.48
Haemoglobin	
Male	140–180 g/L
Female	120–160 g/L
Iron	9–27 μ mol/L
Leukocytes (total)	$4.3\text{--}10.8 \times 10^9/L$
Osmolarity	285–295 mosmol/L
pH	7.38–7.45

Cardiovascular Response	Units
Systolic Blood Pressure (rest)	
Male 20–30 years	120 mmHg
50–60 years	134 mmHg
Female 20–30 years	120 mmHg
50–60 years	130 mmHg
Diastolic Blood Pressure (rest)	
Male 20–30 years	80 mmHg
50–60 years	84 mmHg

Cardiovascular Response		Units
Female	20–30 years	74 mmHg
	50–60 years	84 mmHg
Systolic Blood Pressure (maximal exercise)		
Male	20–30 years	190 mmHg
	50–60 years	200 mmHg

V_T (tidle volume)	0.4 L/min	
Breathing Pattern (maximal exercise)		
V_E	130 L/min	} Values for 30-year-old untrained males
F_b	45 breaths/min	
V_A	96 L/min	
V_T	2.90 L/min	

A Deeper Look into Chapter 12, The Respiratory System

G.1 Terminology for Respiratory Physiology

Primary symbols

C	Content (or concentration) in blood
D	Delivery (as in $\dot{D}O_2$)
F	Fractional concentration in dry gas
P	Pressure or partial pressure
Q	Volume of blood
$\dot{Q}$	Volume of blood per unit time (also cardiac output)
R	Respiratory exchange ratio
S	Saturation of haemoglobin with O_2
V	Volume of gas
$\dot{V}$	Volume of gas per unit time (flow or ventilation)

Secondary symbols for gas phase

A	alveolar
B	barometric
D	dead space
E	expired
ET	end-tidal
I	inspired
L	lung
T	tidal

Secondary symbols for blood phase

a	arterial
c	capillary
c'	end capillary
i	ideal
v	venous
$\bar{V}$	mixed venous

A time derivative is indicated by a dot over the symbol, a mean (or average) by a bar. The location of a parameter in the gas phase

(e.g., alveoli, inspiratory gas) is denoted by smaller upper case letters, whereas those in the blood phase are indicated by lower case letters.

Other abbreviations

ATPS	ambient temperature, pressure, saturated with water vapour; used for measurements of gas volumes under ambient conditions.
BTPS	body temperature (37°C), pressure (ambient P_B), saturated; used for volumes and flows in the body.
STPD	standard temperature (0°C), pressure (760 mmHg), dry; used for measurements of O_2 consumption ($\dot{V}_{O_2}$) and CO_2 production ($\dot{V}_{CO_2}$).

Note: Measurements of gas volumes under ambient conditions (e.g., in a bag) are given as ATPS. Volumes or flows in the body are always given as BTPS because they always exist at this condition. Volumes of gases diffusing or consumed ($\dot{V}_{O_2}$) or produced ($\dot{V}_{CO_2}$) are always given as STPD to enable comparisons of measurements made under different ambient conditions.

Examples

Ca_{O_2}	O_2 content (or concentration) of arterial blood
F_{EN_2}	Fractional concentration of N_2 in expired gas
$P_{\bar{V}CO_2}$	Partial pressure of CO_2 in mixed venous blood
P_{ETCO_2}	Partial pressure of CO_2 in end-tidal gas
$\dot{V}$	Volume of gas per minute (or second), that is, flow
$\dot{V}_{O_2}$	Consumption or diffusion (context determines which) of O_2

G.2 Gas Laws and Other Variables

1. Gay-Lussac's/Charles's law: Volume and temperature

$$V_1/V_2 = T_1/T_2 \text{ and } P_1/P_2 = T_1/T_2$$

where V is volume, T is temperature, P is pressure, and 1 and 2 are conditions 1 and 2, respectively.

2. Boyle's/Mariotte's law: Volume and pressure

$$P \times V = \text{constant, at constant temperature}$$

or

$$P_1 V_1 = P_2 V_2$$

where P is the pressure, and V is the volume of a perfect gas.

3. Dalton's law of partial pressures: The partial pressure of a given gas x is equal to the product of the total pressure, P_B multiplied by F , the fractional concentration of the gas in the mixture.

$$P_x = P_B \times F$$

For inspired/alveolar gases, when $T = 37^\circ\text{C}$ and $P_{\text{H}_2\text{O}} = 47 \text{ mmHg}$,

$$P_x = (P_B - 47) \times F$$

where F is the fractional concentration of O_2 , CO_2 , or N_2 in the dry gas mixture.

4. Fick's law of diffusion of a gas x :

$$\dot{V}_x = A \times D \times \Delta P / T$$

where $\dot{V}_x$ = the amount (mL) of substance x diffused per unit time

A = surface area for diffusion

D = the diffusion constant for substance x

ΔP = the pressure gradient between the two points across which diffusion occurs

T = the distance over which diffusion occurs

5. Graham's law:

$$\dot{V}_x \propto 1/\sqrt{\text{MW}}.$$

where $\dot{V}_x$ is the amount (mL) of substance x diffused per unit time, and MW is its molecular weight.

G.3 Pressure–Volume Relationship of the Respiratory System

Neither the elastic recoil pressure of the lung (P_l) nor the pleural pressure (P_{pl}) has a unique value; both depend on the volume of the respiratory system. We can determine the relation between system volume and pressure by measuring mouth pressure (P_m) at different lung volumes under conditions when the mouth and nose are closed (or a valve through which the subject is breathing is closed) and there is no activity of the respiratory muscles. At the end of a normal expiration, at the functional residual capacity (FRC), a valve is closed temporarily (so the subject cannot breathe), and she relaxes her respiratory muscles. We measure P_m “inside” the valve. Because there is no tendency to either inhale or exhale, P_m is 0 cm H_2O —that is, atmospheric pressure (P_B). The valve is then opened, the subject breathes in until she cannot inhale any more (total lung capacity, TLC), and again relaxes her respiratory muscles against the reclosed valve.

She will now feel herself wanting to breathe out; in other words, mouth pressure is greater than atmospheric pressure, or positive. If she now repeats this, but this time after breathing all the way to residual volume (RV), she will feel herself wanting to breathe in; in other words, mouth pressure is less than atmospheric pressure, or negative. Recall that these pressures are generated only by the *passive* properties of the respiratory system, not by the respiratory pump muscles. Moreover, because she relaxes her respiratory pump muscles and her upper airway (pharynx) is open, mouth pressure must equal alveolar pressure (P_A); if they were different, flow would occur between the upper airway and alveoli, and that is not happening. If we repeat this experiment at different lung volumes, not just FRC, TLC, and RV, we obtain the relation depicted in Figure 12-10 (p. 508). At lung volumes above the end of a normal expiration (FRC), the respiratory system passively generates positive pressures. At volumes below FRC, the pressures are negative.

You may be puzzled by the arrangement of the axes, with the independent variable, volume (V), on the y -axis and the dependent variable, mouth pressure (P_m), on the x -axis. Under normal circumstances, we change lung (system) volume by changing the pressure, either through changes in the degree of activation of the respiratory pump muscles or, in ventilated individuals, by changing the pressure generated by the ventilator. These pressure changes increase or decrease lung volume.

Mouth pressure (P_m) is the pressure generated by the entire respiratory system (P_{rs}) (i.e., $P_m = P_{rs}$) and the respiratory system is composed of the lung and chest wall (Figure 12-9, p. 507). In other words, the pressure generated by the respiratory system (P_{rs}) equals the sum of the pressure generated by the lung (P_l) and the pressure generated by the chest wall (P_w):

$$P_{rs} = P_l + P_w$$

We know P_{rs} because under the experimental conditions, it is P_m . But how can we measure the recoil pressures of the lung (P_l) and of the chest wall (P_w)? We can measure P_l indirectly by inserting a catheter via the nose into the middle third of the esophagus and measuring its pressure; this, as verified experimentally, provides an excellent approximation of the pleural pressure (P_{pl}). We now repeat the procedures just described and measure pleural pressure at each lung volume. How does this help us? Recall from the rearranged equation describing the transpulmonary pressure that

$$P_l = P_A - P_{pl}$$

We know P_A because, under the conditions of this experiment (valve closed, airways open, and respiratory pump muscles relaxed), $P_m = P_A$. Thus, we know both terms on the right side of the equation and can now calculate P_l at different lung volumes to get the second curve labelled P_l in Figure 12-9.

In addition, because

$$P_{rs} = P_l + P_w$$

and we know both P_{rs} and P_l , we can calculate P_w . The passive recoil pressure of the chest wall at different lung volumes is given by the curve designated P_w in Figure 12-9.

G.4 How We Inspire

At the end of a normal expiration, we return to a lung volume (FRC) at which the tendency of the chest wall to expand is equal and opposite to the tendency of the lung to collapse. This relation can be described in terms of the two pressures acting at the surface of the lung:

- P_A is the pressure inside the alveolus ($= P_B$ when flow is zero and the airway is open)
- P_{pl} is the pleural pressure

The difference between the two pressures is called the transpulmonary pressure (P_{tp}). This pressure is also referred to as the recoil pressure of the lung (P_l). Note too that the difference across a structure, whether the lung or an airway (in which case, we use the term *transmural pressure*) is *always* determined as the pressure inside the structure minus the pressure outside the structure.

Or, using abbreviations,

$$P_{tp} = P_A - P_{pl}$$

At end-expiration when no flow occurs ($\dot{V} = 0$), P_A must equal zero (0) cmH₂O: if it were any other value, flow would occur. Since P_{pl} is -5 cmH₂O,

$$P_{tp} = 0 - (-5) = +5 \text{ cmH}_2\text{O}$$

The positive transpulmonary pressure only means that the lung is inflated—the normal state of affairs. Note too that the positive P_{tp} results from only one component, the negative (subatmospheric) pressure generated by the tendency of the chest wall to expand. The alveolar pressure, as we shall see, is purely passive, determined by the algebraic sum of the pressure generated by the elastic recoil pressure of the lung (P_l) as it “tries” to collapse and the outward recoil of the chest wall as it “tries” to expand.

Note that the recoil pressure of the lung (P_l) must be equal and opposite to the pleural pressure (P_{pl}) to give a $P_A = 0$ cmH₂O, which is required for the zero flow condition to be true.

For flow to occur, P_A has to change. Therefore, we rearrange the equation to place P_A on the left side. (We do this because, as

indicated earlier, this is the variable that has to change in order to produce flow, since pressure at the airway opening [P_B] is always set to zero.) Therefore, rearranging the equation:

$$P_B = P_{tp} + P_{pl}$$

Stated in words, alveolar pressure (P_A) is the algebraic sum of transpulmonary pressure (P_{tp}) and pleural pressure (P_{pl}).

Note that we could also express it slightly differently using the following equation:

$$P_A = P_l + P_{pl}$$

where alveolar pressure is the algebraic sum of the lung recoil and the pleural pressures.

To produce inspiratory flow, P_A has to be negative (subatmospheric). To do this, the negative pressure pulling open the lung (P_{pl}) must be more negative than the transpulmonary pressure is positive (e.g., -6 cmH₂O is more negative than +5 cmH₂O is positive). This is done by contracting the inspiratory muscles, mainly the diaphragm. The diaphragm descends, lowering P_{pl} , decompressing the gas in the lungs and, according to Boyle's/Mariotte's law, decreasing P_A . This creates the negative P_A required for inspiratory flow.

The lung behaves mechanically much like a balloon placed inside a bottle. To inflate the balloon a pressure must be generated to overcome the tendency of the balloon to deflate (i.e., elastic recoil). In this model, the balloon (lung) is connected to the atmosphere via a tube that passes through a stopper. A catheter is placed inside the jar to measure the equivalent of pleural pressure (in cmH₂O), registered on the meter above the jar. As we pull down on the rubber sheet (diaphragm) across the bottom of the jar, the pressure inside the jar (equivalent to pleural pressure) becomes more subatmospheric and the balloon inflates (right-hand figure). Because it takes time for air to flow, due to the resistance to airflow offered by the tubing (airways) and by the gas itself, the balloon (lung) expansion and, therefore, its elastic recoil (P_l) cannot catch up to the more negative P_{pl} as long as we continue to contract the diaphragm more. When, eventually, we stop pulling on the rubber sheet (equivalent to the diaphragm no longer contracting), P_l catches up to and equals P_{pl} , but at greater absolute values (e.g., $P_{pl} = -8$ cmH₂O and $P_l = +8$ cmH₂O). At this point, inspiration stops.

For expiration to occur at rest, all we have to do is relax the diaphragm. The energy stored in the lung, its elastic recoil (due to stretching of the elastic fibres and, more importantly, increased surface tension), is sufficient to generate expiratory flow. Thus, at the onset of expiration, P_{pl} becomes slightly less negative, say -7.9 cmH₂O. But P_l is still 8 cmH₂O. Therefore,

$$P_A = P_{tp} + P_{pl} = +8 + (-7.9) = +0.1 \text{ cmH}_2\text{O}$$

In other words, P_A is now greater than P_B (atmospheric = mouth pressure) and expiratory flow starts.

Glossary

Definitions are provided for selected key terms.

A

A band One of the dark bands that alternate with light (I) bands to create a striated appearance in a skeletal or cardiac muscle fibre when these fibres are viewed with a light microscope (p. 300)

absolute refractory period Along with the *relative refractory period*, one of the two components of the refractory period. These two periods occur as a result of the changing status of the voltage-gated Na^+ and K^+ channels during and after an action potential. (p. 67)

accessory digestive organs Exocrine organs outside the wall of the digestive tract that empty their secretions through ducts into the digestive tract lumen (p. 647)

accessory sex glands Glands that empty their secretions into the reproductive tract (p. 724)

accommodation The ability to adjust the strength of the lens in the eye so that both near and far sources can be focused on the retina (p. 157)

acetylcholine (ACh) (as' -uh-teal-KÖ-lën) The neurotransmitter released from all autonomic preganglionic fibres, parasympathetic postganglionic fibres, and motor neurons (p. 188)

acetylcholinesterase (AChE) (as' -uh-teal-kō-luh-NES-tuh-rās) An enzyme present in the motor-end-plate membrane of a skeletal muscle fibre that inactivates acetylcholine (p. 199)

ACh See acetylcholine. (p. 188)

AChE See *acetylcholinesterase*. (p. 199)

acidaemia A plasma pH that is below 7.35 (p. 621)

acid-base balance The precise regulation of free hydrogen ion concentration in the body fluids (p. 620)

acidic A solution with a pH of less than 7.0 or with a $[\text{H}^+]$ greater than that of pure water (p. 621)

acidosis (as-i-DÖ-sus) Blood pH of less than 7.35 (p. 621)

acids Hydrogen-containing substance that yields a free hydrogen ion and anion on dissociation (p. 620)

acini (ÄS-i-ni) The secretory component of the saclike exocrine glands, such as digestive enzyme-producing pancreatic glands or milk-producing mammary glands (p. 667)

acquired (conditioned) reflexes A new or modified response elicited by a stimulus after conditioning (p. 105)

acquired immunodeficiency syndrome (AIDS) A set of symptoms and infections resulting from damage to the immune system caused by the human immunodeficiency virus (HIV) (p. 482)

acromegaly A disproportionate growth pattern producing a disfiguring condition; bone thickening in the extremities and the face. (p. 238)

ACTH See *adrenocorticotrophic hormone*. (p. 227)

active forces Forces that require expenditure of cellular energy (ATP) in the transport of a substance across the plasma membrane (p. 37)

active hyperaemia The increased blood flow resulting when a tissue is active (p. 398)

active reabsorption A type of tubular reabsorption in which any one of the five steps in the transepithelial transport of a substance reabsorbed across the kidney tubules requires energy expenditure (p. 574)

active transport Active carrier-mediated transport involving transport of a substance against its concentration gradient across the plasma membrane (p. 43)

acuity Discriminative ability; the ability to discern between two different points of stimulation (p. 147)

adaptation A reduction in receptor potential despite sustained stimulation of the same magnitude (p. 145)

addicted Compulsive seeking out and taking a drug at all costs, first to experience the pleasurable sensations and later to avoid the negative withdrawal symptoms, even when the drug no longer provides pleasure (p. 82)

A-delta (δ) fibre Type of sensory fibre associated with cold and pressure. Nociceptor stimulation is interpreted as fast pain information. (p. 149)

adenohypophysis The anterior pituitary (p. 226)

adenosine diphosphate (ADP) (uh-DEN-uh-sën) The two-phosphate product formed from the splitting of ATP to yield energy for the cell's use (p. 24)

adenosine triphosphate (ATP) The body's common energy currency, which consists of an adenosine with three phosphate groups attached; splitting of the high-energy, terminal phosphate bond provides energy to power cellular activities (p. 24)

adenyl cyclase (ah-DEN-il-il si-kläs) The membrane-bound enzyme that is activated by a G protein intermediary in response to the binding of an extracellular messenger with a surface membrane receptor and that, in turn, activates cyclic AMP, an intracellular second messenger (p. 217)

adequate stimulus A property of a sensory receptor that determines the type of energy to which a sensory receptor responds with the initiation of sensory transduction (p. 143)

ADH Antidiuretic hormone. See *vasopressin*. (p. 82)

adipocytes Fat cells in adipose tissue; store triglyceride fat and secrete hormones called *adipokines* (p. 703)

adipokines Hormones secreted by adipose tissue that play important roles in energy balance and metabolism (p. 703)

adipose tissue The tissue specialized for storage of triglyceride fat; found under the skin in the hypodermis (p. 462)

adolescence The stage of physical and mental human development that occurs between childhood and adulthood; involves biological, social, and psychological changes (p. 734)

ADP See *adenosine diphosphate*. (p. 24)

adrenal cortex (uh-DRĒ-nul) The outer portion of the adrenal gland; secretes three classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex hormones (p. 254)

adrenal medulla (muh-DUL-uh) The inner portion of the adrenal gland; an endocrine gland that is a modified sympathetic ganglion that secretes the hormones epinephrine and norepinephrine into the blood in response to sympathetic stimulation (p. 192)

adrenergic fibres (ad' -ruh-NUR-jik) Nerve fibres that release norepinephrine as their neurotransmitter (p. 188)

aerobic Condition in which oxygen is available (p. 28)

aerobic (endurance) exercise Exercise that can be supported by ATP formation, accomplished by oxidative phosphorylation because adequate oxygen is available to support the muscle's modest energy demands; also called endurance-type exercise (p. 320)

afferent arterioles (AF-er-ent ar-TIR-ē-öl) Vessels that carry blood into the glomerulus of the kidney's nephron (p. 562)

afferent neurons Neurons that possess a sensory receptor at their peripheral ending and carry information to the central nervous system (p. 92)

afferent pathway [neuron] Nerve pathway that carries nerve impulses from receptors toward the central nervous system (p. 106)

after hyperpolarization (hi' -pur-pō-luh-ruh-ZA-shun) A slight, transient hyperpolarization that sometimes occurs at the end of an action potential (p. 62)

afterload The pressure that the left ventricle of the heart must generate in order to eject blood from the chamber (p. 369)

agonists Substances that initiate a physiological response when combined with a receptor (p. 193)

AIDS See *acquired immunodeficiency syndrome*. (p. 482)

albumins (al-BEW-min) Smallest and most abundant of the plasma proteins; binds and transports many water-insoluble substances in the blood; contributes extensively to plasma-colloid osmotic pressure (p. 435)

aldosterone (al-dō-steer-OWN) or (al-DOS-tuh-rōn) The adrenocortical hormone that stimulates Na^+ reabsorption by the distal and collecting tubules of the kidney's nephron during urine formation (p. 255)

alkalaemia A plasma pH that is above 7.45 (p. 621)

alkalosis (al' -kuh-LÖ-sus) Blood pH that is greater than 7.45 (p. 621)

allergy Acquisition of an inappropriate, specific immune reactivity to a normally harmless environmental substance (p. 491)

all-or-none law An excitable membrane either responds to a stimulus with an action potential that

spreads nondecrementally throughout the membrane or does not respond with an action potential at all. (p. 69)

α (alpha) cells The endocrine pancreatic cells that secrete the hormone glucagon (p. 271)

alpha motor neurons Motor neurons that innervate ordinary skeletal muscle fibres (p. 325)

alveolar dead space (al-VE-o-lur) The difference between physiological dead space and anatomical dead space, which represents that part of the physiological dead space resulting from ventilation of relatively non-perfused alveoli (p. 529)

alveolar surface tension (al-VE-o-lur) The surface tension of the fluid lining the alveoli in the lungs (p. 509)

alveolar ventilation (V_A) The volume of air exchanged between the atmosphere and alveoli per minute; equals (tidal volume minus dead space volume) multiplied by respiratory rate (p. 522)

alveoli [of lungs] (al-VĒ-ō-li) The air sacs across which oxygen and carbon dioxide are exchanged between the blood and air in the lungs (p. 502)

amniotic cavity The fluid-filled cavity surrounding the developing embryo (p. 761)

amniotic fluid The fluid within the amnion that surrounds, nourishes, and protects the fetus from injury (p. 761)

AMPA receptors Primarily responsible for generating EPSPs in response to glutamate activation (p. 130)

ampulla A dilated portion of a canal or duct (p. 178)

amyotrophic lateral sclerosis (ALS) A neurological disorder characterized by progressive degeneration of motor cells in the spinal cord and brain, often referred to as Lou Gehrig's disease (p. 195)

anabolic See *anabolism*. (p. 22)

anabolism (ah-NAB-ō-li-zum) The buildup, or synthesis, of larger organic molecules from the small organic molecular subunits (p. 267)

anaemia A reduction below normal in O_2 -carrying capacity of the blood (p. 441)

anaerobic (an'-uh-RŌ-bik) Condition in which oxygen is not present (p. 28)

anaerobic (high-intensity) exercise High-intensity exercise that can be supported by ATP formation accomplished by anaerobic glycolysis for brief periods of time when O_2 delivery to a muscle is inadequate to support oxidative phosphorylation (p. 28)

analgesic system Neural pathway that includes the secretion of endorphins by the brain in response to the perception of pain (p. 150)

anatomic dead space (V_d) The volume of the conducting airways, including the nose, mouth, trachea, and alveoli; represents that portion of inspired gas that is unavailable for exchange with pulmonary capillary blood (p. 521)

anatomy A branch of biology that considers the structure of living things; closely interrelated with physiology because body functions are highly dependent on the structure of the body parts that carry them out (p. 4)

androgens Masculinizing, male sex hormone; includes testosterone from the testes and dehydroepiandrosterone from the adrenal cortex (p. 232)

angiogenesis A physiological process involving the formation and growth of new blood vessels from pre-existing vessels (p. 399)

anion gap The unmeasured negatively charged ions in the plasma, calculated by taking the difference

between the laboratory measured cations and the laboratory anions (p. 634)

antagonism Actions opposing each other; in the case of hormones, when one hormone causes the loss of another hormone's receptors, reducing the effectiveness of the second hormone (p. 214)

antagonistic Of or relating to an antagonist or its action (p. 192)

antagonists Substances that interfere with or inhibit the physiological action of another (p. 193)

anterior pituitary gland The glandular portion of the pituitary that synthesizes, stores, and secretes six different hormones: growth hormone, TSH, ACTH, FSH, LH, and prolactin (p. 225)

antibodies Immunoglobulins produced by a specific activated B lymphocyte (plasma cell) against a particular antigen; bind with the specific antigen against which they are produced and promote the antigenic invader's destruction by augmenting non-specific immune responses already initiated against the antigen (p. 475)

antibody-mediated (humoural) immunity A specific immune response accomplished by antibody production by B cells (p. 473)

antidiuretic hormone (an'-ti-di'-yū-RET-ik) See *vasopressin*. (p. 592)

antigen A large, complex molecule that triggers a specific immune response against itself when it gains entry into the body (p. 474)

antioxidant A substance that helps inactivate biologically damaging free radicals (p. 242)

antrum [of ovary] The fluid-filled cavity formed within a developing ovarian follicle (p. 656)

antrum [of stomach] The lower portion of the stomach (p. 656)

aorta (a-OR-tah) The large vessel that carries blood from the left ventricle (p. 347)

aortic valve A one-way valve that permits the flow of blood from the left ventricle into the aorta during ventricular emptying but prevents the back-flow of blood from the aorta into the left ventricle during ventricular relaxation (p. 350)

aphasias Language disorders caused by damage to specific cortical areas, mostly resulting from strokes; not to be confused with speech impediments, which are caused by a defect in the mechanical aspect of speech, such as weakness or incoordination of the muscles controlling the vocal apparatus (p. 132)

apnea The cessation of breathing (p. 550)

aquaporins (water channels) Membrane proteins that form channels used for the passage of water. About a billion water molecules can pass single file through an aquaporin channel in one second. (p. 38)

aqueous humour (Ā-kwē-us) The clear, watery fluid in the anterior chamber of the eye; provides nourishment for the cornea and lens (p. 153)

arachnoid mater A delicate, richly vascularized layer with a cobweb appearance. The space between the arachnoid layer and the underlying pia mater, the subarachnoid space, is filled with CSF. (p. 100)

arachnoid villi Protrusions of arachnoid tissue that penetrate through gaps in the overlying dura and project into the dural sinuses. CSF is reabsorbed across the surfaces of these villi into the blood circulating within the sinuses. (p. 100)

arcuate nucleus (ARE-kyou-it') Subcortical brain region that houses neurons that secrete appetite-enhancing neuropeptide Y and those that secrete appetite-suppressing melanocortins (p. 703)

arrhythmia Variation from the normal rhythm of the heartbeat, encompassing abnormalities of rate, regularity, origin of impulse, and sequence of activation (p. 359)

arterioles (ar-TIR-ē-ōlz) The highly muscular, high-resistance vessels, the calibre of which can be changed subject to control to determine how much of the cardiac output is distributed to each of the various tissues (p. 394)

arteries Vessels that carry blood away from the heart (p. 346)

ascending tracts Bundles of nerve fibres of similar function that travel up the spinal cord to transmit signals derived from afferent input to the brain (p. 103)

association areas Areas of the brain that make up much of the cerebral cortex and are free to process all kinds of information; enable the brain to produce behaviours requiring the coordination of many brain areas (p. 133)

asthma An obstructive pulmonary disease characterized by profound constriction of the smaller airways caused by allergy-induced spasm of the smooth muscle in the walls of these airways (p. 492)

astigmatism A defect in the eye or lens caused by a deviation from spherical curvature, resulting in distorted images, as light rays are prevented from meeting at a common focus (p. 156)

astrocytes A type of glial cell in the brain, whose major functions include holding the neurons together in proper spatial relationship, inducing the brain capillaries to form tight junctions important in the blood-brain barrier, and enhancing synaptic activity (p. 95)

asynchronous recruitment of motor units Condition in which the body alternates motor unit activity to give motor units that have been active an opportunity to rest while others take over; involves a carefully coordinated shift of motor unit activity so that sustained contraction is smooth rather than jerky (p. 310)

atherosclerosis (ath-uh-rō-skluh-RŌ-sus) A progressive, degenerative arterial disease that leads to gradual blockage of affected vessels, reducing blood flow through them (p. 374)

ATP See *adenosine triphosphate*. (p. 24)

ATP synthase Converts ADP 1 Pi to ATP, providing a rich yield of 32 more ATP molecules for each glucose molecule processed (p. 27)

atria (*atrium*, singular) (Ā-tree-a) Upper chambers of the heart that receive blood from the veins and transfers it to the ventricles (p. 346)

atrioventricular node (AV node) (ā'-trē-ō-ven-TRIK-yuh-lur) A small bundle of specialized cardiac cells at the junction of the atria and ventricles that is the only site of electrical contact between the atria and ventricles (p. 352)

atrophy (AH-truh-fē) Decrease in mass of an organ (p. 320)

auditory (cochlear) nerve A bundle of nerve fibres that carries hearing information between the cochlea and the brain (p. 174)

autoimmune disease Disease characterized by erroneous production of antibodies against one of the body's own tissues (p. 486)

autonomic nervous system (ANS) The portion of the efferent division of the peripheral nervous system that innervates smooth and cardiac muscle and exocrine glands; composed of two subdivisions—the sympathetic nervous system and the parasympathetic nervous system (p. 92)

autorhythmicity The ability of an excitable cell to rhythmically initiate its own action potentials (p. 352)

AV nodal delay The delay in impulse transmission between the atria and ventricles at the AV node to allow enough time for the atria to become completely depolarized and contract, emptying their contents into the ventricles, before ventricular depolarization and contraction occur (p. 355)

axon A single, elongated tubular extension of a neuron that conducts action potentials away from the cell body; also known as a *nerve fibre* (p. 65)

axon hillock The first portion of a neuronal axon plus the region of the cell body from which the axon leaves; the site of action-potential initiation in most neurons (p. 65)

axon terminals The branched endings of a neuronal axon, which release a neurotransmitter that influences target cells in close association with the axon terminals (p. 66)

B

baroreceptor reflex An autonomically mediated reflex response that influences the heart and blood vessels to oppose a change in mean arterial blood pressure (p. 420)

baroreceptors Receptors located within the circulatory system that monitor blood pressure (p. 419)

basal metabolic rate (BMR) (BĀ-sul) The minimal waking rate of internal energy expenditure; occurs when the body is at rest (p. 701)

basal ganglia Several masses of grey matter located deep within the white matter of the cerebrum of the brain; play an important inhibitory role in motor control (p. 123)

base A substance that can combine with a free hydrogen ion and remove it from solution (p. 346)

basic behavioural patterns Behaviours controlled at least in part by the limbic system; include those aimed at individual survival (attack, searching for food) and those directed toward perpetuating the species (sociosexual behaviours conducive to mating)(p. 124)

basic electrical rhythm (BER) Self-induced electrical activity of the digestive-tract smooth muscle (p. 650)

basic or alkaline A solution with a pH of greater than 7.0 or with a $[H^+]$ less than that of pure water (p. 621)

basilar membrane (BAS-ih-lar) The membrane that forms the floor of the middle compartment of the cochlea and bears the organ of Corti, the sense organ for hearing (p. 172)

basophils (BAY-so-fills) White blood cells that synthesize, store, and release histamine, which is important in allergic responses, and heparin, which hastens the removal of fat particles from the blood as well as prevents blood clotting (p. 447)

BER See *basic electrical rhythm*. (p. 650)

β (beta) cells The endocrine pancreatic cells that secrete the hormone insulin (p. 271)

bicarbonate ion (HCO_3^-) The anion resulting from dissociation of carbonic acid, H_2CO_3 (p. 437)

bile salts Cholesterol derivatives secreted in the bile that facilitate fat digestion through their detergent action and facilitate fat absorption through their micellar formation (p. 673)

biliary system (BIL-ē-air-ē) The bile-producing system, consisting of the liver, gallbladder, and associated ducts (p. 671)

bilirubin (bill-eh-RU-bin) A bile pigment, which is a waste product derived from the degradation of haemoglobin during the breakdown of old red blood cells (p. 674)

binocular field of vision The field of vision simultaneously received by both eyes; varies depending on the position of the eyes in the skull (p. 167)

bipolar cells Specialized sensory neurons that display graded potentials and have action potentials that do not originate until the ganglion cells propagate the sensory message over long distances to the brain; includes smell, sight, taste, hearing, and vestibular functions (p. 157)

bitter taste The most sensitive of the tastes, and perceived by most to be unpleasant, sharp, or disagreeable; includes tastes associated with unsweetened cocoa, coffee, beer, and olives (p. 184)

blastocyst The developmental stage of the fertilized ovum by the time it is ready to implant; consists of a single-layered sphere of cells encircling a fluid-filled cavity (p. 758)

blind spot An area that cannot be directly observed under existing circumstances; physiologically, the small, circular, optically insensitive region in the retina, where fibres of the optic nerve emerge from the eyeball (p. 158)

blood–brain barrier (BBB) Special structural and functional features of the brain capillaries that limit access of materials from the blood into the brain tissue (p. 100)

B lymphocytes (B cells) White blood cells that produce antibodies against specific targets to which they have been exposed (p. 447)

body [of the stomach] The main, or middle, part of the stomach (p. 7)

body systems Collection of organs that perform related functions and interact to accomplish a common activity that is essential for survival of the whole body; for example, the digestive system (p. 7)

bone marrow The soft, highly cellular tissue that fills the internal cavities of bones; the source of most blood cells (p. 437)

botulism Food poisoning caused by a bacterium (*botulinum*) growing on improperly sterilized meats and preserved foods (p. 199)

Bowman's capsule The beginning of the tubular component of the kidney's nephron that cups around the glomerulus and collects the glomerular filtrate as it is formed (p. 563)

Boyle's/Mariotte's law (boils) At any constant temperature, the pressure exerted by a gas varies inversely with the volume of the gas (p. 511)

bradycardia A resting heart rate less than 60 beats per minute; seldom symptomatic until the rate drops below 50 beats per minute (p. 359)

bradykinin A compound sometimes released in the blood that causes contraction of smooth muscle and vasodilation; increases capillary permeability, constricts smooth muscle, and stimulates pain receptors (p. 150)

brain stem The portion of the brain that is continuous with the spinal cord; serves as an integrating link between the spinal cord and higher brain levels, and controls many life-sustaining processes, such as breathing, circulation, and digestion (p. 109)

bronchioles (BRONG-kē-ōlz) The small, branching airways within the lungs (p. 502)

bronchoconstriction Narrowing of the respiratory airways (p. 515)

bronchodilation Widening of the respiratory airways (p. 515)

brush border The collection of microvilli projecting from the luminal border of epithelial cells lining the digestive tract and kidney tubules (p. 678)

bulbourethral glands (bul-bo-you-RĒTH-ral) Male accessory sex glands that secrete mucus for lubrication (p. 740)

bulk flow Movement in bulk of a protein-free plasma across the capillary walls between the blood and surrounding interstitial fluid; encompasses ultrafiltration and reabsorption (p. 409)

bundle of His (atrioventricular bundle) (hiss) A tract of specialized cardiac cells that rapidly transmits an action potential down the interventricular septum of the heart (p. 352)

C

cadherins Connective tissue fibres that interlace on the surface of adjacent cells and interlock in zipper fashion to help hold the cells within tissues and organs together (p. 32)

calcitonin (kal'-suh-TŌ-nun) A hormone secreted by the thyroid C cells that lowers plasma Ca^{2+} levels (p. 248)

calcium balance Maintenance of a constant total amount of Ca^{2+} in the body; accomplished by slowly responding adjustments in intestinal Ca^{2+} absorption and in urinary Ca^{2+} excretion (p. 285)

calcium homeostasis Maintenance of a constant free plasma Ca^{2+} concentration, accomplished by rapid exchanges of Ca^{2+} between the bone and ECF and, to a lesser extent, by modifications in urinary Ca^{2+} excretion (p. 284)

calmodulin (kal'-MA-jew-lin) An intracellular Ca^{2+} -binding protein that, on activation by Ca^{2+} , induces a change in structure and function of another intracellular protein; especially important in smooth-muscle excitation–contraction coupling (p. 219)

CAMs See *cell adhesion molecules*. (p. 32)

capacitance vessels The distensibility of blood vessels, mainly veins, which are capable of holding and storing approximately 60–70 percent of the body's blood volume (p. 414)

capillaries The thin-walled, pore-lined smallest of blood vessels, across which exchange between the blood and surrounding tissues takes place (p. 441)

capsaicin A colourless, pungent compound derived from capsicum; the source of the hotness of hot peppers (p. 149)

carbonic anhydrase (an-HĪ-drās) The enzyme that catalyzes the conversion of CO_2 and H_2O into carbonic acid, H_2CO_3 (p. 437)

cardiac muscle The specialized muscle found only in the heart (p. 326)

cardiac output (CO) The volume of blood pumped by each ventricle each minute; equals stroke volume multiplied by heart rate (p. 365)

cardiovascular control centre The integrating centre located in the medulla of the brain stem that controls mean arterial blood pressure (p. 402)

carrier-mediated transport Transport of a substance across the plasma membrane, facilitated by a carrier molecule (p. 41)

carrier molecules Membrane proteins, which, by undergoing reversible changes in shape so that specific binding sites are alternately exposed at either

side of the membrane, can bind with and transfer particular substances otherwise unable to cross the plasma membrane on their own (p. 31)

cartilage Tough and flexible connective tissue found in many areas of the body for structure and support (p. 233)

cascade A series of sequential reactions that culminates in a final product, such as a clot (p. 220)

catabolic See *catabolism*. (p. 267)

catabolism (kuh-TAB-ō-li-zum) The breakdown, or degradation, of large, energy-rich molecules within cells (p. 267)

cataract A cloudiness or opacity in the normally transparent lens of the eye that can cause a decrease in vision and lead to blindness (p. 157)

cauda equina The thick bundle of elongated nerve roots within the lower vertebral canal; called the cauda equina ("horse's tail") because of its appearance (p. 102)

C cells The thyroid cells that secrete calcitonin (p. 248)

CD4 cells See *helper T cells*. (p. 482)

CD8 cells (cytotoxic, or killer, T cells) The population of T cells that destroys host cells bearing foreign antigen, such as body cells invaded by viruses or cancer cells (p. 482)

cell The smallest unit capable of carrying out the processes associated with life; the basic unit of both structure and function of living organisms (p. 5)

cell adhesion molecules (CAMs) Proteins that protrude from the surface of the plasma membrane and form loops or other appendages that the cells use to grip one another and the surrounding connective tissue fibres (p. 32)

cell body The portion of a neuron that houses the nucleus and organelles (p. 64)

cell differentiation The process by which less specialized cells become more specialized (p. 5)

cell-mediated immunity A specific immune response accomplished by activated T lymphocytes, which directly attack unwanted cells (p. 473)

central chemoreceptors (kē-mō-rē-SEP-turz) Receptors located in the medulla near the respiratory centre; respond to changes in ECF H^+ concentration resulting from changes in arterial P_{CO_2} and adjust respiration accordingly (p. 547)

central fatigue Occurs when the CNS no longer adequately activates the motor neurons supplying the working muscles; causes a person to slow down or stop exercising even though the muscles can still perform; often psychologically based (p. 318)

central lacteal (LAK-tē-ul) The initial lymphatic vessel that supplies each of the small-intestinal villi (p. 680)

central nervous system (CNS) The brain and spinal cord (p. 92)

central sulcus (SUL-kus) A deep infolding of the brain surface that runs roughly down the middle of the lateral surface of each cerebral hemisphere and separates the parietal and frontal lobes (p. 115)

cerebellum (ser'-uh-BEL-um) The part of the brain attached at the rear of the brain stem; concerned with maintaining proper position of the body in space and subconscious coordination of motor activity (p. 121)

cerebral cortex The outer shell of grey matter in the cerebrum; site of initiation of all voluntary motor output and final perceptual processing of all

sensory input, as well as integration of most higher neural activity (p. 114)

cerebral hemispheres The cerebrum's two halves, which are connected by a thick band of neuronal axons (p. 113)

cerebrocerebellum Pertaining to the cerebrum and the cerebellum (p. 122)

cerebrospinal fluid (CSF) (ser'-uh-brō-SPI-nul) or (sah-REE-brō-SPI-nul) A special cushioning fluid that is produced by, surrounds, and flows through the central nervous system (p. 100)

cerebrovascular accident (CVA) Brain damage that occurs when a brain (cerebral) blood vessel is blocked by a clot or ruptures and the brain tissue supplied by that vessel loses its vital oxygen and glucose supply; results in damage and usually death of the deprived tissue (p. 114)

cerebrum (SER-uh-brum) or (sah-REE-brum) The division of the brain that consists of the basal nuclei and cerebral cortex (p. 94)

cerumen A brownish yellow, waxy secretion of the ceruminous glands of the external auditory meatus; commonly known as earwax (p. 172)

C fibres Afferent fibres in the peripheral nerves of the somatic sensory system; convey input signals from the periphery to the central nervous system (p. 149)

channels Small, water-filled passageways through the plasma membrane; formed by membrane proteins that span the membrane and provide highly selective passage for small water-soluble substances such as ions (p. 58)

chemical buffer system A mixture in a solution of two or more chemical compounds that minimize pH changes when either an acid or a base is added to or removed from the solution (p. 623)

chemical disequilibrium The concept of having an unequal distribution of solutes in different fluid compartments (p. 611)

chemical gradient A passive process in which ions move down an electrochemical gradient through open channels (from high to low concentration and by attraction of ion to area of opposite charge) (p. 37)

chemically gated channels Channels in the plasma membrane that open or close in response to the binding of a specific chemical messenger with a membrane receptor site that is in close association with the channel (p. 58)

chemical nociceptors Pain receptors (e.g., TRP) that respond to noxious chemical stimuli (p. 149)

chemiosmotic mechanism A four-step process that collectively harnesses the energy stored in the H^+ gradient across the inner mitochondrial membrane to synthesize ATP (p. 27)

chemoreceptors (kē-mo-rē-sep'-tur) Sensory receptors sensitive to specific chemicals (p. 144)

chief cells The cells in the gastric pits that secrete pepsinogen (p. 661)

cholecystokinin (CCK) (kō'-luh-sis-tuh-kī-nun) A hormone released from the duodenal mucosa primarily in response to the presence of fat; inhibits gastric motility and secretion, stimulates pancreatic enzyme secretion, stimulates gallbladder contraction, and acts as a satiety signal (p. 659)

cholesterol A type of fat molecule that serves as a precursor for steroid hormones and bile salts and is a stabilizing component of the plasma membrane (p. 29)

cholinergic fibres (kō'-lin-ER-jik) Nerve fibres that release acetylcholine as their neurotransmitter (p. 188)

choroid The pigmented vascular layer of the eyeball between the retina and the sclera (p. 153)

choroid plexuses Tissue found in particular regions of the ventricle cavities of the brain; consist of richly vascularized, cauliflower-like masses of pia mater tissue that dip into pockets formed by ependymal cells; have a key role in the production of cerebrospinal fluid as a result of selective transport mechanisms across their membranes (p. 100)

chronic obstructive pulmonary disease (COPD) A group of lung diseases characterized by increased airway resistance resulting from narrowing of the lumen of the lower airways; includes asthma, chronic bronchitis, and emphysema (p. 516)

chyme (kim) A thick liquid mixture of food and digestive juices (p. 657)

ciliary body The portion of the eye that produces aqueous humour and contains the ciliary muscle (p. 153)

ciliary muscle A circular ring of smooth muscle within the eye whose contraction increases the strength of the lens to accommodate for near vision (p. 157)

circular (constrictor) muscle Circularly oriented muscle layer contained within the iris of the eye that contracts in response to parasympathetic stimulation to decrease the size of the pupil and reduce the amount of light entering the eye (p. 155)

circulatory shock Condition that occurs when mean arterial blood pressure falls so low that adequate blood flow to the tissues can no longer be maintained (p. 426)

circumventricular organs Highly vascularized structures in the brain lacking a blood-brain barrier (p. 101)

citric acid cycle A cyclic series of biochemical reactions that involves the further processing of intermediate breakdown products of nutrient molecules, resulting in the generation of carbon dioxide and the preparation of hydrogen-carrier molecules for entry into the high-energy-yielding electron transport chain (p. 25)

classical neurotransmitters Synthesized in nerve terminals (acetylcholine, GABA, etc.), and generally present within the neuron; stimulus-dependent for release, act on postsynaptic cells, and have a mechanism of removal (p. 80)

CNS See *central nervous system*. (p. 92)

cochlea (KOK-lē-uh) The snail-shaped portion of the inner ear that houses the receptors for sound (p. 172)

cochlear duct An endolymph-filled cavity inside the cochlea, between the scala tympani and the scala vestibule; separated from these compartments by the basilar membrane and Reissner's membrane, respectively (p. 172)

cochlear implants Surgically implanted electronic device that provides a sense of sound to a person who is well below normal hearing (p. 177)

cognition The act or process of knowing, including both awareness and judgment (p. 93)

collagen Protein that forms cable-like fibres or sheets that provide tensile strength (resistance to longitudinal stress) (p. 34)

collateral circulation Occurs when an area of tissue or an organ has been cut off from its normal blood supply; forms new pathways (i.e., anastomoses) to deliver blood to the tissue or organ (p. 378)

collateral ganglia Sympathetic ganglia that lie about halfway between the CNS and the target organ (p. 188)

collecting duct (tubule) The last portion of tubule in the kidney's nephron that empties into the renal pelvis (p. 564)

colloid (KOL-oid) The thyroglobulin-containing substance enclosed within the thyroid follicles (p. 248)

colour blindness Condition that occurs in individuals who lack a particular type of cone, so their colour vision is a product of the differential sensitivity of only two types of cones; causes a different perception of colours and an inability to distinguish as many varieties of colours (p. 165)

colour vision The ability to distinguish objects that are observed when incoming light reacts with the several types of cone photoreceptors in the eye; a process in which the brain and the nervous system respond to the stimuli (p. 165)

competition Occurs when several closely related compounds compete for a ride across the membrane on the same carrier. If a given binding site can be occupied by more than one type of molecule, the rate of transport of each substance is less when both molecules are present than when either is present by itself. (p. 42)

complement system A collection of plasma proteins activated in cascade fashion on exposure to invading microorganisms, ultimately producing a membrane attack complex that destroys the invaders (p. 473)

compliance The distensibility of a hollow, elastic structure, such as a blood vessel or the lungs; a measure of how easily the structure can be stretched (p. 391)

concave Curved in, as a surface of a lens that diverges light rays (p. 155)

concentration gradient A difference in concentration of a particular substance between two adjacent areas (p. 37)

concentric muscle contraction A dynamic contraction that produces tension during a shortening motion; most familiar type of muscle contraction; occurs when actin filaments are pulled together by the myosin filaments, which move the Z lines closer together, shortening the sarcomere, and thus shortening the whole muscle (p. 315)

conductive deafness Condition that occurs when sound waves are not adequately conducted through the external and middle portions of the ear to set the fluids in the inner ear in motion (p. 177)

cones The eye's photoreceptors used for colour vision in the light (p. 153)

congestive heart failure The inability of the cardiac output to keep pace with the body's needs for blood delivery, with blood damming up in the veins behind the failing heart (p. 371)

connective tissue Tissue that serves to connect, support, and anchor various body parts; distinguished by relatively few cells dispersed within an abundance of extracellular material (p. 7)

connexon Six protein subunits arranged in a hollow tubelike structure. Two connexons extend outward, one from each of the plasma membranes of two adjacent cells, and join end to end to form the connecting tunnel between the two cells (p. 35)

consciousness The subjective awareness of both the external world and self, including awareness of thoughts, perceptions, and dreams; involves conscious experience that depends on the integrated functioning of many parts of the nervous system, even though the final level of awareness resides in the cerebral cortex and a crude sense of awareness is detected by the thalamus (p. 134)

consolidation Stabilization of memory by a process of transferring and fixing short-term memory traces into long-term memory stores (p. 126)

contiguous conduction The means by which an action potential is propagated throughout an unmyelinated nerve fibre; occurs when local current flow between an active and an adjacent inactive area brings the inactive area to threshold, triggering an action potential in a previously inactive area (p. 66)

contractile component The cross bridges formed by the actin and myosin molecules contained within the smallest functional unit of the muscle cell, the sarcomere (p. 313)

contractile proteins Myosin and actin, whose interaction brings about the shortening (contraction) of a muscle fibre (p. 301)

contraction time The period of time it takes for a muscle to generate force; varies among human skeletal muscle fibre types, for example, fast twitch and slow twitch (p. 308)

control centre The operation centre that integrates incoming information (p. 14)

controlled variable Some factor that can vary, but is controlled to reduce the amount of variability and keep the factor at a relatively steady state (p. 14)

convection Transfer of heat energy by air or water currents (p. 502)

convergence The converging of many presynaptic terminals from thousands of other neurons on a single neuronal cell body and its dendrites so that activity in the single neuron is influenced by the activity in many other neurons (p. 83)

convex Curved out, as a surface in a lens that converges light rays (p. 155)

core temperature The temperature within the inner core of the body (abdominal and thoracic organs, central nervous system, and skeletal muscles) that is homeostatically maintained at about 37.8°C (p. 711)

cornea (KOR-nee-ah) The clear, most anterior, outer layer of the eye through which light rays pass to the interior of the eye (p. 153)

coronary artery disease (CAD) Atherosclerotic plaque formation and narrowing of the coronary arteries that supply the heart muscle (p. 374)

coronary circulation The blood vessels that supply the heart muscle (p. 373)

corpus callosum The neural connection that enables the brain's two hemispheres to communicate and cooperate with each other by means of constant exchange of information; the body's "information superhighway" (p. 113)

corpus luteum (LOO-tē-um) The ovarian structure that develops from a ruptured follicle after ovulation (p. 749)

corticospinal (or pyramidal) motor system Efferent motor neurons that terminate within the spinal cord (p. 323)

cortisol (KORT-uh-sol) The adrenocortical hormone that plays an important role in carbohydrate, protein, and fat metabolism and helps the body resist stress (p. 256)

cotransport carriers Carriers, such as the luminal carriers in intestinal and kidney cells that have two binding sites, each of which interacts with a different molecule to be transported; for example, the Na⁺ and nutrient cotransporters, or the Na⁺-K⁺ ATPase (p. 44)

cranial nerves The 12 pairs of peripheral nerves, the majority of which arise from the brain stem (p. 110)

creatine kinase (CK) An enzyme expressed by various tissues and cell types; catalyzes the conversion of creatine and ATP to phosphocreatine (p. 24)

creatine phosphate A phosphorylated creatine molecule that acts as a rapidly mobilizable reserve of high-energy phosphates in skeletal muscle and brain tissues (p. 24)

CREB Refers to cAMP response element-binding, which is a cellular transcription factor; binds to particular DNA sequences, called cAMP response elements, increasing or decreasing their transcription of the downstream genes; commonly associated with the formation of long-term memory (p. 131)

CREB2 This second messenger plays a regulatory role in LTP as well as in simpler forms of short-term memory, such as sensitization (p. 131)

cross bridges (myosin heads) The myosin molecules' globular heads that protrude from a thick filament within a muscle fibre and interact with the actin molecules in the thin filaments to bring about shortening of the muscle fibre during contraction (p. 300)

crossed extensor reflex Ensures that the opposite limb will be in a position to bear the weight of the body as an injured limb is withdrawn from a stimulus (p. 109)

cupula An overlying, caplike, gelatinous layer, in which the imbedded hairs protrude into the ampulla; sways in the direction of the surrounding endolymph movement, much like seaweed leaning in the direction of the prevailing tide (p. 178)

curare An alkaloid that will interfere with neuromuscular junction activity by blocking the effect of released ACh; reversibly binds to the ACh receptor sites on the motor end plate (p. 199)

current A flow of electrical charges; by convention, the direction of current flow is always designated by the direction in which the positive charges are moving (p. 59)

cyclic adenosine monophosphate (cyclic AMP or cAMP) An intracellular second messenger derived from adenosine triphosphate (ATP) (p. 217)

cyclic AMP See *cyclic adenosine monophosphate*. (p. 217)

cyclic guanosine monophosphate (cyclic GMP or cGMP) A second messenger in a system analogous to the cAMP system (p. 220)

cytokines All chemicals other than antibodies that are secreted by lymphocytes (p. 470)

cytoplasm (SĪ-tō-plaz'-um) Portion of the cell interior not occupied by the nucleus (p. 22)

D

deafness Classified into two types—*conductive deafness* and *sensorineural deafness*—depending on the part of the hearing mechanism that fails to function adequately (p. 177)

declarative memories A capacity that requires conscious recall and involves the significant role of the hippocampus and associated temporal/limbic structures in maintaining a durable record of the everyday episodic events (p. 128)

dehydration A water deficit in the body (p. 614)

dehydroepiandrosterone (DHEA) (dē-HĪ-drō-ep-i-and-row-steer-own) The androgen (masculinizing hormone) secreted by the adrenal cortex in both sexes (p. 258)

denervation atrophy Condition that occurs after the nerve supply to a muscle is lost (p. 320)

dense-core vesicles Vesicles that undergo Ca^{2+} -induced exocytosis and release neuropeptides at the same time that the neurotransmitter is released from the synaptic vesicles (p. 80)

depolarization (de'-pō-luh-ruh_ZĀ-shun) A reduction in membrane potential from resting potential; movement of the potential from resting toward 0 mV (p. 58)

depolarization block A prolonged depolarization of the diaphragm, resulting in respiratory paralysis; occurs when the voltage-gated Na^+ channels are trapped in an inactivated state, thereby prohibiting the initiation of new action potentials and resultant contraction of the diaphragm; results in the inability to breathe (p. 199)

depression A mental disorder associated with defects in limbic system neurotransmitters, specifically, a functional deficiency of serotonin or norepinephrine or both; characterized by a pervasive negative mood accompanied by a generalized loss of interests, an inability to experience pleasure, and suicidal tendencies (p. 126)

depth perception The slight disparity in the information received from the two eyes allows the brain to estimate distance, which enables perception of three-dimensional objects in spatial depth; some depth perception possible using only one eye, based on experience and comparison with other cues (p. 167)

dermatome A specific region of the body surface that is supplied by a particular spinal nerve; concerns sensory input (p. 103)

dermis The connective tissue layer that lies under the epidermis in the skin; contains the skin's blood vessels and nerves (p. 461)

descending tracts Bundles of nerve fibres of similar function that travel down the spinal cord to relay messages from the brain to efferent neurons (p. 103)

desmosomes (dez'-muh-sōm) Adhering junctions between two adjacent, but nontouching, cells formed by the extension of filaments between the cells' plasma membranes; most abundant in tissues that are subject to considerable stretching (p. 34)

DHEA See *dehydroepiandrosterone*. (p. 258)

diabetes insipidus (in-SIP'-ud-us) An endocrine disorder characterized by a deficiency of vasopressin (p. 614)

diabetes mellitus (muh-LĪ-tus) An endocrine disorder characterized by inadequate insulin action (p. 275)

diacylglycerol (DAG) The product of PIP_2 breakdown, a component of the tails of the phospholipid molecules within the cell membrane itself (p. 219)

diaphragm (DIE-uh-fram) A dome-shaped sheet of skeletal muscle that forms the floor of the thoracic cavity; the major inspiratory muscle (p. 503)

diaphysis The fairly uniform cylindrical shaft of a long bone (p. 233)

diastole (di-AS-tō-lē) The period of cardiac relaxation and filling (p. 361)

diastolic pressure The lowest pressure during the resting phase of the cardiac cycle; the period of time when the heart fills with blood following systole (contraction), and thus the ventricles are relaxed (p. 391)

diencephalon (di'-un-SEF-uh-lan) The division of the brain that consists of the thalamus and hypothalamus (p. 112)

diffusion Random collisions and intermingling of molecules as a result of their continuous thermally induced random motion (p. 37)

digestion The breaking-down process whereby the structurally complex foodstuffs of the diet are converted into smaller absorbable units by the enzymes produced within the digestive system (p. 646)

diploid number (DIP-loid) A complete set of 46 chromosomes (23 pairs), as found in all human somatic cells (p. 727)

dipsogen A molecule that increases the urge to drink (p. 618)

dissociation constant, K The number that represents the proportion of molecules of a particular acid that separate to liberate free H^+ (p. 620)

distal tubule A highly convoluted tubule that extends between the loop of Henle and the collecting duct in the kidney's nephron (p. 564)

diurnal (circadian) rhythm (dī-URN'-ul) (sir-KĀ-dē-un) Oscillations in the set point of various body activities, such as hormone levels and body temperature, that are very regular and have a frequency of one cycle every 24 hours, usually linked to the light-dark cycle; also known as biological rhythm (p. 212)

divergence The diverging, or branching, of a neuron's axon terminals so that activity in this single neuron influences the many other cells with which its terminals synapse (p. 83)

docking marker A protein located at a specific destination within the cell where an appropriate vesicle can "dock" and "unload" its cargo (p. 31)

docking-marker acceptors A protein that binds lock-and-key fashion with the docking markers of secretory vesicles (p. 31)

dorsal (posterior) horn The posterior column of grey matter in the spinal cord when viewed in cross-section; receives several types of sensory information, including light touch, proprioception, and vibration (p. 103)

dorsal root Area where afferent fibres carrying incoming signals from peripheral receptors enter the spinal cord (p. 103)

dorsal root ganglion A cluster of afferent neuronal cell bodies located adjacent to the spinal cord (p. 103)

down regulation A reduction in the number of receptors for (and thereby the target cell's sensitivity to) a particular hormone as a direct result of the effect that an elevated level of the hormone has on its own receptors (p. 214)

dura mater A tough, inelastic covering consisting of two layers (*dura* means "tough") (p. 98)

dural sinuses The smaller of the two types of cavities that receive venous blood from the brain and from which the blood returns to the heart. The larger cavities are known as venous sinuses. (p. 98)

duration A continuance of length of time (p. 144)

dwarfism Hyposecretion of GH in a child is one cause of dwarfism, where the predominant feature is short stature caused by retarded skeletal growth. GH deficiency may be caused by a pituitary defect (lack of GH) or may occur secondary to hypothalamic dysfunctions (lack of GHRH). (p. 238)

dyslexia Stems from a deficit in phonological processing, meaning an impaired ability to break down written words into their underlying phonetic components. Dyslexics have difficulty decoding and thus identifying and assigning meaning to words. The condition is in no way related to intellectual ability. (p. 132)

E

ear A prominent skin-covered flap of cartilage; collects sound waves and channels them down the external ear canal. The ear consists of three parts: the *external*, the *middle*, and the *inner ear*. (p. 169)

ear canal A tube running from the outer ear to the middle ear; also called the external auditory meatus; (p. 172)

ECG See *electrocardiogram*. (p. 357)

EDV See *end-diastolic volume*. (p. 361)

EEG See *electroencephalogram*. (p. 357)

effector The component of the physiological system used to bring about the desired effect as determined by the control centre (p. 14)

effector organs The muscles or glands that are innervated by the nervous system and that carry out the nervous system's orders to bring about a desired effect, such as a particular movement or secretion (p. 92)

efferent division (EF-er-ent) The portion of the peripheral nervous system that carries instructions from the central nervous system to effector organs (p. 92)

efferent neurons Neurons that carry information from the central nervous system to an effector organ (p. 93)

efferent pathway Nerve pathways that carry nerve impulses away from the central nervous system to effectors such as muscles or glands (p. 106)

ejection fraction The fraction of blood pumped out of the ventricle with each heart beat (p. 370)

elastic recoil Rebound of the lungs after having been stretched (p. 508)

elastin A rubber-like protein fibre most abundant in tissues that must be capable of easily stretching and then recoiling after the stretching force is removed; found, for example, in the lungs, which stretch and recoil as air moves in and out (p. 34)

electrical gradient A difference in charge between two adjacent areas (p. 38)

electrocardiogram (ECG) The graphic record of the electrical activity that reaches the surface of the body as a result of cardiac depolarization and repolarization (p. 357)

electrochemical gradient The simultaneous existence of an electrical gradient and a concentration (chemical) gradient for a particular ion (p. 38)

electroencephalogram (EEG) (i-lek'-trō-in-SEF-uh-luh-gram') A graphic record of the collective postsynaptic potential activity in the cell bodies and dendrites located in the cortical layers under a recording electrode (p. 357)

electron transport chain Consists of electron carrier molecules located in the inner mitochondrial membrane lining the cristae. The high-energy electrons extracted from the hydrogens held in NADH and FADH₂ are transferred through a series of steps from one electron-carrier molecule to another, within the cristae membrane, in a kind of assembly line. (p. 27)

embolus (emboli, plural) (EM-bō-lus) A freely floating clot (p. 378)

emotion A complex experience involving biochemical and environmental processes within the limbic association cortex, which is located mostly on the bottom and adjoining inner portion of each temporal lobe (p. 124)

emphysema (em'-fuh-ZĒ-muh) A pulmonary disease characterized by collapse of the smaller airways and a breakdown of alveolar walls (p. 517)

end-diastolic volume (EDV) The volume of blood in the ventricle at the end of diastole, when filling is complete (p. 361)

endocrine glands Ductless glands that secrete hormones into the blood (p. 7)

endocrine system One of the body's two major regulatory systems; the other is the nervous system. Through its relatively slowly acting hormone messengers, the endocrine system generally regulates activities that require duration rather than speed. (p. 209)

endocrinology The study of the homeostatic chemical adjustments and other activities that hormones accomplish (p. 210)

endocytosis (en'-dō-sī-TŌ-sis) Internalization of extracellular material within a cell as a result of the plasma membrane forming a pouch that contains the extracellular material, then sealing at the surface of the pouch to form a small, intracellular, membrane-enclosed vesicle with the contents of the pouch trapped inside (p. 46)

endocytotic vesicle A vesicle within the cell that is formed during the process of endocytosis and contains substances being imported from outside the cell (p. 48)

endogenous pyrogen (EP) (pi'-ruh-jun) A chemical released from macrophages during inflammation that acts by means of local prostaglandins to raise the set point of the hypothalamic thermostat to produce a fever (p. 470)

endolymph The fluid within the cochlear duct (p. 172)

endometrium (en'-dō-MĒ-trĒ-um) The lining of the uterus (p. 753)

endothelium (en'-dō-THĒ-le-um) The thin, single-celled layer of epithelial cells that lines the entire circulatory system (p. 350)

end-plate potential (EPP) The graded receptor potential that occurs at the motor end plate of a skeletal muscle fibre in response to binding with acetylcholine (p. 197)

end-systolic volume (ESV) The volume of blood in the ventricle at the end of systole, when emptying is complete (p. 363)

enterogastrones (ent'-uh-rō-GAS-trōnz) Hormones secreted by the duodenal mucosa that inhibit gastric motility and secretion; include secretin and cholecystokinin (p. 659)

enterohepatic circulation (en'-tur-ō-hi-PAT-ik) The recycling of bile salts and other bile constituents between the small intestine and liver by means of the hepatic portal vein (p. 673)

entrained To pull along after itself (p. 212)

eosinophils (ē'-uh-SIN-uh-fils) White blood cells that are important in allergic responses and in combating internal parasite infestations (p. 446)

ependymal cells Cells that line the internal, fluid-filled cavities of the CNS (p. 98)

epidermis (ep'-uh-DER-mus) The outer layer of the skin, consisting of numerous layers of epithelial cells, with the outermost layers being dead and flattened (p. 461)

epilepsy A neurological disorder characterized by seizures (p. 120)

epinephrine (adrenaline) (ep'-uh-NEF-rin) The primary hormone secreted by the adrenal medulla; important in preparing the body for fight-or-flight responses and in regulating arterial blood pressure; also known as adrenaline (p. 192)

epiphyseal plate (eh-pif-i-SEE-al) A layer of cartilage that separates the diaphysis (shaft) of a long bone from the epiphysis (flared end); the site of growth of bones in length before the cartilage ossifies (turns into bone) (p. 233)

epiphysis The flared articulating knob at either end of a long bone (p. 233)

epithelial tissue (ep'-uh-THĒ-lē-ul) A functional grouping of cells specialized in the exchange of materials between the cell and its environment; lines and covers various body surfaces and cavities and forms secretory glands (p. 6)

EPSP See *excitatory postsynaptic potential*. (p. 76)

equilibrium potential The membrane voltage at which there is no net movement of a particular ion across the membrane (p. 55)

erythrocytes (red blood cells or RBCs) (i-RITH-ruh-sits) Red blood cells, which are plasma membrane-enclosed bags of haemoglobin that transport oxygen and, to a lesser extent, carbon dioxide and hydrogen ions in the blood (p. 436)

erythropoiesis (i-rith'-rō-poi-Ē-sus) Erythrocyte production by the bone marrow (p. 437)

erythropoietin (EPO) The hormone released from the kidneys in response to a reduction in O₂ delivery to the kidneys; stimulates the bone marrow to increase erythrocyte production (p. 438)

esophagus (i-SOF-uh-gus) A straight muscular tube that extends between the pharynx and stomach (p. 501)

estrogen Feminizing, female sex hormone (p. 724)

ESV See *end-systolic volume*. (p. 363)

eustachian (auditory) tube Connects the middle ear to the pharynx; exposes the inside of the ear drum facing the middle ear cavity to atmospheric pressure (p. 172)

excitable tissues Tissues capable of producing electrical signals when excited; include nervous and muscle tissue (p. 57)

excitation-contraction coupling The series of events linking muscle excitation (the presence of an action potential) to muscle contraction (filament sliding and sarcomere shortening) (p. 303)

excitatory postsynaptic potential (EPSP) (pöst'-si-NAP-tik) A small depolarization of the postsynaptic membrane in response to neurotransmitter binding, bringing the membrane closer to threshold (p. 76)

excitatory synapse (SIN-aps') Synapse in which the postsynaptic neuron's response to neurotransmitter release is a small depolarization of the postsynaptic membrane, bringing the membrane closer to threshold (p. 76)

exocrine glands Glands that secrete through ducts to the outside of the body or into a cavity that communicates with the outside (p. 7)

exocytosis (eks'-ō-sī-TŌ-sis) Fusion of a membrane-enclosed intracellular vesicle with the plasma membrane, followed by the opening of the vesicle and the emptying of its contents to the outside (p. 46)

expiratory muscles The skeletal muscles whose contraction reduces the size of the thoracic cavity and lets the lungs recoil to a smaller size, bringing about movement of air from the lungs to the atmosphere (p. 513)

expiratory reserve volume (ERV) The amount of additional air that can be breathed out after the end-expiratory level of normal breathing; if

a person exhales as much as possible, only the residual volume remains (p. 518)

external eye muscles A set of six external eye muscles, for each eye, that position and move the eye so that it can better locate, see, and track objects. Eye movements are among the fastest, most discretely controlled movements of the body. (p. 169)

external intercostal muscles Inspiratory muscles whose contraction elevates the ribs, thereby enlarging the thoracic cavity (p. 504)

external work Energy expended by contracting skeletal muscles to move external objects or to move the body in relation to the environment (p. 700)

extracellular fluid (ECF) All the body's fluid outside the cells; consists of interstitial fluid and plasma (p. 9)

extracellular matrix (ECM) An intricate meshwork of fibrous proteins embedded in a watery, gel-like substance; secreted by local cells (p. 34)

extrafusal fibres Class of muscle fibre innervated by alpha motor neurons (p. 325)

extrinsic controls Regulatory mechanisms initiated outside an organ that alter the activity of the organ; accomplished by the nervous and endocrine systems (p. 14)

extrinsic nerves The nerves that originate outside the digestive tract and innervate the various digestive organs (p. 651)

eye A sense organ that enables vision by reacting to light; rod and cone cells within the retina allow vision (p. 191)

eyelashes Protection for the eyes that trap fine, airborne debris, such as dust, before it can fall into the eye (p. 153)

eyelids Act like shutters to protect the anterior portion of the eye from environmental insults; close reflexly to cover the eye under threatening circumstances, such as rapidly approaching objects, dazzling light, and instances when the exposed surface of the eye or eyelashes are touched (p. 152)

F

facilitated diffusion Passive carrier-mediated transport involving transport of a substance down its concentration gradient across the plasma membrane (p. 43)

fasted (postabsorptive) state The metabolic state after a meal is absorbed during which endogenous energy stores must be mobilized and glucose must be spared for the glucose-dependent brain; fasting state (p. 270)

fast pain Pain that's easily localized and typically perceived initially as a brief, sharp, prickling sensation. The fast pain pathway originates from specific mechanical or heat nociceptors. (p. 149)

fatigue Inability to maintain muscle tension at a given level despite sustained stimulation (p. 310)

feedback Responses made after a change has been detected (p. 14)

feedforward A response designed to prevent an anticipated change in a controlled variable (p. 14)

feeding or appetite signals Appetite signals that give rise to the sensation of hunger and promote the desire to eat (p. 703)

fibrinogen (fi-BRIN-uh-jun) A large, soluble plasma protein converted into an insoluble, thread-like molecule that forms the meshwork of a clot during blood coagulation (p. 435)

fibronectin Protein fibres that promote cell adhesion and hold cells in position (p. 34)

Fick's law of diffusion The rate of net diffusion of a substance across a membrane is directly proportional to the substance's concentration gradient, the membrane's permeability to the substance, and the surface area of the membrane and inversely proportional to the substance's molecular weight and the diffusion distance. (p. 527)

fight-or-flight response The changes in activity of the various organs innervated by the autonomic nervous system in response to sympathetic stimulation, which collectively prepare the body for strenuous physical activity in the face of an emergency or stressful situation, such as a physical threat from the environment (p. 191)

fire State of an excitable cell when it undergoes an action potential (p. 62)

first messenger An extracellular messenger, such as a hormone, that binds with a surface membrane receptor and activates an intracellular second messenger to carry out the desired cellular response (p. 53)

flavine adenine dinucleotide (FAD) Redox cofactor involved in several important metabolic reactions (p. 26)

fluid mosaic model A model of membrane structure, in which the lipid bilayer is embedded with membrane proteins (p. 30)

follicular cells [of ovary] (fah-LIK-you-lar) Collectively, the granulosa and thecal cells (p. 248)

follicular cells [of thyroid gland] The cells that form the walls of the colloid-filled follicles in the thyroid gland and secrete thyroid hormone (p. 248)

forced or active expiration Emptying of the lungs more completely than when at rest by contracting the expiratory muscles; also called *forced expiration* (p. 513)

fovea The small central pit in the retina with a high density of cones (p. 158)

Frank-Starling law of the heart Intrinsic control of the heart such that increased venous return resulting in increased end-diastolic volume leads to an increased strength of contraction and increased stroke volume—that is, the heart normally pumps out all the blood returned to it (p. 368)

free radicals Very unstable electron-deficient particles that are highly reactive and destructive (p. 114)

frontal lobes The lobes of the cerebral cortex that lie at the top of the brain in front of the central sulcus and that are responsible for voluntary motor output, speaking ability, and elaboration of thought (p. 115)

FSH See *follicle-stimulating hormone*. (p. 227)

functional residual capacity (FRC) Volume of air present in the lungs at the end of passive expiration (p. 518)

functional syncytium (sin-sish'-ē-um) A group of smooth or cardiac muscle cells that are interconnected by gap junctions and function electrically and mechanically as a single unit (p. 328)

functional unit The smallest component of an organ that can perform all the functions of the organ (p. 300)

G

gametes (reproductive or germ cells) (GAM-ētz) Reproductive, or germ, cells, each containing a haploid set of chromosomes; sperm and ova (p. 724)

gamma (γ) globulins Antibody proteins produced by the immune system to identify and destroy foreign objects; also called immunoglobulins (im'-ū-nō-GLOB-yū-lunz) (p. 435)

gamma motor neuron A motor neuron that innervates the fibres of a muscle spindle receptor (p. 325)

ganglion cells The nerve cells in the outermost layer of the retina and whose axons form the optic nerve (p. 157)

gap junction A communicating junction formed between adjacent cells by small connecting tunnels that permit passage of charge-carrying ions between the cells, so that electrical activity in one cell is spread to the adjacent cell (p. 35)

gastrin A hormone secreted by the pyloric gland area of the stomach that stimulates the parietal and chief cells to secrete a highly acidic gastric juice (p. 664)

gated channels Channels that have gates that can alternately be open, permitting ion passage through them, or closed, preventing ion passage through them. The opening and closing of gates results from a change in the three-dimensional conformation (shape) of the protein that forms the gated channel, (p. 58)

gestation (pregnancy) The period during which an embryo develops in the uterus (p. 767)

gigantism A rapid growth in height without distortion of body proportions; occurs when overproduction of GH begins in childhood before the epiphyseal plates close (p. 238)

glands Epithelial tissue derivatives that are specialized for secretion (p. 6)

glial cells (glē-ul) Serve as the connective tissue of the CNS and help support the neurons both physically and metabolically; include astrocytes, oligodendrocytes, ependymal cells, and microglia (p. 95)

glomerular filtration (glow-MER-yū-lur) Filtration of a protein-free plasma from the glomerular capillaries into the tubular component of the kidney's nephron as the first step in urine formation (p. 568)

glomerular filtration rate (GFR) The rate at which glomerular filtrate is formed (p. 568)

glomeruli (*glomerulus*, singular) (glow-MER-yū-li) Ball-like tuft of capillaries in the kidney's nephron that filters water and solute from the blood as the first step in urine formation (p. 185)

glucagon (GLOO-kuh-gon) The pancreatic hormone that raises blood glucose and blood fatty-acid levels (p. 280)

glucagon-like peptide I (GLP-I) Gastrointestinal hormone involved in digestion; primarily secreted by intestinal L cells; subject of research as a potential treatment for diabetes mellitus. (p. 693)

glucocorticoids (gloo'-kō-KOR-ti-koidz) The adrenocortical hormones that are important in intermediary metabolism and in helping the body resist stress; primarily cortisol (p. 254)

gluconeogenesis (gloo'-kō-nē-ō-JEN-uh-sus) The conversion of amino acids into glucose (p. 256)

glycogen (GLI-kō-jen) The storage form of glucose in the liver and muscle (p. 646)

glycogenesis (gli'-kō-JEN-i-sus) The conversion of glucose into glycogen (p. 272)

glycogenolysis (gli'-kō-juh-NOL-i-sus) The conversion of glycogen to glucose (p. 262)

glycolysis (gli-KOL-uh-sus) A biochemical process that takes place in the cell's cytosol and involves the breakdown of glucose into two pyruvic acid molecules (p. 25)

GnRH See *gonadotropin-releasing hormone*. (p. 738)

Golgi tendon organs Proprioceptive sensor receptor organ located at the insertion of skeletal muscle fibres into the skeletal muscle (p. 326)

gonadotropin-releasing hormone (GnRH) (gō-nad'-uh-TRŌ-pin) The hypothalamic hormone that stimulates the release of FSH and LH from the anterior pituitary (p. 738)

gonadotropins FSH and LH; hormones that are tropic to the gonads (p. 227)

G protein A membrane-bound intermediary, which, when activated on binding of an extracellular first messenger to a surface receptor, activates the enzyme adenylyl cyclase on the intracellular side of the membrane in the cAMP second-messenger system (p. 217)

graded potentials Local change in membrane potential that occurs in varying grades of magnitude; serves as a short-distance signal in excitable tissues (p. 59)

grand postsynaptic potential (GPSP) Spatial or temporal summation of many small potentials; dictated by the rates of firing of many presynaptic neurons that jointly control the (grand) membrane potential in the body of a single postsynaptic cell. (p. 78)

granular cells Pericytes modified to become secretory cells; also called juxtaglomerular cells; contain large quantities of secretory vesicles that contain renin (p. 570)

granulocytes (gran'-yuh-lō-sits) Leukocytes that contain granules, including neutrophils, eosinophils, and basophils (p. 446)

granulosa cells (gran'-yuh-LO-suh) The layer of cells immediately surrounding a developing oocyte within an ovarian follicle (p. 745)

grey matter The portion of the central nervous system composed primarily of densely packaged neuronal cell bodies and dendrites (p. 102)

growth hormone (GH, somatotropin) An anterior pituitary hormone primarily responsible for regulating overall body growth and also important in intermediary metabolism (p. 227)

growth hormone-releasing hormone (GHRH) Regulatory hormone that stimulates growth hormone secretion; one of two antagonistic hormones from the hypothalamus involved in controlling growth hormone secretion. (p. 227)

guanosine diphosphate (GDP) A nucleotide sugar that is a substrate for glycosyltransferase reaction in metabolism (p. 27)

guanosine triphosphate (GTP) A high-energy molecule (similar to ATP) whose energy is transferred to ATP (p. 27)

gustation The sensation of taste (p. 181)

H

habituation A decreased responsiveness to repetitive presentations of an indifferent stimulus—that is, one that's neither rewarding nor punishing (p. 128)

haematocrit (hi-MAT'-uh-krit) The percentage of blood volume occupied by erythrocytes when they are packed down in a centrifuged blood sample (p. 434)

haemoglobin (Hb) (hĕ-muh-glō'-bun) A large, iron-bearing protein molecule found within erythrocytes that binds with and transports most oxygen in the blood; also carries some of the carbon dioxide and hydrogen ions in the blood (p. 27)

haemolysis (hĕ-MOL-uh-sus) Rupture of red blood cells (p. 441)

haemostasis (hĕ'-mō-STĀ-sus) The stopping of bleeding from an injured vessel (p. 448)

haploid number (HAP-loid) The number of chromosomes found in gametes; a half set of chromosomes, one member of each pair, for a total of 23 chromosomes in humans (p. 727)

Hb See *haemoglobin*. (p. 27)

hCG See *human chorionic gonadotropin*. (p. 763)

hearing The sense by which sound is perceived (p. 169)

heart failure An inability of the cardiac output to keep pace with the body's demands for supplies and for removal of wastes (p. 371)

helper T cells The population of T cells that enhances the activity of other immune-response effector cells; also called *CD4 cells* (p. 482)

Henderson-Hasselbalch equation The mathematical relationship between $[H^+]$ and the members of a buffer pair (p. 625)

hepatic portal system (hi-PAT-ik) A complex vascular connection between the digestive tract and liver, such that venous blood from the digestive system drains into the liver for processing of absorbed nutrients before being returned to the heart (p. 671)

hippocampus (hip-oh-CAM-pus) The elongated, medial portion of the temporal lobe that is a part of the limbic system and crucial for forming long-term memories (p. 128)

histamine A chemical released from mast cells or basophils that brings about vasodilation and increased capillary permeability; important in allergic responses and inflammation (p. 664)

homeostasis (hō'-mē-ō-STĀ-sus) The maintenance by the highly coordinated, regulated actions of the body systems of relatively stable chemical and physical conditions in the internal fluid environment that bathes the body's cells (p. 9)

homeostatic drives The subjective urges associated with specific bodily needs that motivate appropriate behaviour to satisfy those needs (p. 125)

hormone response element (HRE) The specific attachment site on DNA for a given steroid hormone and its nuclear receptor (p. 221)

hormones Long-distance chemical mediators secreted by an endocrine gland into the blood, which transports them to their target cells (p. 52)

host cell A body cell infected by a virus (p. 460)

HRE See *hormone response element*. (p. 221)

human chorionic gonadotropin (hCG) (kō-rĕ-ON-ik gō-nad'-uh-TRŌ-pin) A hormone secreted by the developing placenta that stimulates and maintains the corpus luteum of pregnancy (p. 763)

human physiology (fiz-ē-OL-ō-gē) The study of body functions (p. 3)

hydrocephalus A condition in which there is an abnormal accumulation of cerebrospinal fluid (p. 100)

hydrolysis (hĭ-DROL-uh-sis) The digestion of a nutrient molecule by the addition of water at a bond site (p. 647)

hydrophilic "Water loving"; substances that can interact with water molecules. Phospholipids have hydrophilic, polar (electrically charged) heads, containing a negatively charged phosphate group; the polar heads line up on the outsides of a lipid bilayer. (p. 29)

hydrophilic hormones Hormones that bind with surface membrane receptors and thereby trigger a chain of intracellular events by means of a second-messenger system that ultimately alters pre-existing cell proteins, usually enzymes, which exert the effect leading to the target cell's response to the hormone (p. 214)

hydrophobic "Water fearing"; substances that will not mix with water. The hydrophobic tails of the molecules in a lipid bilayer bury themselves in the centre away from the water, whereas the hydrophilic heads line up on both sides of the lipid bilayer, in contact with the water (p. 29)

hydrostatic (fluid) pressure (hĭ-dro-STAT-ik) The pressure exerted by fluid on the walls that contain it (p. 39)

hypercapnia A condition in which there is too much carbon dioxide in the blood (p. 540)

hyperopia Condition in which the eyeball is too short or the lens is too weak. Far objects are focused by accommodation, whereas near objects are focused behind the retina. (p. 157)

hyperplasia (hĭ-pur-PLĀ-zē-uh) An increase in the number of cells (p. 233)

hyperpnea Abnormally deep or rapid breathing (p. 540)

hyperpolarization An increase in membrane potential from resting potential; potential becomes even more negative than at resting potential (p. 62)

hypersecretion Too much of a particular hormone secreted (p. 213)

hypertension (hĭ'-pur-TEN-chun) Sustained, above-normal mean arterial blood pressure (p. 424)

hypertonicity The excessive concentration of solutes in the extracellular fluid compartment (p. 614)

hypertonic solution (hĭ-pur-TON-ik) A solution having an osmolarity greater than that of normal body fluids; more concentrated than normal (p. 41)

hypertrophy (hĭ-PUR-truh-fē) Increase in the size of an organ as a result of an increase in the size of its cells (p. 233)

hyperventilation Overbreathing; rate of ventilation in excess of the body's metabolic needs for CO_2 removal (p. 540)

hypophysiologic hormones (hi-PO-fiz-e-oh-) Hormones secreted by the hypothalamus that regulate the secretion of anterior pituitary hormones; see also *releasing hormone* and *inhibiting hormone* (p. 229)

hyposecretion Too little of a particular hormone secreted (p. 213)

hypotension (hĭ-pō-TEN-chun) Sustained, below-normal mean arterial blood pressure (p. 424)

hypothalamic-hypophyseal portal system (hĭ-pō-thuh-LAM-ik hĭ-pō-FIZ-ē-ul) The vascular connection between the hypothalamus and anterior pituitary gland used for the pickup and delivery of hypophysiologic hormones (p. 229)

hypothalamic osmoreceptors The specialized sensory receptor located near the vasopressin-secreting cells and thirst centre; the predominant excitatory input for both vasopressin secretion and thirst (p. 617)

hypothalamus (hĭ'-pō-THAL-uh-mus) The brain region located beneath the thalamus that is concerned with regulating many aspects of the internal fluid environment, such as water and salt balance and food intake; serves as an important link between the autonomic nervous system and endocrine system (p. 113)

hypotonicity A lower than normal concentration of solutes in the extracellular fluid compartment, often associated with an excess of free (p. 614)

hypotonic solution (hĭ'-pō-TON-ik) A solution having an osmolarity less than that of normal body fluids; more dilute than normal (p. 41)

hypoventilation Underbreathing; ventilation inadequate to meet the metabolic needs for O_2 delivery and CO_2 removal (p. 540)

hypoxia (hĭ-POK-sē-uh) Insufficient oxygen at the cellular level (p. 539)

iatrogenic A condition that arises as a result of medical intervention (p. 614)

I band One of the light bands that alternate with dark (A) bands to create a striated appearance in a skeletal or cardiac muscle fibre when these fibres are viewed with a light microscope (p. 300)

insensible loss The elimination of water from the body that a person has no sensory awareness of, for example, from the lungs and nonsweating skin (p. 616)

IGF-I A protein hormone similar to insulin (hence the name) (p. 235)

IGF-II A growth-promoting hormone that promotes the growth of bone and soft tissues (p. 235)

immediate early genes (IEGs) Genes that play a critical role in memory consolidation, governing the synthesis of the proteins that encode long-term memory (p. 132)

immune surveillance Recognition and destruction of newly arisen cancer cells by the immune system (p. 489)

immunity The body's ability to resist or eliminate potentially harmful foreign materials or abnormal cells (p. 444)

impermeable Prohibiting passage of a particular substance through the plasma membrane (p. 36)

implantation The burrowing of a blastocyst into the endometrial lining (p. 758)

inflammation An innate, nonspecific series of highly interrelated events, especially involving neutrophils, macrophages, and local vascular changes, that are set into motion in response to foreign invasion or tissue damage (p. 466)

inhibin (in-HIB-un) A hormone secreted by the Sertoli cells of the testes or by the ovarian follicles that inhibits FSH secretion (p. 738)

inhibiting hormones Hypothalamic hormone that inhibits the secretion of a particular anterior pituitary hormone (p. 229)

inhibitory postsynaptic potential (IPSP) (pōst'-si-NAP-tik) A small hyperpolarization of the postsynaptic membrane in response to neurotransmitter binding, thereby moving the membrane farther from threshold (p. 76)

inhibitory synapse (SIN-aps') Synapse in which the postsynaptic neuron's response to neurotransmitter release is a small hyperpolarization of the postsynaptic membrane, moving the membrane farther from threshold (p. 76)

innate immune system Inherent defence system that nonselectively defends against foreign or abnormal material, even on initial exposure to it; see also *inflammation*, *interferon*, *natural killer cells*, and *complement system* (p. 465)

innervate When a neuron terminates on a muscle or a gland, the neuron is said to innervate the structure. (p. 74)

inositol triphosphate (IP₃) A secondary messenger molecule involved in signal transduction (p. 219)

inspiration A breath in (p. 504)

inspiratory capacity (IC) The volume that can be inhaled after a tidal breath out (p. 518)

inspiratory muscles The skeletal muscles whose contraction enlarges the thoracic cavity, bringing about lung expansion and movement of air into the lungs from the atmosphere (p. 503)

insulin (IN-suh-lin) The pancreatic hormone that lowers blood levels of glucose, fatty acids, and amino acids and promotes their storage (p. 272)

insulin-like growth factor (IGF) See *somatomedins*. (p. 235)

integrating centre A region that determines efferent output based on the processing of afferent input (p. 106)

integrins Membrane proteins that serve as a structural link between the outer membrane surface and its extracellular surroundings and also connect the inner membrane surface to the intracellular cytoskeletal scaffolding (p. 32)

intercostal muscles (int-ur-KOS-tul) The muscles that lie between the ribs; see also *external intercostal muscles* and *internal intercostal muscles* (p. 504)

interferon (in'-tur-FĒR-on) A chemical released from virus-invaded cells that provides nonspecific resistance to viral infections by transiently interfering with replication of the same or unrelated viruses in other host cells (p. 471)

intermediary metabolism The collective set of intracellular chemical reactions that involve the degradation, synthesis, and transformation of small nutrient molecules; also known as fuel metabolism (p. 22)

internal environment The body's aqueous extracellular environment, which consists of the plasma and interstitial fluid and which must be homeostatically maintained for the cells to make life-sustaining exchanges with it (p. 9)

internal intercostal muscles Expiratory muscles whose contraction pulls the ribs downward and inward, thereby reducing the size of the thoracic cavity (p. 504)

internal (cellular) respiration The intracellular metabolic reactions and processes by which living organisms (cells) convert biochemical energy (e.g., glucose) from nutrients into adenosine triphosphate (ATP) for energy (p. 498)

internal work All forms of biological energy expenditure that do not accomplish mechanical work outside the body (p. 700)

interneurons Neurons that lie entirely within the central nervous system and are important for integrating peripheral responses to peripheral information as well as for the abstract phenomena associated with the human mind (p. 93)

interstitial cell-stimulating hormone (ICSH) In males, the hormone that stimulates the interstitial Leydig cells in the testes to secrete the male sex

hormone, testosterone, a chemical produced by the body that regulates the activity of certain cells or certain organs (p. 227)

interstitial fluid (in'-tur-STISH-ul) The portion of the extracellular fluid that surrounds and bathes all the body's cells (p. 10)

intracellular fluid (ICF) The fluid collectively contained within all the body's cells (p. 9)

intrinsic (local) controls Local control mechanisms inherent to an organ (p. 14)

intrinsic factor A special substance secreted by the parietal cells of the stomach that must be combined with vitamin B₁₂ for this vitamin to be absorbed by the intestine. Deficiency produces pernicious anaemia. (p. 664)

intrinsic nerve plexuses Interconnecting networks of nerve fibres within the digestive tract wall (p. 651)

ion concentration gradient A gradient that results from an unequal distribution of ions across the cell membrane; for example, an Na⁺ gradient (p. 44)

IPSP See *inhibitory postsynaptic potential*. (p. 76)

islets of Langerhans (LAHNG-er-honz) The endocrine portion of the pancreas that secretes the hormones insulin and glucagon into the blood (p. 271)

isometric contraction (i'-sō-MET-rik) A muscle contraction in which the development of tension occurs at constant muscle length (p. 315)

isotonic contraction A muscle contraction in which muscle tension remains constant as the muscle fibre changes length (p. 314)

isotonic solution (i'-sō-TON-ik) A solution having an osmolarity equal to that of normal body fluids (p. 40)

J

jet lag When one's inherent rhythm (dictated by the SCN and pineal gland) is out of step with external cues; typically a temporary disorder that causes fatigue, insomnia, and other symptoms as a result of flight across time zones; disrupts circadian rhythm, which disrupts sleep (p. 240)

juxtaglomerular apparatus (juks'-tuh-glō-MER-yū-lur) A cluster of specialized vascular and tubular cells at a point where the ascending limb of the loop of Henle passes through the fork formed by the afferent and efferent arterioles of the same nephron in the kidney (p. 563)

K

Krebs cycle Consists of a series of eight separate biochemical reactions directed by the enzymes of the mitochondrial matrix, a series of biochemical reactions (p. 25)

L

lacrimal gland The gland located in the upper lateral corner under the eyelid; produces tears to moisten and cleanse the eye (p. 153)

lactation Milk production by the mammary glands (p. 771)

language The method of human communication, either spoken or written, consisting of the use of words in a structured and conventional way; an excellent example of early cortical plasticity coupled with later permanence (p. 132)

Laron dwarfism Condition that involves abnormally short stature, despite normal levels of growth hormone, due to inability of tissues to respond

normally to growth hormone. This condition is in contrast with the more typical dwarfism that involves abnormally short stature due to growth hormone deficiency. (p. 238)

larynx (voice box) (LARE-inks) The structure at the entrance of the trachea that contains the vocal cords (p. 501)

lateral horn The lateral column of grey matter of the spinal cord when viewed in cross-section; involved with sympathetic activity of the autonomic nervous system (p. 103)

lateral inhibition The phenomenon in which the most strongly activated signal pathway originating from the centre of a stimulus area inhibits the less excited pathways from the fringe areas by means of lateral inhibitory connections within sensory pathways (p. 147)

lateral sacs The expanded saclike regions of a muscle fibre's sarcoplasmic reticulum; store and release calcium, which plays a key role in triggering muscle contraction (p. 304)

law of mass action If the concentration of one of the substances involved in a reversible reaction is increased, the reaction is driven toward the opposite side, and if the concentration of one of the substances is decreased, the reaction is driven toward that side. (p. 532)

leak channels Ion channels that are more frequently open than closed (p. 58)

learning The acquisition of knowledge or skills as a consequence of experience, instruction, or both. It is widely believed that rewards and punishments are integral parts of many types of learning. (p. 126)

left atrial volume receptors The receptors in the left atrium of the heart that monitor the pressure of blood flowing through the left atrium (p. 618)

left cerebral hemisphere Region of the brain that excels in logical, analytic, sequential, and verbal tasks, such as math, language forms, and philosophy (p. 134)

length-tension relationship The relationship between the length of a muscle fibre at the onset of contraction and the tension the fibre can achieve on a subsequent tetanic contraction (p. 312)

lens A transparent, biconvex structure of the eye that refracts (bends) light rays, and whose strength can be adjusted to accommodate for vision at different distances (p. 153)

leptin A hormone released from adipose tissue that plays a key role in long-term regulation of body weight, by acting on the hypothalamus to suppress appetite (p. 703)

leukocytes (white blood cells or WBCs) (LOO-kuh-sits) White blood cells, which are the immune system's mobile defence units (p. 444)

Leydig (interstitial) cells (LI-dig) The interstitial cells of the testes that secrete testosterone (p. 732)

LH See *luteinizing hormone*. (p. 227)

LH surge The burst in LH secretion that occurs at midcycle of the ovarian cycle and triggers ovulation (p. 750)

limbic association cortex Area of the brain located mostly on the bottom and adjoining inner portion of each temporal lobe; concerned primarily with motivation and emotion and extensively involved in memory (p. 134)

limbic system (LIM-bik) A functionally interconnected ring of forebrain structures that surrounds

the brain stem and is concerned with emotions, basic survival and sociosexual behavioural patterns, motivation, and learning (p. 124)

lipid bilayer A non-rigid plasma membrane structure made of two layers of lipid molecules. Lipid bilayers are flat sheets that form a continuous barrier around cells, and that surround the nucleus, organelles, and other subcellular structures. (p. 29)

lipid emulsion A suspension of small fat droplets held apart as a result of adsorption of bile salts on their surface (p. 673)

lipophilic hormones Hormones (steroids and thyroid hormone) that bind with intracellular receptors and primarily produce their effects in their target cells by activating specific genes to cause the synthesis of new enzymatic or structural proteins (p. 215)

long-term memory Capacity to process, codify, and store for the long-term informational aspects of memory along with other memories of the same type; a form of organization that facilitates future searching of memory stores to retrieve desired information (p. 126)

long-term potentiation (LTP) Molecular mechanism of short-term memory that involves a prolonged increase in the strength of existing synaptic connections in activated pathways following brief periods of repetitive stimulation (p. 130)

loop of Henle (HEN-lē) A hairpin loop that extends between the proximal and distal tubule of the kidney's nephron (p. 563)

lumen (LOO-men) The interior space of a hollow organ or tube (p. 6)

luteal phase (LOO-tē-ul) The phase of the ovarian cycle dominated by the presence of a corpus luteum (p. 747)

luteinization (loot' -ē-un-uh-ZĀ-shun) Formation of a postovulatory corpus luteum in the ovary (p. 749)

luteinizing hormone (LH) An anterior pituitary hormone that stimulates ovulation, luteinization, and secretion of estrogen and progesterone in females, and stimulates testosterone secretion in males (p. 227)

lymph Interstitial fluid that is picked up by the lymphatic vessels and returned to the venous system, meanwhile passing through the lymph nodes for defence purposes (p. 411)

lymphocytes White blood cells that provide immune defence against targets for which they are specifically programmed (p. 447)

lymphoid tissues Tissues that produce and store lymphocytes, such as lymph nodes and tonsils (p. 445)

M

macrophages (MAK-ruh-fĀjs) Large, tissue-bound phagocytes (p. 464)

major histocompatibility complex (MHC) molecules Major histocompatibility complex molecules are found on cell surfaces and mediate interactions with leukocytes; also called human leukocyte antigen (HLA) (p. 482)

mast cells Cells located within connective tissue that synthesize, store, and release histamine, as during allergic responses (p. 447)

mean arterial pressure The average pressure responsible for driving blood forward through the arteries into the tissues throughout the cardiac

cycle; equals cardiac output multiplied by total peripheral resistance (p. 394)

mechanically gated channels Channels that open or close in response to stretching or other mechanical deformation (p. 58)

mechanical nociceptors Pain receptors that respond to mechanical damage (p. 149)

mechanistic approach Explanation of body functions in terms of mechanisms of action—that is, the “how” of events that occur in the body (p. 4)

mechanoreceptors (meh-CAN-oh-rē-SEP-tur) or (mek' -uh-nō-rē-SEP-tur) A sensory receptor sensitive to mechanical energy, such as stretching or bending (p. 143)

medicine The art and science of healing (p. 3)

medullary respiratory centre (MED-you-LAIR-ē) Several aggregations of neuronal cell bodies within the medulla that provide output to the respiratory muscles and receive input important for regulating the magnitude of ventilation (p. 542)

meiosis (mī-ō-sis) Cell division in which the chromosomes replicate followed by two nuclear divisions so that only a half set of chromosomes is distributed to each of four new daughter cells (p. 727)

Meissner's corpuscles A type of mechanoreceptor located in the skin; responds to light touch and very sensitive to vibration. (p. 148)

melanin A pigment that is the primary determinant of skin colour; also found in hair, the pigmented tissue underlying the iris of the eye, and the stria vascularis of the inner ear. In the skin melanin is produced by melanocytes located in the basal layer of the epidermis. (p. 226)

melanocyte-stimulating hormone (MSH) (mel-AH-nō-sit) A hormone produced by the anterior pituitary in humans and by the intermediate lobe of the pituitary in lower vertebrates; regulates skin colouration by controlling the dispersion of melanin granules in lower vertebrates; involved with control of food intake and possibly memory and learning in humans (p. 226)

melanopsin A protein found in a special retinal ganglion cell; the receptor for light that keeps the body in tune with external time (p. 242)

melatonin (mel-uh-TŌ-nin) A hormone secreted by the pineal gland during darkness that helps entrain the body's biological rhythms with the external light/dark cues (p. 240)

membrane attack complex (MAC) A collection of the five, final, activated components of the complement system that aggregate to form a porelike channel in the plasma membrane of an invading microorganism, with the resultant leakage leading to destruction of the invader (p. 473)

membrane-bound enzymes Surface-located proteins that control specific chemical reactions at either the inner or the outer cell surface. Cells are specialized in the types of enzymes embedded within their plasma membranes. (p. 31)

membrane potential A separation of charges across the membrane; most often a slight excess of negative charges lined up along the inside of the plasma membrane and separated from a slight excess of positive charges on the outside (p. 54)

membrane proteins Proteins with unique combinations of sugar chains projecting from them that serve as the trademark of a particular cell type, enabling a cell to recognize others of its own kind (p. 30)

memory cells B or T cells that are newly produced in response to a microbial invader, but do not

participate in the current immune response against the invader; remain dormant, ready to launch a swift, powerful attack should the same microorganism invade again in the future (p. 479)

meninges The three membranes (dura mater, arachnoid, and pia mater) that line the skull and vertebral canal and enclose the brain and spinal cord (p. 98)

menstrual (uterine) cycle (men' -stroo-ul) The cyclic changes in the uterus that accompany the hormonal changes in the ovarian cycle (p. 753)

menstrual phase The phase of the menstrual cycle characterized by sloughing of endometrial debris and blood out through the vagina (p. 753)

Merkel's discs The most sensitive of the mechanoreceptors to low frequency vibrations (5–15 Hz), with a receptive field of about 2–3 mm; classified as slowly adapting type I myelinated mechanoreceptors, which provide touch information (p. 148)

metabolic acidosis (met-uh-bol' -ik) Acidosis resulting from any cause other than excess accumulation of carbonic acid in the body (p. 598)

metabolic alkalosis (al' -kuh-LŌ-sus) Alkalosis caused by a relative deficiency of noncarbonic acid (p. 635)

metabolic rate Energy expenditure per unit of time (p. 700)

metabolic water The H₂O produced as a result of biochemical reactions within the cells of the body (p. 616)

MHC molecules See *Major histocompatibility complex (MHC) molecules*. (p. 482)

micelle (mī-SEL) A water-soluble aggregation of bile salts, lecithin, and cholesterol that has a hydrophilic shell and a hydrophobic core; carries the water-insoluble products of fat digestion to their site of absorption (p. 674)

microglia The immune cells of the CNS; scavengers cells that are “cousins” of monocytes, a type of white blood cell that leaves the blood and sets up residence as a front-line (i.e., with innate immunity) defence agent in various tissues throughout the body (p. 97)

microvilli (mī' -krō-VIL-i) Actin-stiffened, non-motile, hairlike projections from the luminal surface of epithelial cells lining the digestive tract and kidney tubules; tremendously increase the surface area of the cell exposed to the lumen (p. 678)

micturition (urination) (mik-too-RISH-un) or (mik-chuh-RISH-un) The process of bladder emptying (p. 598)

middle ear The portion of the ear internal to the eardrum and external to the oval window of the cochlea (p. 172)

milk ejection (milk letdown) The squeezing out of milk produced and stored in the alveoli of the breasts by means of contraction of the myoepithelial cells that surround each alveolus (p. 771)

millivolt (mV) 1 millivolt = 1/1000 volt (p. 54)

mineralocorticoids (min-uh-rul-ō-KOR-ti-koidz) The adrenocortical hormones that are important in Na⁺ and K⁺ balance; primarily aldosterone (p. 254)

mitosis (mī-TŌ-sis) Cell division in which the chromosomes replicate before nuclear division so that each of the two daughter cells receives a full set of chromosomes (p. 727)

mitral cells Cells on which the olfactory receptors terminate in the glomeruli that refine the smell signals and relay them to the brain for further processing (p. 185)

modality Determined by the type of sensory neuron that's activated and its point of termination in the brain. (p. 143)

monocytes (MAH-nō-sits) White blood cells that emigrate from the blood, enlarge, and become macrophages; large-tissue phagocytes (p. 447)

monosaccharides (mah'-nō-SAK-uh-rīdz) Simple sugars, such as glucose; the absorbable unit of digested carbohydrates (p. 646)

monosynaptic reflex A reflex arc that contains only one synapse (p. 106)

motion sickness Sensitivity to particular motions that activate the vestibular apparatus and cause symptoms of dizziness and nausea (p. 180)

motivation The ability to direct behaviour toward specific goals, some of which are aimed at satisfying specific identifiable physical needs related to homeostasis (p. 125)

motor end plate The specialized portion of a skeletal muscle fibre that lies immediately underneath the terminal button of the motor neuron and possesses receptor sites for binding acetylcholine released from the terminal button (p. 197)

motor homunculus Visual representation of the connection between different body parts and the areas in brain hemispheres responsible for movement within those body parts (p. 116)

motor neurons The neurons that innervate skeletal muscle and whose axons constitute the somatic nervous system (p. 194)

motor program The different, related functions carried out by the three higher motor areas of the cortex and the cerebellum; important in programming and coordinating complex movements involving simultaneous contraction of many muscles; includes signals transmitted through efferent and afferent pathways that allow the central nervous system to anticipate and plan movement (p. 119)

motor unit One motor neuron plus all the muscle fibres it innervates (p. 310)

motor unit recruitment The progressive activation of a muscle fibre's motor units to accomplish increasing gradations of contractile strength (p. 310)

mucosa (mew-KŌ-sah) The innermost layer of the digestive tract that lines the lumen (p. 184)

multiunit smooth muscle A smooth muscle mass that consists of multiple discrete units that function independently of one another and that must be separately stimulated by autonomic nerves to contract (p. 328)

muscarinic receptors (MUS-ka-rin'-ik) Type of cholinergic receptors found at the effector organs of all parasympathetic postganglionic fibres (p. 192)

muscle biopsy Procedure in which a piece of muscle tissue is removed with the use of a needle for the purpose of examination (p. 318)

muscle fibre A single muscle cell, which is relatively long and cylindrical in shape (p. 197)

muscle spindles Sensory receptors within the belly of a muscle; primarily detect changes in the length of the muscle, which is sent by sensory neurons to the central nervous system (p. 325)

muscle tissue A functional grouping of cells specialized for contraction and force generation (p. 6)

muscular dystrophy A degenerative disease in which muscles get progressively weaker (p. 321)

myasthenia gravis A disease involving the neuromuscular junction, characterized by extreme muscular weakness; an autoimmune condition in which the body erroneously produces antibodies against its own motor-end-plate ACh receptors (p. 201)

myelin (MĪ-uh-lun) An insulative lipid covering that surrounds myelinated nerve fibres at regular intervals along the axon's length (p. 70)

myelinated fibres Neuronal axons covered at regular intervals with insulative myelin (p. 70)

myoblast Undifferentiated cell in the mesoderm of the embryo; precursor of a muscle cell (p. 22)

myocardial ischemia (mī-ō-KAR-dē-ul is-KĒ-mē-uh) Inadequate blood supply to the heart tissue (p. 360)

myocardium (mī'-ō-KAR-dē-um) The cardiac muscle within the heart wall (p. 350)

myofibrils (mī'-ō-FĪ-B-rul) Specialized intracellular structures of muscle cells that contain the contractile apparatus (p. 298)

myoglobin Iron-containing protein found in muscle fibres; structurally similar to haemoglobin but having a higher affinity for oxygen than blood haemoglobin (p. 318)

myometrium (mī'-ō-mē-TRĒ-um) The smooth muscle layer of the uterus (p. 753)

myosin (MĪ-uh-sun) The contractile protein that forms the thick filaments in muscle fibres (p. 300)

myopia Condition in which the eyeball is too long or the lens is too strong. A near light source is focused on the retina without accommodation (even though accommodation is normally used for near vision), whereas a far light source is focused in front of the retina and is blurry. (p. 157)

N

pump See $\text{Na}^+ - \text{K}^+$ ATPase pump. (p. 44)

ATPase pump A carrier that actively transports Na^+ out of the cell and K^+ into the cell; also known as $\text{Na}^+ - \text{K}^+$ ATPase pump (p. 44)

Na^+ load The total mass of Na^+ salts in the ECF

Na^+ permeability (P_{Na^+}) The relative ability for Na^+ diffusing down its chemical gradient from a higher concentration outside the cell to a lower concentration inside the cell. During an action potential, once threshold is met, enough Na^+ gates have opened to allow a significant influx of Na^+ into the cell. (p. 63)

natural killer (NK) cells Naturally occurring, lymphocyte-like cells that nonspecifically destroy virus-infected cells and cancer cells by directly lysing their membranes on first exposure to them (p. 472)

negative balance Situation in which the losses for a substance exceed its gains, so that the total amount of the substance in the body decreases (p. 608)

negative feedback A regulatory mechanism in which a change in a controlled variable triggers a response that opposes the change, thus maintaining a relatively steady set point for the regulated factor (p. 14)

neostigmine A medication in the category of anticholinesterases; prolongs the action of acetylcholine, found naturally in the body (p. 201)

nerve A bundle of peripheral neuronal axons, some afferent and some efferent, enclosed by a connective tissue covering and following the same pathway (p. 103)

nervous system One of the two major regulatory systems of the body; in general, coordinates rapid

activities of the body, especially those involving interactions with the external environment (p. 91)

nervous tissue A functional grouping of cells specialized for initiation and transmission of electrical signals (p. 6)

net diffusion The difference between two opposing movements (p. 37)

net filtration pressure The net difference in the hydrostatic and osmotic forces acting across the glomerular membrane that favours the filtration of a protein-free plasma into Bowman's capsule (p. 568)

neuroendocrine reflexes Cells that receive neuronal input (neurotransmitters released by nerve cells) and, as a result, release message hormones to the blood for communication (p. 212)

neuroendocrinology The study of the interactions between the nervous system and the endocrine system (p. 222)

neuroglia See *glial cells*. (p. 95)

neuroglobin An oxygen-binding protein in the brain (p. 101)

neurohormone A substance released by a neurosecretory cell directly into the blood that functions as a hormone; generally structurally identical to neurotransmitters (p. 53)

neurohypophysis An alternative name for the posterior pituitary, which is composed of nervous tissue (p. 225)

neuromodulators (ner'ō-MA-jew-lā'-torz) Chemical messengers that bind to neuronal receptors at nonsynaptic sites (i.e., not at the subsynaptic membrane), and bring about long-term changes that subtly depress or enhance synaptic effectiveness (p. 80)

neuromuscular junction The juncture between a motor neuron and a skeletal muscle fibre (p. 197)

neuron (NER-on) A nerve cell, typically consisting of a cell body, dendrites, and an axon and specialized to initiate, propagate, and transmit electrical signals (p. 64)

neuropeptides Large, slowly acting peptide molecules released from axon terminals along with classical neurotransmitters; most neuropeptides function as neuromodulators (p. 80)

neurotransmitters Chemical messengers released from the axon terminal of a neuron in response to an action potential; influence another neuron or an effector with which the neuron is anatomically linked (p. 80)

neutrophils (new'-truh-filz) White blood cells that are phagocytic specialists and important in inflammatory responses and defence against bacterial invasion (p. 446)

nicotinamide adenine dinucleotide (NAD⁺) Coenzyme found in all living cells; involved in metabolism, carrying electrons from one reaction to another (p. 26)

nicotinic receptors (nick'-o-TIN-ik) Type of cholinergic receptors found at all autonomic ganglia and the motor end plates of skeletal muscle fibres (p. 192)

night blindness Condition of sight related to dietary deficiency of vitamin A; reduced photopigment concentrations in both rods and cones, although sufficient cone photopigment exists to allow response to the intense stimulation of bright light, except in the most severe cases (p. 165)

nitric oxide A recently identified local chemical mediator released from endothelial cells and other

tissues; exerts a wide array of effects, which include causing local arteriolar vasodilation, acting as a toxic agent against foreign invaders, and serving as a unique type of neurotransmitter (p. 130)

NMDA receptors A glutamate receptor, the predominant molecular device for controlling synaptic plasticity and memory function (p. 114)

nociceptor (nō-sē-SEP-tur) A pain receptor, sensitive to tissue damage (p. 149)

nodes of Ranvier (RAN-vē-ā) The portions of a myelinated neuronal axon between the segments of insulative myelin; the axonal regions where the axonal membrane is exposed to the ECF and membrane potential exists (p. 70)

noradrenaline Chemically very similar to *adrenaline* (*epinephrine*), the primary hormone product secreted by the adrenal medulla gland (p. 188)

norepinephrine (nor'-ep-uh-NEF-run) The neurotransmitter released from sympathetic postganglionic fibres; noradrenaline (p. 188)

nucleus [of cells] A distinct spherical or oval structure that is usually located near the centre of a cell and that contains the cell's genetic material, deoxyribonucleic acid (DNA) (p. 22)

nursing A healthcare profession that works collaboratively with other healthcare professionals for the care of an individual (p. 3)

O

obligatory loss The loss of a substance from the body that cannot be avoided by any control mechanisms (p. 612)

O₂-Hb dissociation curve A graphic depiction of the relationship between arterial P_{O₂} and percent haemoglobin saturation (p. 532)

occipital lobes (ok-SIP'-ut-ul) The lobes of the cerebral cortex that are located posteriorly and that initially process visual input (p. 115)

odourants Molecules that yield odours or fragrance and that act through second-messenger systems to trigger receptor potentials. The afferent signals arising from the olfactory receptors are sorted according to scent component by the glomeruli within the olfactory bulb. (p. 184)

oedema (i-DE-muh) Swelling of tissues as a result of excess interstitial fluid (p. 413)

off response Situation in which the receptor rapidly adapts by no longer responding to a maintained stimulus, but typically responds with a slight depolarization when the stimulus is removed (p. 145)

olfaction The sense of smell (p. 181)

olfactory bulb A complex neural structure containing several different layers of cells that are functionally similar to the retinal layers of the eye; two olfactory bulbs, one on each side of the head, are about the size of small grapes (p. 185)

olfactory mucosa A 3 cm² patch of mucosa in the ceiling of the nasal cavity; contains three cell types: *olfactory receptor cells*, *supporting cells*, and *basal cells* (p. 184)

olfactory nerve The axons of the olfactory receptor cells collectively form the olfactory nerve (p. 184)

olfactory receptor cell An afferent neuron whose receptor portion lies in the olfactory mucosa in the nose and whose afferent axon traverses into the brain (p. 184)

oligodendrocytes (ol-i-gō'-DEN-drō-sitz) The myelin-forming cells of the central nervous system (p. 70)

on-centre and off-centre ganglion cells Ganglion cells that respond in opposite ways, depending on the relative illumination of the centre and the periphery of their receptive fields (p. 166)

opiate receptors A type of protein found in the central nervous system and the gastrointestinal tract. Opiates activate pain relief and stimulate pleasure centres of the brain. (p. 150)

opsin A group of light-sensitive membrane-bound proteins found in photoreceptor cells of the retina (p. 161)

opsonins (OP'-suh-nuns) Body-produced chemical that links bacteria to macrophages, thereby making the bacteria more susceptible to phagocytosis (p. 469)

optic chiasm Area beneath the hypothalamus where the optic fibres from the medial half of each retina cross to the opposite side, and those from the lateral half remain on the original side (p. 166)

optic disc The point on the retina at which the optic nerve leaves and through which blood vessels pass; the region often called the blind spot since it has no rods and cones and no image can be detected in this area (p. 158)

optic nerve The bundle of nerve fibres that leave the retina, relaying information about visual input (p. 158)

optic radiations Fibre bundles that relay information received from the lateral geniculate nucleus in the thalamus to different zones in the cortex, each of which processes different aspects of the visual stimulus (e.g., colour, form, depth, movement) (p. 167)

optimal length (lo) The length before the onset of contraction of a muscle fibre at which maximal force can be developed on a subsequent tetanic contraction (p. 312)

organ of Corti (KOR-tē) The sense organ of hearing within the inner ear; contains hair cells whose hairs are bent in response to sound waves, setting up action potentials in the auditory nerve (p. 173)

organophosphates A group of chemicals that modify neuromuscular junction activity by irreversibly inhibiting AChE, which prevents the inactivation of released ACh (p. 200)

organism A living entity, either single celled (unicellular) or made up of many cells (multicellular) (p. 5)

organs Distinct structural units composed of two or more types of primary tissue organized to perform one or more particular functions; for example, the stomach (p. 7)

osmolarity (oz'-mō-LAR-ut-ē) A measure of the concentration of solute molecules in a solution (p. 613)

osmosis (os-MO-sis) Movement of water across a membrane down its own concentration gradient toward the area of higher solute concentration (p. 38)

osmotic pressure A measure of the tendency for water to move into a solution because of its relative concentration of nonpenetrating solutes and water. Net movement of water continues until the opposing hydrostatic pressure exactly counterbalances the osmotic pressure. (p. 40)

ossification The natural process of bone formation; the hardening or calcification of soft tissue into a bonelike material (p. 233)

osteoblasts (OS-tē-ō-blasts') Bone cells that produce the organic matrix of bone (p. 233)

osteoclasts Bone cells that dissolve bone in their vicinity (p. 233)

osteocytes Osteoblasts that retire from active bone-forming duty, because their imprisonment prevents them from laying down new bone; also involved in the hormonally regulated exchange of calcium between bone and the blood (p. 233)

osteoporosis A disease of bone that leads to an increased risk of fracture (p. 286)

outer hair cells Sound receptor cells found in the organ of Corti. The 16 000 hair cells within each cochlea are arranged in four parallel rows along the length of the basilar membrane: one row of inner hair cells, and three rows of outer hair cells. (p. 173)

oval window The membrane-covered opening that separates the air-filled middle ear from the upper compartment of the fluid-filled cochlea in the inner ear (p. 172)

overhydration Water excess in the body (p. 614)

overshoot When a signal exceeds its steady-state value (p. 62)

ovulation (ov'-yuh-LĀ-shun) Release of an ovum from a mature ovarian follicle (p. 749)

oxidative phosphorylation (fos'-fōr-i-LĀ-shun) The entire sequence of mitochondrial biochemical reactions that uses oxygen to extract energy from the nutrients in food and transforms it into ATP, producing carbon dioxide and water in the process (p. 27)

oxyhaemoglobin (HbO₂) (ok-si-HE-muh-glō-bun) Haemoglobin combined with oxygen (p. 532)

oxyntic mucosa (ok-SIN-tic) The mucosa that lines the body and fundus of the stomach; contains gastric pits that lead to the gastric glands lined by mucous neck cells, parietal cells, and chief cells (p. 661)

P

Pacinian corpuscles Mechanoreceptors located in the skin that respond to touch and deep pressure; useful in detecting moderately rough to rougher surfaces and are very sensitive to vibration (p. 147)

pancreas (PAN-krē-us) A mixed gland composed of an exocrine portion that secretes digestive enzymes and an aqueous alkaline secretion into the duodenal lumen and an endocrine portion that secretes the hormones insulin and glucagon into the blood (p. 271)

paracrines (PEAR-uh-krin) Local chemical messengers whose effect is exerted only on neighbouring cells in the immediate vicinity of its site of secretion (p. 51)

paradoxical sleep A 10- to 15-minute episode that punctuates the end of each slow-wave sleep cycle (p. 134)

parasympathetic nervous system (pear'-uh-sim-puh-THET-ik) The subdivision of the autonomic nervous system that dominates in quiet, relaxed situations and promotes body maintenance activities such as digestion and emptying of the urinary bladder (p. 92)

parathyroid glands (pear'-uh-THĪ-roid) Four small glands located on the posterior surface of the thyroid gland that secrete parathyroid hormone (p. 285)

parathyroid hormone (PTH) A hormone that raises plasma Ca²⁺ levels (p. 285)

paresthesias The sensation of numbness and/or tingling in the skin (p. 622)

parietal (oxyntic) cells (puh-RĪ-ut-ul) The stomach cells that secrete hydrochloric acid and intrinsic factor (p. 661)

parietal lobes The lobes of the cerebral cortex that lie at the top of the brain behind the central sulcus and contain the somatosensory cortex (p. 115)

parietal-temporal-occipital association cortex A region concerned with integrating such sensory inputs as sight, sound, and touch (p. 133)

Parkinson's disease (PD) Condition associated with a deficiency of dopamine, an important neurotransmitter in the basal ganglia (p. 82)

partial pressure The individual pressure exerted independently by a particular gas within a mixture of gases (p. 524)

partial pressure gradients Difference in the partial pressure of a gas between two regions that promotes the movement of the gas from the region of higher partial pressure to the region of lower partial pressure (p. 524)

parturition (labour, delivery, birth) (par'-too-RISH-un) Delivery of a baby (p. 767)

passive forces Forces that do not require expenditure of cellular energy to accomplish transport of a substance across the plasma membrane (p. 37)

passive reabsorption When none of the steps in the transepithelial transport of a substance reabsorbed across the kidney tubules requires energy expenditure (p. 574)

pathogens (PATH-uh-junz) Disease-causing microorganisms, such as bacteria or viruses (p. 445)

pathophysiology (path'-ō-fiz-ē-OL-ō-gē) Abnormal functioning of the body associated with disease (p. 16)

pepsin An enzyme involved in protein digestion (p. 663)

pepsinogen (pep-SIN-uh-jun) A peptide secreted by the stomach that is the inactive precursor of pepsin (p. 663)

percent haemoglobin (% Hb) saturation A measure of the extent to which the haemoglobin present in the blood is combined with oxygen (p. 532)

perception The conscious interpretation of the external world as created by the brain from a pattern of nerve impulses delivered to it from sensory receptors (p. 143)

perilymph Fluid contained in the scala vestibuli and scala tympani (p. 172)

peripheral chemoreceptors (kē'-mō-rē-SEP-turz) The carotid and aortic bodies, which respond to changes in arterial P_{O_2} , P_{CO_2} , and H^+ and adjust respiration accordingly (p. 545)

peripheral nervous system (PNS) Nerve fibres that carry information between the central nervous system and other parts of the body (p. 92)

peristalsis (per'-uh-STOL-sus) Ringlike contractions of the circular smooth muscle of a tubular organ that move progressively forward with a striping motion, pushing the contents of the organ ahead of the contraction (p. 656)

peritubular capillaries (per'-i-TŪ-bū-lur) Capillaries that intertwine around the tubules of the kidney's nephron; supply the renal tissue and participate in exchanges between the tubular fluid and blood during the formation of urine (p. 563)

permeable Permitting passage of a particular substance through a plasma membrane (p. 36)

permissiveness Situation in which one hormone must be present in adequate amounts for the effect of another hormone to become fully exerted (p. 214)

pernicious anaemia (per-NEE-shus) The anaemia produced as a result of intrinsic factor deficiency (p. 441)

pH The logarithm to the base 10 of the reciprocal of the hydrogen ion concentration; $pH = \log 1/[H^+]$ or $pH = -\log[H^+]$ (p. 620)

phagocytosis (fag'-oh-sī-TŌ-sus) A type of endocytosis in which large, multimolecular, solid particles are engulfed by a cell (p. 48)

phantom pain An experience of pain that may arise due to extensive remodelling of the brain region that originally handled sensations from a severed limb (p. 147)

pharynx (FARE-inks) The back of the throat, which serves as a common passageway for the digestive and respiratory systems (p. 172)

phasic receptors Receptors that are useful in situations where it is important to signal a change in stimulus intensity rather than to relay status quo information (p. 145)

pheromones Chemical factor that is secreted to induce sexual response (p. 186)

phosphatidylinositol bisphosphate (PIP₂) A component of the tails of the phospholipid molecules within the cell membrane (p. 219)

phospholipase C An enzyme that cleaves phospholipids just in front of the phosphate group (p. 218)

phospholipids A class of lipids that are a major component of all cell membranes because they form lipid bilayers (p. 29)

photons Particle-like individual packets of electromagnetic radiation that travel in wave-like fashion (p. 155)

photopigments Molecules that undergo chemical alterations when activated by light. Through a series of steps, this light-induced change and subsequent activation of photopigments brings about a receptor potential that ultimately leads to the generation of action potentials, which transmit this information to the brain for visual processing. (p. 161)

photoreceptors Sensory receptors responsive to light (p. 143)

phototransduction The mechanism of converting light stimuli into electrical activity by the rods and cones of the eye (p. 161)

physical therapy The treatment of disease, injury, or deformity by physical methods such as active mobilization (p. 3)

physiological range The normal range for a physiological variable (e.g., temperature, pH) found in the population of interest (e.g., humans) that will be maintained most of the time (>85%) (p. 9)

physiologist Person who specializes in the study of physiology (p. 4)

pia mater The innermost layer of the meninges (*mater* means "mother," indicative of this membrane's protective and supportive role) (p. 100)

pineal gland (PIN-ē-ul) A small endocrine gland located in the centre of the brain that secretes the hormone melatonin (p. 240)

pinna A prominent skin-covered flap of cartilage that collects sound waves and channels them down the external ear canal. Many species (dogs, for

example) can cock their ears in the direction of sound to collect more sound waves, but human ears are relatively immobile. (p. 171)

pinocytosis (pin-oh-cī-TŌ-sus) Type of endocytosis in which the cell internalizes fluid (p. 48)

pitch The tone of a sound, determined by the frequency of vibrations (e.g., whether a sound is a C or G note) (p. 171)

pitch discrimination The ability to distinguish between various frequencies of incoming sound waves; depends on the shape and properties of the basilar membrane, which is narrow and stiff at its oval window end and wide and flexible at its helicotrema end (p. 174)

pituitary gland (hypophysis) (pih-TWO-ih-tair-ee) A small endocrine gland connected by a stalk to the hypothalamus; consists of the anterior pituitary and posterior pituitary (p. 225)

placenta (plah-SEN-tah) The organ of exchange between the maternal and fetal blood; also secretes hormones that support the pregnancy (p. 761)

plasma The liquid portion of the blood (p. 10)

plasma cell An antibody-producing derivative of an activated B lymphocyte (p. 475)

plasma clearance The volume of plasma that is completely cleared of a given substance by the kidneys per minute (p. 586)

plasma-colloid osmotic pressure (Πp) (KOL-oid os-MOT-ik) The force caused by the unequal distribution of plasma proteins between the blood and surrounding fluid; encourages fluid movement into the capillaries (p. 409)

plasma membrane A protein-studded lipid bilayer that encloses each cell, separating it from the extracellular fluid (p. 5)

plasma proteins The proteins that remain within the plasma, where they perform important functions; include albumins, globulins, and fibrinogen (p. 435)

plasticity (plas-TIS-uh-tē) The ability of portions of the brain to assume new responsibilities in response to the demands placed on it (p. 120)

platelets (thrombocytes) (PLA-T-lets) Specialized cell fragments in the blood that participate in haemostasis by forming a plug at a vessel defect (p. 447)

pluripotent stem cells Precursor cells; for example, those that reside in the bone marrow and continuously divide and differentiate to give rise to each of the types of blood cells (p. 438)

polarization Any time at which the membrane potential is not 0 mV (p. 62)

poliovirus A contagious causative agent; a human enterovirus that destroys motor neuron cells (p. 195)

polycythaemia (pol-i-si-THĒ-mē-uh) Excess circulating erythrocytes, accompanied by an elevated haematocrit (p. 444)

polymodal nociceptors Nociceptors that respond to more than one type of noxious stimuli (p. 150)

polysaccharides (pol'-i-SAK-uh-ridz) Complex carbohydrates, consisting of chains of interconnected glucose molecules (p. 646)

polysynaptic Term that means "many synapses" (p. 106)

positive balance Situation in which the gains via input for a substance exceed its losses via output, so that the total amount of the substance in the body increases (p. 608)

positive feedback A regulatory mechanism in which the input and the output in a control system continue to enhance each other, so that the controlled variable is progressively moved farther from a steady state (p. 15)

posterior parietal cortex Part of the brain that plays a key role in producing planned movements. Before an effective movement can be started, the central nervous system must know the original positions of the body parts that are to be moved, and the positions of any external objects that the body may contact. (p. 119)

posterior pituitary gland The neural portion of the pituitary that stores and, upon hypothalamic stimulation, releases into the blood two hormones produced by the hypothalamus—vasopressin and oxytocin (p. 225)

postganglionic fibre (pōst'-gan-glē-ON-ik) The second neuron in the two-neuron autonomic nerve pathway; originates in an autonomic ganglion and terminates on an effector organ (p. 188)

postsynaptic neuron (pōst'-si-NAP-tik) The neuron that conducts its action potentials away from a synapse (p. 74)

prefrontal association cortex The front portion of the frontal lobe just anterior to the premotor cortex; the part of the brain involved in brainstorming and, specifically, in planning for voluntary activity, decision making, creativity, and personality traits (p. 133)

preganglionic fibre The first neuron in the two-neuron autonomic nerve pathway; originates in the central nervous system and terminates on an autonomic ganglion (p. 188)

preload The pressure stretching the ventricle of the heart, after atrial contraction and subsequent passive filling of the ventricle; describes the initial stretching of a single cardiac myocyte prior to contraction (p. 369)

premotor cortex Part of the brain that works in coordination with the motor cortex (a few millimetres anterior of the primary motor cortex) to plan and execute movements (p. 119)

pressure gradient A difference in pressure between two regions that drives the movement of blood or air from the region of higher pressure to the region of lower pressure (p. 387)

presynaptic facilitation Enhanced release of neurotransmitter from a presynaptic axon terminal as a result of excitation of another neuron that terminates on the axon terminal (p. 81)

presynaptic inhibition A reduction in the release of a neurotransmitter from a presynaptic axon terminal as a result of excitation of another neuron that terminates on the axon terminal (p. 81)

presynaptic neuron (prē-si-NAP-tik) The neuron that conducts its action potentials toward a synapse (p. 74)

primary active transport A carrier-mediated transport system in which energy is directly required to operate the carrier and move the transported substance against its concentration gradient (p. 44)

primary auditory cortex The part of the brain located in the temporal lobe that is responsible for the processing of auditory information (p. 176)

primary follicles Primary oocyte surrounded by a single layer of granulosa cells in the ovary (p. 745)

primary motor cortex The portion of the cerebral cortex that lies anterior to the central sulcus and is responsible for voluntary motor output (p. 115)

primary olfactory cortex A portion of the cortex involved in olfaction (p. 185)

primary reproductive organs (gonads) The primary reproductive organs, which produce the gametes and secrete the sex hormones; testes and ovaries (p. 724)

primary tastes Salty, sour, sweet, bitter, umami, and the recently added fifth taste—a meaty, “amino-acid” taste (p. 182)

procedural memories Type of memory associated with motor skills gained through repetitive training, such as memorizing a dance routine. The cortical areas important for a given procedural memory are the specific motor or sensory systems engaged in performing the routine. (p. 128)

prolactin (PRL) (prō-LAK-tun) An anterior pituitary hormone that stimulates breast development and milk production in females (p. 227)

prolactin-inhibiting hormone (PIH) Hormone that inhibits the release of prolactin; acts as a neurotransmitter and as a neuromodulator. For example, PIH is identical to *dopamine*, a major neurotransmitter in the basal nuclei and elsewhere. (p. 229)

proliferative phase The phase of the menstrual cycle during which the endometrium repairs itself and thickens following menstruation; lasts from the end of the menstrual phase until ovulation (p. 755)

pro-opiomelanocortin (POMC) (prō-op'-Ē-ō-ma-LAN-oh-kor'-tin) A large precursor molecule produced by the anterior pituitary that is cleaved into adrenocorticotrophic hormone, melanocyte-stimulating hormone, and endorphin (p. 257)

proprioception (prō'-prē-ō-SEP-shun) Awareness of position of body parts in relation to one another and to surroundings (p. 117)

prostaglandins (pros'-tuh-GLAN-dins) Local chemical mediators derived from a component of the plasma membrane, arachidonic acid (p. 741)

prostate gland A male accessory sex gland that secretes an alkaline fluid, which neutralizes acidic vaginal secretions (p. 740)

protein kinase A (KŪ-nase) An enzyme that phosphorylates and thereby induces a change in the shape and function of a particular intracellular protein (p. 217)

proteolytic enzymes (prōt'-ē-uh-LIT-ik) Enzymes that digest protein (p. 667)

proximal tubule (PROKS-uh-mul) A highly convoluted tubule that extends between Bowman's capsule and the loop of Henle in the kidney's nephron (p. 563)

pseudopods Surface projections from a white blood cell that completely surround or engulf large multimolecular particles, such as a bacterium or tissue debris, and trap it within an internalized vesicle (p. 48)

psychoactive drugs Drugs that affect human moods; some have been shown to influence self-stimulation in experimental animals (p. 125)

PTH See *parathyroid hormone*. (p. 285)

pulmonary artery (PULL-mah-nair-ē) The large vessel that carries blood from the right ventricle to the lungs (p. 347)

pulmonary circulation The closed loop of blood vessels carrying blood between the heart and lungs (p. 346)

pulmonary surfactant (sur-FAK-tunt) A phospholipoprotein complex secreted by the Type II alveolar

cells that intersperses between the water molecules that line the alveoli, thereby lowering the surface tension within the lungs (p. 509)

pulmonary valve A one-way valve that permits the flow of blood from the right ventricle into the pulmonary artery during ventricular emptying, but prevents the backflow of blood from the pulmonary artery into the right ventricle during ventricular relaxation (p. 350)

pulmonary veins The large vessels that carry blood from the lungs to the heart (p. 347)

pump An active transport mechanism in living cells by which specific ions are moved through the cell membrane against a concentration or electrochemical gradients (p. 44)

pupil An adjustable round opening in the centre of the iris through which light passes to the interior portions of the eye (p. 154)

Purkinje fibres (pur-KIN-jē) Small terminal fibres that extend from the bundle of His and rapidly transmit an action potential throughout the ventricular myocardium (p. 353)

pyloric gland area (PGA) (pi-LÖR-ik) The specialized region of the mucosa in the antrum of the stomach that secretes gastrin (p. 661)

pyloric sphincter (pī-lör'-ik SFINGK-tur) The junction between the stomach and duodenum (p. 656)

pyramidal cells Neurons with cone-shaped cell bodies (p. 114)

R

radial (dilator) muscle Muscle fibres that project out from the pupil and, when stimulated by the autonomic nervous system, contract to increase the size of the pupil (p. 155)

radiation Emission of heat energy from the surface of a warm body in the form of electromagnetic waves (p. 712)

reabsorption The net movement of interstitial fluid into the capillary (p. 409)

reactive hyperaemia Hyperaemia (an increase in blood flow) in a tissue or organ, resulting from the restoration of temporarily occluded (blocked) blood flow (p. 400)

receptive field Refers to the area surrounding a receptor within which the receptor can detect stimuli (p. 147)

receptor See *sensory receptor or receptor site*. (p. 31)

receptor-mediated endocytosis A highly selective process that enables cells to import specific large molecules that it needs from its environment; triggered by the binding of a specific molecule, such as a protein, to a surface membrane receptor site specific for that protein (p. 48)

receptor potential The graded potential change that occurs in a sensory receptor in response to a stimulus; generates action potentials in the afferent neuron fibre (p. 144)

receptor sites Membrane proteins that bind with a specific extracellular chemical messenger, thereby bringing about a series of membrane and intracellular events that alter the activity of the particular cell (p. 31)

reconsolidated To combine into one system, back into a restabilized, inactive state (p. 126)

red, green, and blue cones Photoreceptor cells that respond selectively to various wavelengths of light, making colour vision possible (p. 161)

reduced haemoglobin (deoxyhaemoglobin) Haemoglobin that is not combined with oxygen (p. 532)

referred pain Pain that appears in one part of the body, but originates from another. For example, pain originating in the heart may appear to come from the left shoulder and arm, suggesting that inputs arising from the heart may share a pathway to the brain in common with inputs from the left upper extremity, but the mechanism responsible for referred pain is not completely understood. (p. 103)

reflex Any response that occurs automatically without conscious effort; controlled by a reflex arc that includes a receptor, afferent pathway, integrating centre, efferent pathway, and effector (p. 105)

reflex arc A neural pathway that controls an action reflex (e.g., patellar reflex). In humans, most sensory neurons do not pass directly into the brain, but synapse in the spinal cord and include afferent neurons, interneurons, and efferent neurons to complete the arc. (p. 105)

refraction Bending of a light ray (p. 155)

refractory period (rē-FRAK-tuh-rē) The time period when a recently activated patch of membrane is refractory (unresponsive) to further stimulation, preventing the action potential from spreading backward into the area through which it has just passed, thereby ensuring the unidirectional propagation of the action potential away from the initial site of activation (p. 67)

regeneration tube Formed by Schwann cells to guide a regenerating nerve fibre to its proper destination. The remaining portion of the axon connected to the cell body starts to grow and move forward within the Schwann cell column by amoeboid movement. (p. 72)

regulatory proteins Troponin and tropomyosin, which play a role in regulating muscle contraction by either covering or exposing the sites of interaction between the contractile proteins (p. 302)

regulatory T cells (T_{reg}) A class of T lymphocytes that suppresses the activity of other lymphocytes (p. 482)

relative refractory period The interval immediately following the absolute refractory period, during which initiation of a second action potential is inhibited but not impossible (p. 68)

releasing hormones Hypothalamic hormone that stimulates the secretion of a particular anterior pituitary hormone (p. 229)

renal cortex An outer, granular-appearing region of the kidney (p. 254)

renal medulla (RĒ-nul muh-DUL-uh) An inner, striated-appearing region of the kidney (p. 192)

renal threshold The plasma concentration at which the T_m of a particular substance is reached and the substance first starts appearing in the urine (p. 580)

renin (RĒ-nin) An enzymatic hormone released from the kidneys in response to a decrease in NaCl/ECF volume/arterial blood pressure; activates angiotensinogen (p. 576)

renin-angiotensin-aldosterone system (RAAS) (an 'jē-ō-TEN-sun al-dō-steer-OWN) The salt-conserving system triggered by the release of renin from the kidneys, which activates angiotensin, which stimulates aldosterone secretion, which stimulates Na⁺ reabsorption by the kidney tubules during the formation of urine (p. 576)

repolarization (rē'-pō-luh-ruh-ZĀ-shun) Return of membrane potential to resting potential following a depolarization (p. 58)

reproductive tract The system of ducts specialized to transport or house the gametes after they are produced (p. 724)

residual volume (RV) The minimum volume of air remaining in the lungs even after a maximal expiration (p. 518)

resistance Hindrance of flow of blood or air through a passageway (blood vessel or respiratory airway, respectively) (p. 60)

rest-and-digest Bodily functions promoted by the parasympathetic system; coincides with a slowing down of activities enhanced by the sympathetic system (p. 192)

resting membrane potential The membrane potential that exists when an excitable cell is not displaying an electrical signal (p. 54)

reticular activating system (RAS) (ri-TIK-ū-lur) Ascending fibres that originate in the reticular formation and carry signals upward to arouse and activate the cerebral cortex (p. 112)

reticular formation A network of interconnected neurons that runs throughout the brain stem and initially receives and integrates all synaptic input to the brain (p. 110)

retina The innermost layer in the posterior region of the eye that contains the eye's photoreceptors, the rods and cones (p. 153)

retinene The light-absorbing part of the photopigment. There are four different photopigments, one in the rods and one in each of three types of cones. (p. 161)

retino-hypothalamic tract A photic input pathway involved in the circadian rhythms. The message regarding light status relayed from the SCN to the pineal gland is the major way the internal clock is coordinated to a 24-hour day. (p. 242)

rhodopsin A pigment of the retina that is responsible for both the formation of the photoreceptor cells and the first events in the perception of light (p. 161)

right and left atrioventricular (AV) valves One-way valves that permit the flow of blood from the atrium to the ventricle during filling of the heart, but prevent the backflow of blood from the ventricle to the atrium during emptying of the heart (p. 347)

right cerebral hemisphere Part of the brain that excels in nonlanguage skills, especially spatial perception and artistic and musical talents; generates a big-picture, holistic view, in contrast to the left hemisphere that tends to process information in a fine-detail, fragmentary way (p. 134)

rods The eye's photoreceptors used for night vision (p. 153)

round window The membrane-covered opening that separates the lower chamber of the cochlea in the inner ear from the middle ear (p. 172)

Ruffini corpuscles Myelinated, slow-adapting nerve endings found in the deep layers of the skin (subcutaneous tissue) and joints; encapsulated, tied into the local collagen matrix, and respond to stretch (deformation) and torque; register mechanical deformation within joints (sensitivity of 2 degrees), as well as continuous pressure (p. 148)

S

sacculi Contains hairs that respond selectively to tilting of the head away from a horizontal position (such as getting up from bed) and to vertically directed linear acceleration and deceleration (p. 178)

salivary amylase (AM-uh-lās') An enzyme produced by the salivary glands that begins carbohydrate digestion in the mouth and continues in the body of the stomach after the food and saliva have been swallowed (p. 653)

saltatory conduction (SAL-tuh-tōr'-ē) The means by which an action potential is propagated throughout a myelinated fibre, with the impulse jumping over the myelinated regions from one node of Ranvier to the next (p. 70)

salt balance The equalization of the body's salt input and output to prevent salt accumulation or deficit (p. 612)

salty taste One of the five basic tastes; stimulated by chemical salts, especially NaCl (table salt). Direct entry of positively charged Na⁺ through specialized Na⁺ channels in the receptor cell membrane, a movement that reduces the cell's internal negativity, is responsible for receptor depolarization in response to salt. (p. 182)

SA node See *sinoatrial node*. (p. 352)

sarcomere (SAR-kō-mir) The functional unit of skeletal muscle; the area between two Z lines within a myofibril (p. 300)

sarcoplasmic reticulum (SR) (ri-TIK-yuh-lum) A fine meshwork of interconnected tubules that surrounds a muscle fibre's myofibrils; contains expanded lateral sacs, which store calcium that is released into the cytosol in response to a local action potential (p. 304)

satellite cells Small mononuclear progenitor cells with virtually no cytoplasm; found in mature muscle (p. 321)

saturation State in which all binding sites on a carrier molecule are occupied (p. 41)

scala media A blind-ended cochlear duct that constitutes the middle compartment of the cochlea (p. 172)

scala tympani The lower compartment of the cochlea; follows the outer contours of the spiral (p. 172)

scala vestibuli The upper compartment of the cochlea; follows the inner contours of the spiral (p. 172)

Schwann cells (shwahn) The myelin-forming cells of the peripheral nervous system (p. 70)

sclera The visible white part of the eye (p. 153)

secondary active transport A transport mechanism in which a carrier molecule for glucose or an amino acid is driven by a Na⁺ concentration gradient established by the energy-dependent Na⁺ pump to transfer the glucose or amino acid uphill without directly expending energy to operate the carrier (p. 44)

secondary (antral) follicle A developing ovarian follicle that is secreting estrogen and forming an antrum (p. 747)

second messenger An intracellular chemical that is activated by binding of an extracellular first messenger to a surface receptor site, and that triggers a preprogrammed series of biochemical events, which result in altered activity of intracellular proteins to control a particular cellular activity (p. 53)

second-order sensory neuron Neurons located in the medulla oblongata that receive input from primary sensory neurons, and thereby form the nucleus of the solitary tract that integrates all visceral information (p. 146)

secretin (si-KRĒT- 'n) A hormone released from the duodenal mucosa primarily in response to the presence of acid; inhibits gastric motility and secretion and stimulates secretion of a NaHCO_3 solution from the pancreas and from the liver (p. 659)

secretion The release to a cell's exterior, on appropriate stimulation, of substances that have been produced by the cell (p. 6)

secretory (progestational) phase The phase of the menstrual cycle characterized by the development of a lush endometrial lining capable of supporting a fertilized ovum; also known as the progestational phase (p. 755)

secretory vesicles (VES-i-kuls) Membrane-enclosed sacs containing proteins that have been synthesized and processed by the endoplasmic reticulum/Golgi complex of the cell, and which are released to the cell's exterior by exocytosis on appropriate stimulation (p. 48)

segmentation The small intestine's primary method of motility; consists of oscillating, ringlike contractions of the circular smooth muscle along the small intestine's length (p. 676)

selectively permeable Permitting some particles to pass through the plasma membrane while excluding others (p. 36)

self-antigens Antigens that are characteristic of a person's own cells (p. 482)

semen (SĒ-men) A mixture of accessory sex gland secretions and sperm (p. 740)

semicircular canals Sense organ in the inner ear that detects rotational or angular acceleration or deceleration of the head (p. 178)

semilunar valves (sem 'i-LEW-nur) The aortic and pulmonary valves (p. 740)

seminal vesicles (VES-i-kuls) Male accessory sex glands that supply fructose to ejaculated sperm and secrete prostaglandins (p. 740)

seminiferous tubules (sem 'uh-NIF-uh-rus) The highly coiled tubules within the testes that produce spermatozoa (p. 732)

sensitization Increased responsiveness to mild stimuli following a strong or noxious stimulus (p. 129)

sensitization period The period of first exposure to a particular allergen, but no symptoms evoked; includes formation of memory cells that can elicit an immune response upon subsequent exposure to the allergen (p. 492)

sensor A cell (receptor) that detects or measures a physical property and records, indicates, or otherwise responds to it (p. 14)

sensorineural deafness Condition wherein sound waves are transmitted to the inner ear but are not translated into nerve signals that are interpreted by the brain as sound sensations (p. 177)

sensory afferent Pathway coming into the central nervous system that carries information that reaches the level of consciousness (p. 142)

sensory homunculus Orderly somatotopic representation of the sensitivity of body parts; gives an upside down and unequal representation on the somatosensory cortex; the larger the cortical representation, the higher the sensitivity and use (p. 118)

sensory receptor An afferent neuron's peripheral ending, which is specialized to respond to a particular stimulus in its environment (p. 92)

Sertoli cells (sur-TŌ-lē) Cells located in the seminiferous tubules that support spermatozoa during their development (p. 737)

set point The desired level at which homeostatic control mechanisms maintain a controlled variable, (nonsteady) physiological state (p. 9)

short-term memory The capacity to hold a small amount (approximately eight elements) of information in mind in a readily available state for a short period of time (seconds) (p. 126)

signal transduction The sequence of events in which incoming signals (instructions from extracellular chemical messengers such as hormones) are conveyed to the cell's interior for execution (p. 53)

simple (basic) reflexes Built-in reflexes requiring no conscious thought (p. 105)

single-unit smooth muscle The most abundant type of smooth muscle; made up of muscle fibres that are interconnected by gap junctions so that they become excited and contract as a unit; also known as *visceral smooth muscle* (p. 328)

sinoatrial node (SA node) (sī-nō-Ā-trē-ul) A small, specialized, autorhythmic region in the right atrial wall of the heart that has the fastest rate of spontaneous depolarizations and serves as the normal pacemaker of the heart (p. 352)

skeletal muscle Striated muscle, which is attached to the skeleton and is responsible for movement of the bones in purposeful relation to one another; innervated by the somatic nervous system and under voluntary control (p. 298)

skin (integument) The covering for the outside of the body, along with the underlying connective tissue; also called integument (in-TEG-yuh-munt) (p. 460)

slow pain Type of persistent pain characterized as dull or aching; originates from chemical nociceptors (p. 149)

slow pain pathway Impulses carried on unmyelinated slow C fibres that carry slow pain, heat, cold, and mechanical stimuli at a much slower rate of $<1-2 \text{ m/s}$ (p. 150)

slow-wave potentials Self-excitability activity of an excitable cell in which its membrane potential undergoes gradually alternating depolarizing and hyperpolarizing swings (p. 331)

smell The ability to perceive odours; olfaction (p. 181)

smooth muscle Involuntary muscle innervated by the autonomic nervous system and found in the walls of hollow organs and tubes (p. 326)

somaesthetic sensations (SŌ-mes-THEH-tik) Awareness of sensory input such as touch, pressure, temperature, and pain from the body's surface (p. 116)

somatic nervous system The portion of the efferent division of the peripheral nervous system that innervates skeletal muscles; consists of the axonal fibres of the alpha motor neurons (p. 92)

somatic sensation Sensory information arising from the body surface, including somaesthetic sensation and proprioception (p. 142)

somatomedins (sō 'mat-uh-MĒ-dinz) Hormones secreted by the liver or other tissues, in response to growth hormone, that act directly on the target cells to promote growth; insulin-like growth factors (IGF) (p. 235)

somatosensory cortex The region of the parietal lobe immediately behind the central sulcus; the site of initial processing of somaesthetic and proprioceptive input (p. 117)

somatosensory pathways Consists of components of the central and peripheral nervous systems that

receive and interpret sensory information from receptors in the joints, ligaments, muscles, and skin (p. 146)

somatosensory receptors Free-nerve endings consisting of a neuron with an exposed receptor; see also *special sense receptor* (p. 143)

somatostatin Hormone secreted by the hypothalamus and the pancreas; acts as a paracrine in the stomach (p. 229)

sound waves Travelling vibrations of air that consist of regions of high pressure caused by compression of air molecules alternating with regions of low pressure caused by rarefaction of the molecules (p. 169)

sour taste Taste caused by acids containing a free hydrogen ion. The citric acid content of lemons, for example, accounts for their distinctly sour taste. (p. 182)

spatial summation The summing of several postsynaptic potentials arising from the simultaneous activation of several excitatory (or several inhibitory) synapses (p. 79)

special senses Vision, hearing, taste, and smell (p. 143)

special senses receptor Used in the ear; turns a mechanical stimulation (non-neural) into a neural signal by synapsing onto a sensory neuron (p. 143)

specificity Ability of carrier molecules to transport only specific substances across the plasma membrane (p. 41)

spermatogenesis (spur 'mat-uh-JEN-uh-sus) Sperm production (p. 735)

sphincter (sfink-tur) A voluntarily controlled ring of skeletal muscle that controls passage of contents through an opening into or out of a hollow organ or tube (p. 598)

spike Recorded appearance of an action potential; a sharp rapid rise followed by a rapid decrease (p. 62)

spinal cord Tubular bundle of nervous tissue and cells connected to the medulla oblongata and extending down the vertebral column (p. 101)

spinal nerves Paired spinal nerves emerge from the spinal cord through spaces formed between the bony, winglike arches (pedicle and lamina) of adjacent vertebrae; named according to the region of the vertebral column from which they originate (p. 101)

spinal reflex A reflex that is integrated by the spinal cord (p. 107)

spinocerebellum Part of the brain that enhances muscle tone and helps coordinate voluntary movement, especially fast, phasic motor activities (p. 121)

spleen A lymphoid tissue in the upper left part of the abdomen that stores lymphocytes and platelets and destroys old red blood cells (p. 437)

spoken languages Capacity for speaking developed in the early years of human life. A hearing impairment can prevent not only the ability to talk but also the ability to understand the spoken word (p. 177)

stable balance The equalization of the total body input of a particular substance and its total body output (p. 608)

stapes The small ossicle in the middle ear, shaped like a stirrup (p. 172)

steady state A dynamic equilibrium (p. 37)

stellate cells Neurons with a starlike shape (p. 114)

Stem Cell Network A Canadian venture that fosters ethical stem cell research by bringing together over 50 leading scientists to investigate the potential of stem cells (p. 11)

stem cells Relatively undifferentiated precursor cells that give rise to highly differentiated, specialized cells (p. 661)

stereocilia Actin-stiffened microvilli that protrude from the surface of each hair cell (p. 173)

stimulus A detectable physical or chemical change in the environment of a sensory receptor (p. 106)

stress The generalized, nonspecific response of the body to any factor that overwhelms, or threatens to overwhelm, the body's compensatory abilities to maintain homeostasis (p. 263)

stretch reflex A monosynaptic reflex in which an afferent neuron originating at a stretch-detecting receptor in a skeletal muscle terminates directly on the efferent neuron supplying the same muscle and causes it to contract and counteract the stretch (p. 106)

stroke volume (SV) The volume of blood pumped out of each ventricle with each contraction, or beat, of the heart (p. 363)

subarachnoid space The space between the arachnoid mater and the pia mater (p. 100)

submucosa The connective tissue layer of the digestive tract that lies under the mucosa and contains the larger blood and lymph vessels and a nerve network (p. 649)

substance P The neurotransmitter released from pain fibres (p. 150)

subs synaptic membrane (sub-sih-NAP-tik) The portion of the postsynaptic cell membrane that lies immediately underneath a synapse and contains receptor sites for the synapse's neurotransmitter (p. 75)

supplementary motor area Part of the sensorimotor cerebral cortex, located on the medial face of the hemisphere, just in front of primary motor cortex (p. 119)

suprachiasmatic nucleus (SCN) (soup'-ra-kī-as-MAT-ik) A cluster of nerve cell bodies in the hypothalamus that serves as the master biological clock, acting as the pacemaker that establishes many of the body's circadian rhythms (p. 240)

suspensory ligaments Structure that attaches the ciliary muscle to the lens (p. 157)

sweet taste Taste evoked by the particular configuration of glucose. From an evolutionary perspective, a craving for sweet foods is associated with the supply of necessary calories in a readily usable form. (p. 184)

sympathetic ganglion chain A chain of ganglia situated ventral and lateral to the spinal cord and extending from the upper neck down to the coccyx (p. 188)

sympathetic nervous system The subdivision of the autonomic nervous system that dominates in emergency (fight-or-flight) or stressful situations and prepares the body for strenuous physical activity (p. 92)

synapse (SIN-aps') The specialized junction between two neurons where an action potential in the presynaptic neuron influences the membrane potential of the postsynaptic neuron by means of the release of a chemical messenger that diffuses across the small cleft that separates the two neurons (p. 76)

synaptic cleft The space between two nerve cells in which neurotransmitters cross over (p. 74)

synaptic knob The bulbous structures on the end of an axon, each of which contains many synaptic vesicles (p. 74)

synaptic vesicles Vesicles that store various neurotransmitters that are released at the synapse. The release is regulated by voltage-dependent calcium channels (p. 74)

synergism (SIN-er-jiz'-um) Several complementary actions that produce a combined effect that is greater than the sum of their separate effects (p. 214)

systemic circulation (sis-TEM-ik) The closed loop of blood vessels carrying blood between the heart and body systems (p. 346)

systole (SIS-tō-lē) The period of cardiac contraction and emptying (p. 361)

systolic pressure Peak pressure in the arteries; occurs near the beginning of the cardiac cycle when the ventricles are contracting (p. 391)

T

T₃ See *triiodothyronine*. (p. 248)

T₄ See *tetraiodothyronine*. (p. 248)

tachycardia The cardiac rhythm, which produces a ventricular rate greater than 100 beats per minute (p. 359)

target cells The cells that a particular extracellular chemical messenger, such as a hormone or a neurotransmitter, influences (p. 51)

tastant A taste-provoking chemical (p. 182)

taste One of the five senses; detected through sensory organs, the taste buds (p. 181)

taste pore A small opening that houses the taste bud, through which fluids in the mouth come into contact with the surface of its receptor cells (p. 182)

taste receptor cells Modified epithelial cells with many surface folds, or microvilli, that protrude slightly through the taste pore, greatly increasing the surface area exposed to the oral contents (p. 182)

tears Eye-washing fluid that is lubricating, cleansing, and bactericidal; produced continuously by the lacrimal gland in the upper lateral corner under the eyelid (p. 153)

tectorial membrane A gelatinous structure that is a highly hydrated, non-cellular matrix found on the cells of the cochlea (p. 173)

teleological approach (tē'-lē-ō-LA-ji-kul) Explanation of body functions in terms of their particular purpose in fulfilling a bodily need—that is, the “why” of body processes (p. 4)

temporal lobes The cerebral cortex lobes that are located laterally and that initially process auditory input (p. 115)

temporal summation The summing of several postsynaptic potentials occurring very close together in time because of successive firing of a single presynaptic neuron (p. 78)

tendon The tough, fibrous tissue that connects muscle to bone (p. 298)

tension The force produced during muscle contraction due to the shortening of the sarcomeres, resulting in stretching and tightening of the muscle's elastic connective tissue and tendon, which transmit the tension to the bone to which the muscle is attached (p. 313)

terminal button A motor neuron's enlarged knob-like ending that terminates near a skeletal muscle fibre and releases acetylcholine in response to an action potential in the neuron (p. 197)

terminal ganglia Very short postganglionic fibres that lie in or near an effector organ and end on the cells of that organ (p. 188)

testosterone (tes-TOS-tuh-rōn) The male sex hormone, secreted by the Leydig cells of the testes (p. 724)

tetanus (TET'-n-us) A smooth, maximal, muscle contraction that occurs when the fibre is stimulated so rapidly that it does not have a chance to relax at all between stimuli (p. 311)

tetraiodothyronine (T₄ or thyroxine) (thī-ROCKS-in) The most abundant hormone secreted by the thyroid gland; important in the regulation of overall metabolic rate; also known as thyroxine or T₄ (p. 248)

thalamus (THAL-uh-mus) The brain region that serves as a synaptic integrating centre for preliminary processing of all sensory input on its way to the cerebral cortex (p. 112)

thecal cells (THAY-kel) The outer layer of specialized ovarian connective tissue cells in a maturing follicle (p. 747)

thermally gated channels Gated channels that respond to local changes in temperature (heat or cold) (p. 58)

thermal nociceptors Nociceptors formed late during neurogenesis, developing from neural crest stem cells, that respond to temperature extremes, especially heat (p. 149)

thermoreceptors (thur'-mō-rē-SEP-tur) Sensory receptors sensitive to heat and cold (p. 144)

thick filaments Specialized cytoskeletal structures within skeletal muscle that are made up of myosin molecules and interact with the thin filaments to shorten the fibre during muscle contraction (p. 298)

thin filaments Specialized cytoskeletal structures within skeletal muscle that are made up of actin, tropomyosin, and troponin molecules and interact with the thick filaments to shorten the fibre during muscle contraction (p. 298)

third-order sensory neuron The long sensory tract that ascends within the spinal cord; found in the thalamic nuclei and transmits information from the thalamus to the primary sensory cortex (p. 146)

thirst The subjective sensation that drives you to drink H₂O (p. 617)

thirst centre An area of the hypothalamus in close proximity to vasopressin secreting cells (p. 617)

thoracic cavity (chest) (thō-RAS-ik) The cavity that lies above the diaphragm and contains the heart and lungs (p. 346)

threshold potential The critical membrane potential that must be reached before an action potential is initiated in an excitable cell (p. 61)

thromboembolism A general term describing both thrombosis and its main complication, embolization; the formation of a blood clot (a thrombus) inside a blood vessel (p. 378)

thrombus An abnormal clot attached to the inner lining of a blood vessel (p. 453)

thymus (THĪ-mus) A lymphoid gland located midline in the chest cavity that processes T lymphocytes and produces the hormone thymosin, which maintains the T-cell lineage (p. 224)

thyroglobulin (Tg) (thī'-rō-GLOB-yuh-lun) A large, complex molecule on which all steps of thyroid hormone synthesis and storage take place (p. 248)

thyroid gland A bi-lobed endocrine gland that lies over the trachea and secretes three hormones: tetraiodothyronine (thyroxine) and triiodothyronine, which regulate overall basal metabolic rate, and

calcitonin, which contributes to control of calcium balance (p. 248)

thyroid hormone Collectively, the hormones secreted by the thyroid follicular cells, namely, tetraiodothyronine (thyroxine) and triiodothyronine (p. 248)

thyroid-stimulating hormone (TSH, thyrotropin) An anterior pituitary hormone that stimulates secretion of thyroid hormone and promotes growth of the thyroid gland (p. 227)

thyrotropin-releasing hormone (TRH) Hormone that stimulates the release of TSH (alias thyrotropin) from the anterior pituitary (p. 229)

tidal volume (V_T) The volume of air entering or leaving the lungs during a single breath (p. 518)

tight junctions Impermeable junctions between two adjacent epithelial cells formed by the sealing together of the cells' lateral edges near their luminal borders; prevent passage of substances between the cells (p. 34)

timbre Quality of a sound that is determined by its characteristic overtones (p. 171)

tip links Structure that pulls on mechanically gated ion channels in the hair cell when the stereocilia are deflected by endolymph movement (p. 178)

tissues (1) Functional aggregation of cells of a single specialized type, such as nerve cells forming nervous tissue; (2) the aggregate of various cellular and extracellular components that make up a particular organ, such as lung tissue (p. 6)

T lymphocytes (T cells) White blood cells that accomplish cell-mediated immune responses against targets to which they have been previously exposed; see also *cytotoxic T cells*, *helper T cells*, and *regulatory T cells* (p. 447)

tolerance Refers to the desensitization to an addictive drug so that the user needs greater quantities of the drug to achieve the same effect (p. 82)

tone [muscle] The ongoing baseline of activity in a given system or structure, as in muscle tone, sympathetic tone, or vascular tone (p. 171)

tone [sound] The quality or character of sound. The characteristic quality or timbre of a particular sound (p. 41)

tonic activity The typically constant activity of some neurons, in contrast to the phasic activity (pulsatile firing) of other neurons. Slowly adapting, or tonic, receptors respond to steady stimulus and produce a steady rate of firing; they most often respond to increased intensity of stimulus by increasing their firing frequency (impulses per second). (p. 192)

tonicity The effect a solution has on cell volume—whether the cell remains the same size, swells, or shrinks—when the solution surrounds the cell (p. 40)

tonic receptors Receptors that adapt slowly or do not adapt at all; important in situations where it is valuable to maintain information about a stimulus; Examples include muscle stretch receptors, which monitor muscle length, and joint proprioceptors, which measure the degree of joint flexion (p. 145)

total lung capacity (TLC) The volume of gas contained in the lung at the end of maximal inspiration (p. 519)

total peripheral resistance The resistance offered by all the peripheral blood vessels, with arteriolar resistance contributing most extensively (p. 401)

trachea (TRĀ-kē-uh) The conducting airway that extends from the pharynx and branches into two

bronchi, each entering a lung; known as the wind-pipe (p. 501)

transcellular fluid A number of small, specialized fluid volumes, all of which are secreted by specific cells into a particular body cavity to perform some specialized function (p. 610)

transducin A G protein found in rod and cone cells (p. 161)

transduction Conversion of stimuli into action potentials by sensory receptors (p. 143)

transepithelial transport (tranz-ep-i-THĒ-lē-al) The entire sequence of steps involved in the transfer of a substance across the epithelium between either the renal tubular lumen or digestive tract lumen and the blood (p. 574)

transporter recruitment The phenomenon of inserting additional transporters (carriers) for a particular substance into the plasma membrane, thereby increasing membrane permeability to the substance in response to an appropriate stimulus (p. 273)

transport maximum (T_m) The maximum rate of a substance's carrier-mediated transport across the membrane when the carrier is saturated; known as *tubular maximum* in the kidney tubules (p. 41)

transverse tubule (T tubule) A perpendicular infolding of the surface membrane of a muscle fibre; rapidly spreads surface electric activity into the central portions of the muscle fibres (p. 304)

tricarboxylic acid cycle The second stage of cellular respiration, which is the three-stage process by which living cells break down organic fuel molecules in the presence of oxygen (p. 25)

triglycerides (tri-GLIS-uh-ridz) Neutral fats composed of one glycerol molecule with three fatty acid molecules attached (p. 647)

triiodothyronine (T_3) (tri-i-ō-dō-THĪ-rō-nēn) The most potent hormone secreted by the thyroid follicular cells; important in the regulation of overall metabolic rate (p. 248)

trilaminar structure The plasma membrane's three-layered appearance due to the specific arrangement of its molecules; consists of two dark layers separated by a light middle layer (p. 29)

trophoblast (TRŌF-uh-blast') The outer layer of cells in a blastocyst that is responsible for accomplishing implantation and developing the fetal portion of the placenta (p. 758)

tropic hormone (TRŌ-pik) A hormone that regulates the secretion of another hormone (p. 210)

tropomyosin (tröp'-uh-MĪ-uh-sun) One of the regulatory proteins in the thin filaments of muscle fibres (p. 301)

troponin (tro-PŌ-nun) One of the regulatory proteins found in the thin filaments of muscle fibres (p. 302)

TSH See *thyroid-stimulating hormone*. (p. 227)

T tubule See *transverse tubule*. (p. 304)

tubular maximum (T_m) The maximum amount of a substance that the renal tubular cells can actively transport within a given time period; the kidney cells' equivalent of transport maximum (p. 579)

tubular reabsorption The selective transfer of substances from tubular fluid into peritubular capillaries during urine formation (p. 565)

tubular secretion The selective transfer of substances from peritubular capillaries into the tubular lumen during urine formation (p. 565)

twitch A brief, weak contraction that occurs in response to a single action potential in a muscle fibre (p. 309)

twitch summation The addition of two or more muscle twitches as a result of rapidly repetitive stimulation, resulting in greater tension in the fibre than that produced by a single action potential (p. 311)

tympanic membrane (tim-PAN-ik) The eardrum, which is stretched across the entrance to the middle ear and which vibrates when struck by sound waves funnelled down the external ear canal (p. 172)

Type I alveolar cells (al-VĒ-ō-lur) The single layer of flattened epithelial cells that forms the wall of the alveoli within the lungs (p. 503)

Type 1 diabetes mellitus A form of diabetes mellitus; an autoimmune disease that results in the permanent destruction of insulin-producing beta cells of the pancreas; also known as insulin-dependent, or juvenile onset, diabetes (p. 278)

Type 2 diabetes mellitus A metabolic disorder characterized by insulin resistance, relative insulin deficiency, and hyperglycaemia; also known as non-insulin-dependent, or maturity-onset, diabetes (p. 278)

U

ultrafiltration The net movement of a protein-free plasma out of the capillary into the surrounding interstitial fluid (p. 409)

umami taste A taste, first identified and named by a Japanese researcher, that is triggered by amino acids, especially glutamate. The presence of amino acids, as found in meat, for example, serves as a marker for a desirable, nutritionally protein-rich food. (p. 184)

urethra (yū-RĒ-thruh) A tube that carries urine from the bladder to outside the body (p. 560)

urine excretion The elimination of substances from the body in the urine; anything filtered or secreted and not reabsorbed is excreted (p. 565)

use-dependent competition Competition for a binding site that is based on use (p. 119)

utricle One of two otolith organs housed within a bony chamber situated between the semicircular canals and the cochlea (p. 178)

V

vagus nerve (VĀ-gus) The tenth cranial nerve, which serves as the major parasympathetic nerve (p. 110)

varicosities Swellings on the terminal branches of autonomic fibres that simultaneously release neurotransmitter over a large area of the innervated organ, rather than on single cells (p. 188)

vasoconstriction (vā-zō-kun-STRIK-shun) The narrowing of a blood vessel lumen due to contraction of the vascular circular smooth muscle (p. 395)

vasodilation The enlargement of a blood vessel lumen due to relaxation of the vascular circular smooth muscle (p. 395)

vasopressin (vā-zō-PRES-sin) A hormone secreted by the hypothalamus, then stored and released from the posterior pituitary; increases the permeability of the distal and collecting tubules of the kidneys to water and promotes arteriolar vasoconstriction; also known as *antidiuretic hormone (ADH)* (p. 592)

veins Vessels that carry blood toward the heart (p. 346)

venae cavae (*vena cava*, singular) (VĒ-nah CĀV-ah; VĒ-nē cāv-ē) Two large veins (superior and inferior) that empty blood into the right atrium (p. 347)

venous return (VĒ-nus) The volume of blood returned to each atrium per minute from the veins (p. 414)

venous sinuses Cavities between the different layers of the brain through which venous blood drains (p. 98)

ventilation The mechanical act of moving air in and out of the lungs; breathing (p. 500)

ventral corticospinal tract Descending pathway that originates in the motor region of the cerebral cortex, then travels down the ventral portion of the spinal cord, and terminates in the spinal cord on the cell bodies of efferent motor neurons supplying skeletal muscles (p. 103)

ventral (anterior) horn The ventral column of grey matter in the spinal cord when viewed in cross-section; contains cell bodies of the efferent motor neurons supplying skeletal muscles (p. 103)

ventral root Area where efferent fibres carrying outgoing signals to skeletal muscles exit the spinal cord (p. 103)

ventral spinocerebellar tract Ascending pathway that originates in the spinal cord, runs up the ventral margin of the cord, has several synapses along the way, and eventually terminates in the cerebellum (p. 103)

ventricles (VEN-tri-kul) Lower chambers of the heart that pump blood into the arteries (p. 98)

vesicular transport Movement of large molecules or multimolecular materials into or out of the cell by being enclosed in a vesicle, as in endocytosis or exocytosis (p. 46)

vestibular apparatus (veh-STIB-yuh-lur) The component of the inner ear that provides information essential for the sense of equilibrium and for coordinating head movements with eye and postural movements; consists of the semicircular canals, utricle, and saccule (p. 178)

vestibular membrane Forms the ceiling of the cochlear duct and separates it from the scala vestibuli (p. 172)

vestibular nerve One of the two branches of the vestibulocochlear nerve, the cochlear nerve being the other; transmits information from the semicircular canals to the vestibular ganglion; receives positional information (p. 178)

vestibular nuclei A cluster of neuronal cell bodies in the brain stem to which signals arising from the various components of the vestibular apparatus are carried through the vestibulocochlear nerve (p. 180)

vestibulocerebellum Part of the brain that helps maintain balance and controls eye movements (p. 121)

vestibulocochlear nerve Nerve that contains both the auditory nerve and the vestibular nerve (p. 178)

villi (*villus*, singular) (VIL-us) Microscopic finger-like projections from the inner surface of the small intestine (p. 679)

virulence (VIR-you-lentz) The disease-producing power of a pathogen (p. 460)

visceral afferent A pathway coming into the central nervous system that carries subconscious information derived from the internal viscera (p. 142)

visceral smooth muscle (VIS-uh-rul) See *single-unit smooth muscle*. (p. 328)

viscosity (vis-KOS-i-tē) The friction developed between molecules of a fluid as they slide over each other during flow of the fluid; the greater the viscosity, the greater the resistance to flow (p. 387)

visual field Area that the eyes view, with each eye having a slightly different vantage point and also tremendous overlap at the same time; overlap giving rise to binocular field of vision, important for depth perception (p. 165)

vital capacity (VC) The maximum volume of air that can be moved out during a single breath following a maximal inspiration (p. 519)

vitreous humour A semifluid, jelly-like substance located in the larger posterior cavity between the lens and retina; important in maintaining the spherical shape of the eyeball (p. 153)

vomer nasal organ (VNO) Organ located about 15 mm inside the human nose next to the vomer bone; common in other mammals, and until recently thought to be nonexistent in humans (p. 186)

voltage-gated channels Channels in the plasma membrane that open or close in response to changes in membrane potential (p. 58)

W

wavelength The distance between two wave peaks (p. 155)

Wernicke's area Receives input from the visual cortex in the occipital lobe, a pathway important in reading comprehension and in describing objects seen, as well as from the auditory cortex in the temporal lobe, a pathway essential for understanding spoken words. Wernicke's area also receives input from the somatosensory cortex, a pathway important in the ability to read Braille (p. 132)

white matter The portion of the central nervous system composed of myelinated nerve fibres (p. 103)

withdrawal reflex A polysynaptic spinal reflex intended to protect the body from damaging stimuli; causes stimulation of sensory, association, and motor neurons (p. 107)

working memory Capacity to temporarily hold and interrelate various pieces of information relevant to a current mental task; involves briefly holding and processing data for immediate use—both newly acquired information and related, previously stored, transiently brought forth, knowledge—and enables the evaluation of incoming data in context (p. 126)

Z

Z line A flattened disclike cytoskeletal protein that connects the thin filaments of two adjoining sarcomeres (p. 300)

zona fasciculata (zō-nah fa-SIK-ū-lah-ta) The middle and largest layer of the adrenal cortex; major source of cortisol (p. 254)

zona glomerulosa (glō-MER-yū-lō-sah) The outermost layer of the adrenal cortex; sole source of aldosterone (p. 254)

zona reticularis (ri-TIK-yuh-lair-us) The innermost layer of the adrenal cortex; produces cortisol, along with the zona fasciculata (p. 254)

1.1 | Introduction to Physiology (pp. 3–4)

- Physiology is the study of body functions.
- Physiologists explain body function in terms of the mechanisms of action involving cause-and-effect sequences of physical and chemical processes.
- Physiology and anatomy are closely interrelated because body functions are highly dependent on the structures of the body parts that carry them out.

1.2 | Levels of Organization in the Body (pp. 4–8)

- The human body is a complex combination of specific atoms and molecules.
- These nonliving chemical components are organized in a precise way to form cells, the smallest entities capable of carrying out the processes associated with life. Cells are the basic structural and functional living building blocks of the body. (*Review Figure 1-1.*)
- The basic functions performed by each cell for its own survival include (1) obtaining oxygen and nutrients, (2) performing energy-generating chemical reactions, (3) eliminating wastes, (4) synthesizing proteins and other cell components, (5) controlling movement of materials between the cell and its environment, (6) moving materials throughout the cell, (7) responding to the environment, and (8) reproducing.
- In addition to its basic functions, each cell in a multicellular organism performs a specialized function.
- Combinations of cells of similar structure and specialized function form the four primary tissues of the body: muscle, nervous, epithelial, and connective.
- Glands are derived from epithelial tissue and specialized for secretion. Exocrine glands secrete through ducts to the body surface or a cavity that communicates with the outside; endocrine glands secrete hormones into the blood. (*Review Figure 1-2.*)
- Organs are combinations of two or more types of tissues that act together to perform one or more functions. An example is the stomach.
- Body systems are collections of organs that perform related functions and interact to accomplish a common activity essential for survival of the whole body. An example is the digestive system. (*Review Figure 1-3.*)
- Organ systems combine to form the organism, or whole body.

1.3 | Concepts of Homeostasis (pp. 9–13)

- The fluid inside the cells of the body is intracellular fluid; the fluid outside the cells is extracellular fluid.

- Because most body cells are not in direct contact with the external environment, cell survival depends on maintaining a relatively stable internal fluid environment with which the cells directly make life-sustaining exchanges.
- The extracellular fluid serves as the internal environment. It consists of the plasma and interstitial fluid. (*Review Figure 1-4.*)
- Homeostasis is the maintenance of a dynamic, steady state in the internal environment.
- The factors of the internal environment that must be homeostatically maintained are its (1) concentration of nutrient molecules; (2) concentration of oxygen and carbon dioxide; (3) concentration of waste products; (4) pH; (5) concentration of water, salt, and other electrolytes; (6) volume and pressure; and (7) temperature.
- The functions performed by the body systems are directed toward maintaining homeostasis. The body systems' functions ultimately depend on the specialized activities of the cells that make up each system. Thus, homeostasis is essential for each cell's survival, and each cell contributes to homeostasis. (*Review Figure 1-5.*)

1.4 | Homeostatic Control Systems (pp. 14–16)

- A homeostatic control system is a network of body components working together to maintain a given factor in the internal environment relatively constant near an optimal set level.
- Homeostatic control systems can be classified as (1) intrinsic (local) controls, which are inherent compensatory responses of an organ to a change; and (2) extrinsic controls, which are responses of an organ triggered by factors external to the organ, namely by the nervous and endocrine systems.
- Both intrinsic and extrinsic control systems generally operate on the principle of negative feedback: A change in a controlled variable triggers a response that drives the variable in the opposite direction of the initial change, thus opposing the change. (*Review Figure 1-6.*)
- In positive feedback, a change in a controlled variable triggers a response that drives the variable in the same direction as the initial change, thus amplifying the change.
- Feedforward mechanisms are compensatory responses that occur in anticipation of a change.
- Pathophysiological states ensue when one or more of the body systems fail to function properly and, therefore, an optimal internal environment can no longer be maintained. Serious homeostatic disruption leads to death.

Sebastian Kaufftz/Shutterstock.com

- The complex organization and interaction of the chemicals within a cell confer the unique characteristics of life.
- Cells are the living building blocks of the body.

2.1 | Observation of Cells (p. 22)

- Cells are too small for the unaided eye to see.
- Using early microscopes, investigators learned that all plant and animal tissues consist of individual cells.
- Through more sophisticated techniques, scientists now know that a cell is a complex, highly organized, compartmentalized structure.

2.2 | An Overview of Cell Structure (p. 22)

- Cells have three major subdivisions: the plasma membrane, the nucleus, and the cytoplasm. (*Review Table 2-2.*)
- The plasma membrane encloses the cell and separates the intracellular and extracellular fluid.
- The cytoplasm consists of cytosol, a complex gel-like mass laced with a cytoskeleton, and organelles, which are highly organized, membrane-enclosed structures dispersed within the cytosol.

2.3 | Cellular Metabolism (pp. 22–29)

- The rod-shaped mitochondria are the energy organelles of the cell. They house the enzymes of the citric acid cycle (in the mitochondrial matrix) and electron transport chain (on the cristae of the mitochondrial inner membrane). Together, these two biochemical processes efficiently convert the energy in food molecules to the usable energy stored in ATP molecules. (*Review Figures 2-1, 2-2, and 2-3.*)
- During this process, which is known as *oxidative phosphorylation*, the mitochondria use molecular O_2 and produce CO_2 and H_2O as by-products.
- A cell is more efficient at converting food energy into ATP when oxygen is available. In an anaerobic (without O_2) condition, a cell can produce only two molecules of ATP for every glucose molecule processed by means of glycolysis, which takes place in the cytosol. In an aerobic (with O_2) condition, the mitochondria further degrade the products of glycolysis to yield another 34 molecules of ATP for every glucose molecule processed.
- Cells use ATP as an energy source for synthesis of new chemical compounds, for membrane transport, and for mechanical work.

2.4 | The Plasma Membrane (pp. 29–33)

- All cells are bounded by a plasma membrane, a thin lipid bilayer in which proteins are interspersed and to which carbohydrates are attached on the outer surface.
- The electron microscopic appearance of the plasma membrane as a trilaminar structure (two dark lines separated by a light interspace) is caused by the arrangement of the molecules composing it. The phospholipids orient themselves to form a

bilayer with a hydrophobic interior (light interspace) sandwiched between the hydrophilic outer and inner surfaces (dark lines). (*Review Figures 2-6, 2-7, and 2-8.*)

- This lipid bilayer forms the structural boundary of the cell, serving as a barrier for water-soluble substances and being responsible for the fluid nature of the membrane.
- Cholesterol molecules tucked between the phospholipids contribute to the fluidity and stability of the membrane.
- According to the fluid mosaic model of membrane structure, the lipid bilayer is embedded with proteins. (*Review Figure 2-8.*) Membrane proteins, which vary in type and distribution among cells, serve as (1) channels for passage of small ions across the membrane, (2) carriers for transport of specific substances in or out of the cell, (3) docking-marker acceptors for fusion with and subsequent exocytosis of secretory vesicles, (4) membrane-bound enzymes that govern specific chemical reactions, (5) receptors for detecting and responding to chemical messengers that alter cell function, and (6) cell adhesion molecules that help hold cells together and serve as a structural link between the extracellular surroundings and intracellular cytoskeleton.
- The membrane carbohydrates, short sugar chains that project from the outer surface only, serve as self-identity markers. (*Review Figure 2-8.*) They are important in the recognition of “self” in cell-to-cell interactions, such as tissue formation and tissue growth.

2.5 | Cell-to-Cell Adhesions (pp. 34–36)

- Special cells locally secrete a complex extracellular matrix (ECM), which serves as a biological glue between the cells of a tissue.
- The ECM consists of a watery, gel-like substance interspersed with three major types of protein fibres: collagen, elastin, and fibronectin.
- Many cells are further joined by specialized cell junctions, of which there are three types: desmosomes, tight junctions, and gap junctions.
- Desmosomes serve as adhering junctions to hold cells together mechanically and are especially important in tissues subject to a great deal of stretching. (*Review Figure 2-9.*)
- Tight junctions actually fuse cells together to seal off passage between cells, thereby permitting only regulated passage of materials through the cells. These impermeable junctions are found in the epithelial sheets that separate compartments with very different chemical compositions. (*Review Figure 2-10.*)
- Gap junctions are communicating junctions between two adjacent, but not touching, cells. Cells joined by gap junctions are connected by small tunnels that permit exchange of ions and small molecules between the cells. Such movement of ions plays a key role in the spread of electrical activity to synchronize contraction in heart and smooth muscle. (*Review Figure 2-11.*)

2.6 | Overview of Membrane Transport (pp. 36–37)

- Materials can pass between the ECF and ICF by unassisted and assisted means.
- Transport mechanisms may also be passive (the particle moves across the membrane without the cell expending energy) or active (the cell expends energy to move the particle across the membrane).

2.7 | Unassisted Membrane Transport (pp. 37–41)

- Lipid-soluble particles and ions can cross the membrane unassisted. Nonpolar (lipid-soluble) molecules of any size can dissolve in and passively pass through the lipid bilayer down concentration gradients by means of the process of diffusion. (Review Figures 2-12 and 2-13.) Small ions traverse the membrane passively down electrochemical gradients through open protein channels specific for the ion.
- Osmosis is a special case of water passively moving down its own concentration gradient to an area of higher solute concentration. (Review Figures 2-14 through 2-18.)

2.8 | Assisted Membrane Transport (pp. 41–51)

- Carrier mechanisms are important for the assisted transfer of small polar molecules and for selected movement of ions across the membrane.
- In carrier-mediated transport, the particle is transported across by specific membrane carrier proteins. Carrier-mediated transport may be passive and move the particle down its concentration gradient (facilitated diffusion), or active and move the particle against its concentration gradient (active transport). (Review Figures 2-19 through 2-22.)
- A given carrier can move a single specific substance in one direction, two substances in opposite directions, or two substances in the same direction. Primary active transport requires the direct use of ATP to drive the pump, whereas secondary active transport is driven by an ion concentration gradient established by a primary active transport system. (Review Figures 2-21 and 2-22.)
- Large polar molecules and multimolecular particles can leave or enter the cell by being wrapped in a piece of membrane to form vesicles that can be internalized (endocytosis) or externalized (exocytosis). (Review Figures 2-23 and 2-24.)
- Cells are differentially selective in what enters or leaves because they possess varying numbers and kinds of channels, carriers, and mechanisms for vesicular transport.
- Large polar molecules (too large for channels and not lipid soluble) for which there are no special transport mechanisms are unable to permeate.

2.9 | Intercellular Communication and Signal Transduction (pp. 51–54)

- The coordination of the diverse activities of cells throughout the body to accomplish life-sustaining and other desired activities depends on the ability of cells to communicate with one another.

2.10 | Membrane Potential (pp. 54–59)

- This potential enables cellular communication in nervous tissue and muscle, and is made possible via the separation of opposite charges. The separation of charges is based on the difference in the relative number of cations (+) and anions (–) in the ICF and ECF.

2.11 | Graded Potentials (pp. 59–61)

- Graded potentials are local changes in membrane potential that occur in varying grades of magnitude or strength, do not travel long distances, and diminish in strength as they travel. Graded potentials may or may not result in an action potential.

2.12 | Action Potentials (pp. 61–71)

- Action potentials are brief, rapid, large changes in membrane potential during which the potential actually reverses, so that the inside of the excitable cell transiently becomes more positive than the outside.

2.13 | Regeneration of Nerve Fibres (pp. 72–73)

- Peripheral nervous system axons that are cut can regenerate, whereas those in the central nervous system cannot.
- Regeneration of peripheral axons is made possible by Schwann cells. In a peripheral nerve axon, the portion of the axon farthest from the cell body degenerates and is removed by the Schwann cells, which remain and form a regeneration tube to guide the restoration of the new nerve fibre to its proper destination.

2.14 | Synapses and Neuronal Integration (pp. 74–83)

- The axon, or nerve fibre (the conducting zone), conducts action potentials in undiminished fashion from the axon hillock to the axon terminals. The axon terminal (the output zone) serves as the presynaptic component, releasing a neurotransmitter that influences other postsynaptic cells in response to action potential propagation down the axon.
- The released neurotransmitter combines with receptor channels on the postsynaptic neuron. (Review Figure 2-44.) (1) If non-specific cation channels that permit passage of both Na^+ and K^+ are opened, the resultant ionic fluxes cause an EPSP, a small depolarization that brings the postsynaptic cell closer to threshold. (2) If either K^+ or Cl^- channels are opened, the likelihood that the postsynaptic neuron will reach threshold is diminished when an IPSP, a small hyperpolarization, is produced. (Review Figure 2-45.)
- If the dominant activity is in its excitatory inputs, the postsynaptic cell will likely be brought to threshold and have an action potential. This can be accomplished by either (1) temporal summation (EPSPs from a single, repetitively firing, presynaptic input occurring so close together in time that they add together) or (2) spatial summation (adding of EPSPs occurring simultaneously from several different presynaptic inputs). (Review Figure 2-46.) If inhibitory inputs dominate, the postsynaptic potential is brought farther than usual from threshold. If excitatory and inhibitory activity to the postsynaptic neuron is balanced, the membrane remains close to resting.

3.1 | Organization of the Nervous System (pp. 92–93)

- The nervous system consists of the central nervous system (CNS), which includes the brain and spinal cord, and the peripheral nervous system, which includes the nerve fibres carrying information to (afferent division) and from (efferent division) the CNS. (Review Figure 3-1.)
- Three functional classes of neurons—afferent neurons, efferent neurons, and interneurons—compose the excitable cells of the nervous system. (Review Figure 3-2.) (1) Afferent neurons inform the CNS about conditions in both the external and internal environment; (2) efferent neurons carry instructions from the CNS to effector organs—namely, muscles and glands; (3) interneurons are responsible for integrating afferent information and formulating an efferent response, as well as for all higher mental functions associated with the human mind.

3.2 | Structure and Function of the Central Nervous System (pp. 93–94)

- Even though no part of the brain acts in isolation of other brain regions, the brain is organized into networks of neurons within discrete locations that are ultimately responsible for carrying out particular tasks.
- The parts of the brain from the lowest, most primitive level to the highest, most sophisticated level are the brain stem, cerebellum, hypothalamus, thalamus, basal ganglia, and cerebral cortex. (Review Table 3-1 and Figure 3-7.)

3.3 | Protection of the Central Nervous System (pp. 95–101)

- Glial cells form the connective tissue within the CNS and physically, metabolically, and functionally support the neurons.
- The four types of glial cells are the astrocytes, oligodendrocytes, microglia, and ependymal cells. (Review Figure 3-3 and Table 3-2.)
- The brain has several protective devices, which is important because neurons cannot divide to replace damaged cells. (1) The brain is wrapped in three layers of protective membranes—the meninges—and is further surrounded by a hard, bony covering. (2) Cerebrospinal fluid flows within and around the brain to cushion it against physical jarring (review Figure 3-6). (3) Protection against chemical injury is conferred by a blood–brain barrier that limits access of blood-borne substances to the brain.
- The brain depends on a constant blood supply for delivery of oxygen and glucose because it cannot generate ATP in the absence of either of these substances.

3.4 | Spinal Cord (pp. 101–109)

- The spinal cord has two vital functions. (1) It serves as the neuronal link between the brain and the peripheral nervous

system. All communication up and down the spinal cord occurs through ascending and descending tracts in the cord's outer white matter. (Review Figures 3-10 and 3-11.) (2) It is the integrating centre for spinal reflexes, including some of the basic protective and postural reflexes and those involved with the emptying of the pelvic organs. (Review Figures 3-15 and 3-17.)

- The basic reflex arc includes a receptor, an afferent pathway, an integrating centre, an efferent pathway, and an effector. (Review Figure 3-15.) The centrally located grey matter of the spinal cord contains the interneurons interposed between the afferent input and efferent output as well as the cell bodies of efferent neurons. (Review Figures 3-9 and 3-12.)

3.5 | Brain Stem (pp. 109–112)

- The brain stem is an important link between the spinal cord and higher brain levels.
- The brain stem is the origin of the cranial nerves. (Review Figure 3-18.) It also contains centres that control cardiovascular, respiratory, and digestive function; regulates postural muscle reflexes; controls the overall degree of cortical alertness; and plays a key role in the sleep–wake cycle.
- The prevailing state of consciousness depends on the cyclical interplay among (1) an arousal system (the reticular activating system) originating in the brain stem, (2) a slow-wave sleep centre in the hypothalamus, and (3) a paradoxical sleep centre in the brain stem. (Review Figure 3-19.)

3.6 | Thalamus and Hypothalamus (pp. 112–113)

- The thalamus and hypothalamus are deep subcortical brain structures that interact extensively with the cortex in performing their functions. (Review Figure 3-20)
- The thalamus serves as a relay station for preliminary processing of sensory input on its way to the cortex. It also accomplishes a crude awareness of sensation and some degree of consciousness.
- The hypothalamus regulates many homeostatic functions, in part through its extensive control of the autonomic nervous system and endocrine system.

3.7 | Cerebral Cortex (pp. 113–121)

- The cerebral cortex is the outer shell of grey matter that caps an underlying core of white matter. The white matter consists of bundles of nerve fibres that interconnect various cortical regions with other areas. (Review Figure 3-28.) The cortex itself consists primarily of neuronal cell bodies, dendrites, and glial cells.
- Ultimate responsibility for many discrete functions is localized in particular regions of the cortex as follows: (1) the occipital lobes house the visual cortex; (2) the auditory cortex is in the temporal lobes; (3) the parietal lobes are responsible for

reception and perceptual processing of somatosensory (somesthetic and proprioceptive) input; and (4) voluntary motor movement is set into motion by the frontal lobe, where the primary motor cortex and higher motor areas are located. (Review Figures 3-22 through 3-24.)

3.8 | Cerebellum (pp. 121–122)

- The vestibulocerebellum helps maintain balance and controls eye movements.
- The spinocerebellum enhances muscle tone and helps coordinate voluntary movement, especially fast, phasic motor activities.
- The cerebrocerebellum plays a role in initiating voluntary movement and in storing procedural memories. (Review Figure 3-27.)

3.9 | Basal Ganglia (pp. 123–124)

- The basal ganglia consist of several masses of grey matter and are associated with motor control, cognition, emotions, and learning. (Review Figure 3-28)
- The basal ganglia inhibit muscle tone; coordinate slow, sustained postural contractions; and suppress useless patterns of movement.

3.10 | The Limbic System and Its Functional Relations with the Higher Cortex (pp. 124–126)

- The limbic system, which includes portions of the hypothalamus and other forebrain structures that encircle the brain stem, is responsible for emotion as well as for basic, inborn behavioural patterns related to survival and perpetuation of the species. It also plays an important role in motivation and learning. (Review Figure 3-29.)

3.11 | Learning, Memory, and Language (pp. 126–134)

- There are two types of memory: (1) a short-term memory with limited capacity and brief retention, coded by modification

of activity at pre-existing synapses; and (2) a long-term memory with large storage capacity and enduring memory traces, involving relatively permanent structural or functional changes, such as the formation of new synapses, between existing neurons. (Review Table 3-3 and Figures 3-30 and 3-31.)

- The hippocampus and associated structures are especially important in declarative, or “what,” memories of specific objects, facts, and events.
- The cerebellum and associated structures are especially important in procedural, or “how to,” memories of motor skills gained through repetitive training.
- The prefrontal association cortex is the site of working memory, which temporarily holds currently relevant data—both new information and knowledge retrieved from memory stores. It manipulates and relates this information to accomplish the higher-reasoning processes of the brain.
- Language ability depends on the integrated activity of two primary language areas—Broca’s area and Wernicke’s area—typically located only in the left cerebral hemisphere. (Review Figure 3-32.)

3.12 | Sleep (pp. 134–136)

- Sleep is an active process, not just the absence of wakefulness. While sleeping, a person cyclically alternates between slow-wave sleep and paradoxical sleep. (Review Table 3-4.)
- Slow-wave sleep is characterized by slow waves on the EEG and little change in behaviour pattern from the waking state, except for not being aware of the external world. (Review Figure 3-34.)
- Paradoxical, or REM, sleep is characterized by an EEG pattern similar to that of an alert, awake individual. Rapid eye movements, dreaming, and abrupt changes in behaviour pattern occur. (Review Figure 3-34.)

4.1 | Introduction (p. 141)

- The peripheral nervous system links the periphery and the central nervous system. It is divided into the afferent division and efferent division.

4.2 | The Peripheral Nervous System: Afferent Division (pp. 142–143)

- The afferent division of the peripheral nervous system carries information about the internal and external environment to the CNS.
- Sensory information, afferent information that reaches the level of conscious awareness, includes (1) somatic sensation (somesthetic sensation and proprioception) and (2) special senses.
- Perception is the conscious interpretation of the external world that the brain creates from sensory input.

4.3 | Receptor Physiology (pp. 143–149)

- A stimulus brings about a graded, depolarizing receptor potential by altering the receptor's membrane permeability. Receptor potentials, if of sufficient magnitude, generate action potentials in the afferent neuronal membrane next to the receptor by opening Na^+ channels in this region. These action potentials self-propagate along the afferent neuron to the CNS. (Review Figure 4-2.)
- Receptor potential size is also influenced by the extent of receptor adaptation, which is a reduction in receptor potential despite sustained stimulation. (1) Tonic receptors adapt slowly or not at all and thus provide continuous information about the stimuli they monitor. (2) Phasic receptors adapt rapidly and frequently exhibit off responses, thereby providing information about changes in the energy form they monitor. (Review Figure 4-4.)
- The term *receptive field* refers to the area surrounding a receptor within which the receptor can detect stimuli. The acuity, or discriminative ability, of a body region varies inversely with the size of its receptive fields and also depends on the extent of lateral inhibition in the afferent pathways arising from receptors in the region. (Review Figure 4-5.)

4.4 | Pain (pp. 149–152)

- Painful experiences are elicited by noxious mechanical, thermal, or chemical stimuli and consist of two components: (1) the perception of pain and (2) the emotional and behavioural responses to it.
- Three categories of nociceptors, or pain receptors, respond to these stimuli: mechanical nociceptors, thermal nociceptors, and chemical nociceptors.
- Pain signals are transmitted over two afferent pathways: (1) a fast pain pathway that carries sharp, prickling pain signals; and (2) a slow pain pathway that carries dull, aching, persistent pain signals. (Review Table 4-2.)

- Afferent pain fibres terminate in the spinal cord on ascending pathways that transmit the signal to the brain for processing. (Review Figure 4-6.)

- Descending pathways from the brain use endogenous opiates to suppress the release of substance P, a pain-signalling neurotransmitter from the afferent pain-fibre terminal. Thus, these descending pathways block further transmission of the pain signal and serve as a built-in analgesic system. (Review Figure 4-6.)

4.5 | Eye: Vision (pp. 152–169)

- Light is a form of electromagnetic radiation that travels in wavelike fashion, with visible light being only a small band in the total electromagnetic spectrum. (Review Figures 4-10 and 4-11.)
- The eye is a specialized structure housing the light-sensitive receptors essential for vision perception—namely, the rods and cones found in its retinal layer. (Review Table 4-4 and Figures 4-7 and 4-19.)
- The cornea and lens are the primary refractive structures that bend the incoming light rays to focus the image on the retina. The cornea contributes most to the total refractive ability of the eye. The strength of the lens can be adjusted through action of the ciliary muscle to accommodate for differences in near and far vision. (Review Figures 4-12 through 4-14.)
- The rod and the cone photoreceptors are activated when the photopigments they contain differentially absorb various wavelengths of light. Light absorption causes a change in the rate of action potential propagation in the visual pathway leaving the retina. The conversion of light stimuli into electrical signals is known as *phototransduction*. (Review Figures 4-16, 4-19, 4-20, and 4-21.)
- The visual message is transmitted via a complex crossed and uncrossed pathway to the visual cortex in the occipital lobe of the brain for perceptual processing. (Review Figure 4-24.)
- The eyes' sensitivity is increased during dark adaptation, by the regeneration of rod photopigments that had been broken down during preceding light exposure. Sensitivity is decreased during light adaptation by the rapid breakdown of cone photopigments.

4.6 | Ear: Hearing and Equilibrium (pp. 169–181)

- Sound waves consist of high-pressure regions of compression alternating with low-pressure regions of rarefaction of air molecules. The pitch (tone) of a sound is determined by the frequency of its waves, the loudness (intensity) by the amplitude of the waves, and the timbre (quality) by its characteristic overtones. (Review Figures 4-26 and 4-27 and Table 4-5.)
- Sound waves are funnelled through the external ear canal to the tympanic membrane, which vibrates in synchrony with the waves.

- Middle ear bones bridging the gap between the tympanic membrane and the inner ear amplify the tympanic movements and transmit them to the oval window, whose movement sets up travelling waves in the cochlear fluid. (Review Figures 4-28 and 4-29.) This sets the basilar membrane in motion. (Review Figure 4-29.)

- On top of the basilar membrane are the receptive inner hair cells of the organ of Corti, whose hairs bend when the basilar membrane deflects up and down in relation to the overhanging stationary tectorial membrane that the hairs contact. (Review Figures 4-28 and 4-30.)

- Neural signals are generated in response to the mechanical deformation of hair cells by specific movement of fluid and related structures within these vestibular sense organs. This information is important for the sense of equilibrium and for maintaining posture. (Review Figures 4-34 and 4-35.)

- Vestibular input goes to the vestibular nuclei in the brain stem and to the cerebellum for use in maintaining balance and posture, controlling eye movement, and perceiving motion and orientation. (Review Figure 4-36.)

4.7 | Chemical Senses: Taste and Smell (pp. 181–187)

- Taste receptors are housed in taste buds on the tongue; olfactory receptors are located in the olfactory mucosa in the upper part of the nasal cavity. (Review Figures 4-37 and 4-38.)

- The five primary tastes are salty, sour, sweet, bitter, and umami. The recently added fifth taste is a meaty, “amino-acid” taste. Taste discrimination beyond the primary tastes depends on the patterns of stimulation of the taste buds, each of which responds in varying degrees to the different primary tastes.

- There are 1000 different types of olfactory receptors, each of which responds to only one discrete component of an odour, an odourant. The afferent signals arising from the olfactory receptors are sorted according to scent component by the glomeruli within the olfactory bulb. Odour discrimination depends on the patterns of activation of the glomeruli. (Review Figure 4-39.)

4.8 | The Peripheral Nervous System: Efferent Division (p. 187)

- There are two types of efferent output: (1) the autonomic nervous system, which is under involuntary control and supplies cardiac and smooth muscle as well as most exocrine and some endocrine glands; and (2) the somatic nervous system, which

is subject to voluntary control and supplies skeletal muscle. (Review Tables 4-10 and 4-11.)

4.9 | Autonomic Nervous System (pp. 187–194)

- The ANS consists of two subdivisions: the sympathetic and parasympathetic nervous systems. (Review Figures 4-41 and 4-42 and Tables 4-8 and 4-9.)

- An autonomic nerve pathway consists of a two-neuron chain. The preganglionic fibre originates in the CNS and synapses with the cell body of the postganglionic fibre in a ganglion outside the CNS. The postganglionic fibre ends on the effector organ. (Review Figures 4-40 and 4-41 and Table 4-9.)

- Tissues innervated by the ANS possess one or more of several different receptor types for the postganglionic chemical messengers. Cholinergic receptors include nicotinic and muscarinic receptors; adrenergic receptors include α_1 , α_2 , β_1 , and β_2 receptors. (Review Figure 4-45 and Table 4-9.)

- The sympathetic system dominates in emergency or stressful (fight-or-flight) situations and promotes responses that prepare the body for strenuous physical activity. The parasympathetic system dominates in quiet, relaxed (rest-and-digest) situations and promotes body-maintenance activities, such as digestion. (Review Tables 4-8 and 4-9.)

- Autonomic activities are controlled by multiple areas of the CNS, including the spinal cord, medulla, hypothalamus, and prefrontal association cortex.

4.10 | Somatic Nervous System (pp. 194–196)

- The somatic nervous system consists of the axons of motor neurons, which originate in the spinal cord or brain stem and end on skeletal muscle. (Review Table 4-10.)

- Acetylcholine, the neurotransmitter released from a motor neuron, stimulates muscle contraction.

4.11 | Neuromuscular Junction (pp. 197–201)

- Each axon terminal of a motor neuron forms a neuromuscular junction with a single muscle cell (fibre). (Review Figure 4-44 and Table 4-12.)

- An action potential in the axon terminal causes the release of ACh from its storage vesicles. The released ACh diffuses across the space separating the nerve and muscle cell and binds to special receptor sites on the underlying motor end plate of the muscle cell membrane. This combination of ACh with the receptors triggers the opening of specific channels in the motor end plate. The subsequent ion movements depolarize the motor end plate, producing the end-plate potential (EPP). (Review Figure 4-45.)

- Local current flow between the depolarized end plate and adjacent muscle cell membrane brings these adjacent areas to threshold, initiating an action potential that is propagated throughout the muscle fibre.

- This muscle action potential triggers muscle contraction.

- Acetylcholinesterase inactivates ACh, ending the EPP and, subsequently, the action potential and resultant contraction. (Review Figure 4-45.)

5.1 | General Principles of Endocrinology (pp. 209–214)

- Hormones are long-distance chemical messengers secreted by the ductless endocrine glands into the blood, which transports the hormones to specific target sites where they control a particular function by altering protein activity within target cells.
- Hormones are grouped into two categories based on differences in their solubility and are further grouped according to their chemical structure: hydrophilic hormones (peptide hormones and catecholamines), and lipophilic hormones (steroid hormones and thyroid hormone).
- The endocrine system is especially important in regulating organic metabolism, water and electrolyte balance, growth, and reproduction and in helping the body cope with stress. (Review Figure 5-1 and Table 5-2.)
- Some hormones are tropic, meaning their function is to stimulate and maintain other endocrine glands.
- The effective plasma concentration of each hormone is normally controlled by regulated changes in the rate of hormone secretion. Secretory output of endocrine cells is primarily influenced by two types of direct regulatory inputs: (1) neural input, which increases hormone secretion in response to a specific need and governs diurnal variations in secretion; and (2) input from another hormone, which involves either stimulatory input from a tropic hormone or inhibitory input from a target-cell hormone in negative-feedback fashion. (Review Figures 5-2, 5-3, and 5-12.)
- The effective plasma concentration of a hormone can also be influenced by its rate of removal from the blood by metabolic inactivation and excretion and, for some hormones, by its rate of activation or its extent of binding to plasma proteins.
- Endocrine dysfunction arises when too much or too little of any particular hormone is secreted or when there is decreased target-cell responsiveness to a hormone. (Review Table 5-1.)

5.2 | Principles of Hormonal Communication (pp. 214–222)

- Hormones are long-distance chemical messengers secreted by the endocrine glands into the blood, which transports the hormones to specific target sites where they control a particular function by altering protein activity within the target cells.
- Hormones are grouped into two categories based on their solubility differences: (1) hydrophilic (water-soluble) hormones, which include peptides (the majority of hormones) and catecholamines (secreted by the adrenal medulla); and (2) lipophilic (lipid-soluble) hormones, which include steroid hormones (the sex hormones and those secreted by the adrenal cortex) and thyroid hormone. (Review Table 5-2.)

- Hydrophilic peptide hormones are synthesized and packaged for export by the endoplasmic reticulum/Golgi complex, stored in secretory vesicles, and released by exocytosis on appropriate stimulation.
- Hydrophilic peptide hormones dissolve freely in the plasma for transport to their target cells.
- At their target cells, hydrophilic hormones bind with surface membrane receptors. On binding, a hydrophilic hormone triggers a chain of intracellular events by means of a second-messenger system that ultimately alters pre-existing cell proteins, usually enzymes, which exert the effect leading to the target cell's response to the hormone. (Review Figures 5-5 and 5-6.)
- Steroids are synthesized by modifications of stored cholesterol by means of enzymes specific for each steroidogenic tissue. (Review Figure 5-4.)
- Steroids are not stored in the endocrine cells. Being lipophilic, they diffuse out through the lipid membrane barrier as soon as they are synthesized. Control of steroids is directed at their synthesis.
- Lipophilic steroids and thyroid hormone are both transported in the blood largely bound to carrier plasma proteins, with only free, unbound hormone being biologically active.
- Lipophilic hormones readily enter through the lipid membrane barriers of their target cells and bind with nuclear receptors. Hormonal binding activates the synthesis of new enzymatic or structural intracellular proteins that carry out the hormone's effect on the target cell. (Review Figure 5-8.)

5.3 | Comparison of the Nervous and Endocrine Systems (p. 222)

- The nervous and endocrine systems are the two main regulatory systems of the body. In general, the nervous system coordinates rapid responses, whereas the endocrine system regulates activities that require duration rather than speed.

5.4 | The Endocrine Tissues (pp. 222–225)

- The endocrine system consists of many tissues that are critical for maintaining homeostasis. Review Table 5-3 for a summary of the major endocrine tissues and their hormones.

5.5 | Hypothalamus and Pituitary (pp. 225–231)

- The pituitary gland consists of two distinct lobes, the posterior pituitary and the anterior pituitary. (Review Figure 5-9.)
- The hypothalamus, a portion of the brain, secretes nine peptide hormones. Two are stored in the posterior pituitary, and seven are carried through a special vascular link—the hypothalamic-hypophyseal portal system—to the anterior pituitary, where they regulate the release of particular anterior pituitary hormones. (Review Figures 5-10 and 5-13.)

- The posterior pituitary is essentially a neural extension of the hypothalamus. Two small peptide hormones, vasopressin and oxytocin, are synthesized within the cell bodies of neurosecretory neurons located in the hypothalamus, from which they pass down the axon to be stored in nerve terminals within the posterior pituitary. These hormones are independently released from the posterior pituitary into the blood in response to action potentials originating in the hypothalamus. (Review Figure 5-10.)

(1) Vasopressin conserves water during urine formation.

(2) Oxytocin stimulates uterine contraction during childbirth and milk ejection during breastfeeding.

- The anterior pituitary secretes six different peptide hormones that it produces itself. Five anterior pituitary hormones are tropic. (1) Thyroid-stimulating hormone (TSH) stimulates secretion of thyroid hormone. (2) Adrenocorticotropic hormone (ACTH) stimulates secretion of cortisol by the adrenal cortex. (3 and 4) The gonadotropic hormones—follicle-stimulating hormone (FSH) and luteinizing hormone (LH)—stimulate production of gametes (eggs and sperm) as well as secretion of sex hormones. (5) Growth hormone (GH) stimulates growth indirectly by stimulating secretion of somatomedins, which in turn promote growth of bone and soft tissues. GH exerts metabolic effects as well. (6) Prolactin stimulates milk secretion and is not tropic to another endocrine gland. (Review Figure 5-11.)

- The anterior pituitary releases its hormones into the blood at the bidding of releasing and inhibiting hormones from the hypothalamus. The hypothalamus, in turn, is influenced by a variety of neural and hormonal controlling inputs. (Review Table 5-4 and Figures 5-12 and 5-13.)

- Both the hypothalamus and anterior pituitary are inhibited in negative-feedback fashion by the product of the target endocrine gland in the hypothalamus–anterior pituitary–target gland axis. (Review Figure 5-12.)

5.6 | Endocrine Control of Growth (pp. 231–240)

- Growth depends not only on growth hormone and other growth-influencing hormones, such as thyroid hormone, insulin, and the sex hormones, but also on genetic determination, an

adequate diet, and freedom from chronic disease or stress. Major growth spurts occur the first few years after birth and during puberty. (Review Figure 5-14.)

- Growth hormone (GH) primarily promotes growth indirectly by stimulating the liver's production of somatomedins. The major somatomedin, or insulin-like growth factor, is IGF-I, which acts directly on bone and soft tissues to bring about most growth-promoting actions. The GH/IGF-I pathway causes growth by stimulating protein synthesis, cell division, and the lengthening and thickening of bones. (Review Figures 5-15 and 5-16.)

- Growth hormone also directly exerts metabolic effects unrelated to growth, such as conservation of carbohydrates and mobilization of fat stores. (Review Figure 5-16.)

- Growth hormone secretion by the anterior pituitary is regulated in negative-feedback fashion by two hypothalamic hormones: growth hormone–releasing hormone, and growth hormone–inhibiting hormone (somatostatin). (Review Figure 5-16.)

- Growth hormone levels are not highly correlated with periods of rapid growth. The primary signals for increased growth hormone secretion are related to metabolic needs rather than growth, namely, deep sleep, exercise, stress, low blood glucose, increased blood amino acids, or decreased blood fatty acids. (Review Figure 5-16.)

5.7 | Pineal Gland and Circadian Rhythms (pp. 240–242)

- The suprachiasmatic nucleus (SCN) is the body's master biological clock. Self-induced cyclic variations in the concentration of clock proteins within the SCN bring about cyclic changes in neural discharge from this area. Each cycle takes about a day and drives the body's circadian (daily) rhythms.

- The inherent rhythm of this endogenous oscillator is a bit longer than 24 hours. Therefore, each day the body's circadian rhythms must be entrained or adjusted to keep pace with environmental cues so that the internal rhythms are synchronized with the external light–dark cycle.

- In the eyes, special photoreceptors that respond to light but are not involved in vision send input to the SCN. Acting through the SCN, the pineal gland's secretion of the hormone melatonin rhythmically fluctuates with the light–dark cycle, decreasing in the light and increasing in the dark. Melatonin, in turn, is believed to synchronize the body's natural circadian rhythms, such as diurnal (day–night) variations in hormone secretion and body temperature, with external cues such as the light–dark cycle.

- Other proposed roles for melatonin include (1) promoting sleep; (2) influencing reproductive activity, including the onset of puberty; (3) acting as an antioxidant to remove damaging free radicals; and (4) enhancing immunity.

6.1 | Thyroid Gland (pp. 248–254)

- The thyroid gland contains two types of endocrine secretory cells: (1) follicular cells, which produce the iodine-containing hormones, T_4 (thyroxine or tetraiodothyronine) and T_3 (triiodothyronine), collectively known as thyroid hormones; and (2) C cells, which synthesize a Ca^{2+} -regulating hormone, calcitonin. (Review Figure 6-1.)

- All steps of thyroid hormone synthesis take place on the large thyroglobulin molecules within the colloid—an extracellular site located within the interior of the thyroid follicles. Thyroid hormone is secreted by means of the follicular cells phagocytizing a piece of colloid and freeing T_4 and T_3 , which diffuse across the plasma membrane and enter the blood. (Review Figures 6-1 and 6-2.)

- Thyroid hormone is the primary determinant of the overall metabolic rate of the body. By accelerating the metabolic rate of most tissues, it increases heat production. Thyroid hormone also enhances the actions of the chemical mediators of the sympathetic nervous system. Through this and other means, thyroid hormone indirectly increases cardiac output. Finally, thyroid hormone is essential for normal growth as well as the development and function of the nervous system.

- Thyroid hormone secretion is regulated by a negative-feedback system between hypothalamic TRH, anterior pituitary TSH, and thyroid gland T_3 and T_4 . The feedback loop maintains thyroid hormone levels relatively constant. Cold exposure in newborn infants is the only input to the hypothalamus known to be effective in increasing TRH and thereby thyroid hormone secretion. (Review Figure 6-3.)

6.2 | Adrenal Glands (pp. 254–263)

- Each adrenal gland (of the pair) consists of two separate endocrine organs: (1) an outer, steroid-secreting adrenal cortex; and (2) an inner, catecholamine-secreting adrenal medulla. (Review Figure 6-7.)

- The adrenal cortex secretes three different categories of steroid hormones: (1) mineralocorticoids (primarily aldosterone); (2) glucocorticoids (primarily cortisol); and (3) adrenal sex hormones (primarily the weak androgen, dehydroepiandrosterone).

- Aldosterone regulates Na^+ and K^+ balance and is important for blood pressure homeostasis, which is achieved secondarily by the osmotic effect of Na^+ in maintaining the plasma volume—a lifesaving effect.

- Control of aldosterone secretion is related to Na^+ and K^+ balance and to blood pressure regulation and is not influenced by ACTH.

- Cortisol helps regulate fuel metabolism and is important in stress adaptation. It increases blood levels of glucose, amino acids, and fatty acids and spares glucose for use by the

glucose-dependent brain. The mobilized organic molecules are available for use as needed for energy or for repair of injured tissues. (Review Figure 6-8 and Table 6-3.)

- Cortisol secretion is regulated by a negative-feedback loop involving hypothalamic CRH and pituitary ACTH. Stress is the most potent stimulus for increasing activity of the CRH–ACTH–cortisol axis. Cortisol also displays a characteristic diurnal rhythm. (Review Figures 6-8, and 6-12.)

- Dehydroepiandrosterone (DHEA) governs the sex drive and growth of pubertal hair in females.

- The adrenal medulla consists of modified sympathetic postganglionic neurons, which secrete the catecholamine epinephrine into the blood in response to sympathetic stimulation. For the most part, epinephrine reinforces the sympathetic system in mounting general systemic fight-or-flight responses and in maintaining arterial blood pressure. Epinephrine also exerts important metabolic effects, namely, increasing blood glucose and blood fatty acids. (Review Figure 4-43, and Table 6-2.)

- The primary stimulus for increased adrenomedullary secretion is activation of the sympathetic system by stress. (Review Table 6-3, and Figure 6-12.)

6.3 | Integrated Stress Response (pp. 263–266)

- The term *stress* refers to the generalized nonspecific response of the body to any factor that overwhelms, or threatens to overwhelm, the body's compensatory ability to maintain homeostasis. The term *stressor* refers to any noxious stimulus that elicits the stress response.

- In addition to specific responses to various stressors, all stressors produce the following similar generalized stress response: (1) activation of the sympathetic nervous system accompanied by epinephrine secretion, which together prepare the body for a fight-or-flight response; (2) activation of the CRH–ACTH–cortisol system, which helps the body cope with stress primarily by mobilizing metabolic resources; (3) elevation of blood glucose and fatty acids through decreased insulin and increased glucagon secretion; and (4) maintenance of blood volume and blood pressure through increased activity of the renin–angiotensin–aldosterone system along with increased vasopressin secretion. All these actions are coordinated by the hypothalamus. (Review Figures 6-11 and 6-12, and Table 6-3.)

6.4 | Endocrine Control of Fuel Metabolism (pp. 267–283)

- Intermediary or fuel metabolism is, collectively, the synthesis (anabolism), breakdown (catabolism), and transformation of the three classes of energy-rich organic nutrients—carbohydrate, fat, and protein—within the body. (Review Table 6-4 and Figure 6-13.)

© 2016 Cengage

- Glucose and fatty acids derived from carbohydrates and fats, respectively, are primarily used as metabolic fuels, whereas amino acids derived from proteins are primarily used for synthesis of structural and enzymatic proteins. (Review Table 6-5.)

- During the absorptive state following a meal, excess absorbed nutrients not immediately needed for energy production or protein synthesis are stored to a limited extent as glycogen in the liver and muscle but mostly as triglycerides in adipose tissue. (Review Table 6-6.)

- During the postabsorptive state between meals when no new nutrients are entering the blood, the glycogen and triglyceride stores are catabolized to release nutrient molecules into

the blood. If necessary, body proteins are degraded to release amino acids for conversion into glucose. The blood glucose concentration must be maintained above a critical level even during the postabsorptive state, because the brain depends on blood-delivered glucose as its energy source. Tissues not dependent on glucose switch to fatty acids as their metabolic fuel, sparing glucose for the brain. (Review Table 6-6.)

- These shifts in metabolic pathways between the absorptive and postabsorptive state are hormonally controlled. The most important hormone in this regard is insulin. Insulin is secreted by the α cells of the islets of Langerhans, the endocrine portion of the pancreas. The other major pancreatic hormone, glucagon, is secreted by the β cells of the islets. (Review Table 6-7.)

- Insulin is an anabolic hormone; it promotes the cellular uptake of glucose, fatty acids, and amino acids and enhances their conversion into glycogen, triglycerides, and proteins, respectively. In so doing, it lowers the blood concentrations of these small organic molecules.

- Insulin secretion is increased during the absorptive state, primarily by a direct effect of an elevated blood glucose on the cells, and is largely responsible for directing the organic traffic into cells during this state. (Review Figures 6-14 through 6-18.)

- Glucagon mobilizes the energy-rich molecules from their stores during the postabsorptive state. Glucagon, which is secreted in response to a direct effect of a fall in blood glucose on the pancreatic α cells, in general opposes the actions of insulin. (Review Figures 6-17 and 6-18.)

6.5 | Endocrine Control of Calcium Metabolism (pp. 284–292)

- Changes in the concentration of free, diffusible plasma Ca^{2+} , the biologically active form of this ion, produce profound and life-threatening effects, most notably on neuromuscular excitability. Hypercalcaemia reduces excitability, whereas hypocalcaemia brings about overexcitability of nerves and muscles. If the overexcitability is severe enough, fatal spastic contractions of respiratory muscles can occur.

- Three hormones regulate the plasma concentration of Ca^{2+} (and concurrently regulate PO_4^{3-})—parathyroid hormone (PTH), calcitonin, and vitamin D.

- PTH, whose secretion is directly increased by a fall in plasma Ca^{2+} concentration, acts on bone, kidneys, and the intestine to raise the plasma Ca^{2+} concentration. In so doing, it is essential for life by preventing the fatal consequences of hypocalcaemia. The

specific effects of PTH on bone promote Ca^{2+} movement from the bone fluid into the plasma in the short term and promote localized dissolution of bone by enhancing activity of the osteoclasts (bone-dissolving cells) in the long term. (Review Figures 6-19 through 6-22.)

- Dissolution of the calcium phosphate bone crystals releases PO_4^{3-} as well as Ca^{2+} into the plasma. PTH acts on the kidneys to enhance the reabsorption of filtered Ca^{2+} , thereby reducing the urinary excretion of Ca^{2+} and increasing its plasma concentration. Simultaneously, PTH reduces renal PO_4^{3-} reabsorption, in this way increasing PO_4^{3-} excretion and lowering plasma PO_4^{3-} levels. This is important because a rise in plasma PO_4^{3-} would force the redeposition of some of the plasma Ca^{2+} back into the bone.

- Furthermore, PTH facilitates the activation of vitamin D, which in turn stimulates Ca^{2+} and PO_4^{3-} absorption from the intestine. (Review Figures 6-23 and 6-24.)

- Vitamin D can be synthesized from a cholesterol derivative in the skin when exposed to sunlight, but frequently this endogenous source is inadequate, so vitamin D must be supplemented by dietary intake. From either source, vitamin D must be activated first by the liver and then by the kidneys (the site of PTH regulation of vitamin D activation) before it can exert its effect on the intestine. (Review Figure 6-23.)

- Calcitonin, a hormone produced by the C cells of the thyroid gland, is the third factor that regulates Ca^{2+} . In negative-feedback fashion, calcitonin is secreted in response to an increase in plasma Ca^{2+} concentration and acts to lower plasma Ca^{2+} levels by inhibiting activity of bone osteoclasts. Calcitonin is unimportant except during the rare condition of hypercalcaemia. (Review Figure 6-22.)

NOTES

This image shows a single sheet of white paper with horizontal ruling lines. The lines are evenly spaced and run across the width of the page. There are no margins, text, or other markings on the paper.

7.1 | Introduction (pp. 297–298)

■ Muscles are specialized for contraction. Through their highly developed ability to move specialized cytoskeletal components, they are able to develop tension, shorten, produce movement, and accomplish work. The three types of muscle—skeletal, cardiac, and smooth—are categorized in two different ways according to common characteristics. (1) Skeletal muscle and cardiac muscle are striated, whereas smooth muscle is unstriated. (2) Skeletal muscle is voluntary, whereas cardiac muscle and smooth muscle are involuntary. (Review Figure 7-1 and Table 7-4.)

7.2 | Structure of Skeletal Muscle (pp. 298–302)

■ Skeletal muscles are made up of bundles of long, cylindrical muscle cells known as muscle fibres, wrapped in connective tissue.

■ Muscle fibres are packed with myofibrils, each myofibril consisting of alternating, slightly overlapping stacked sets of thick and thin filaments. This arrangement leads to a skeletal muscle fibre's striated microscopic appearance, which consists of alternating dark A bands and light I bands. (Review Figures 7-2, 7-3, and 7-4.)

■ Thick filaments consist of the protein myosin. Cross bridges made up of the myosin molecules' globular heads project from each thick filament toward the surrounding thin filaments. (Review Figures 7-2 and 7-5.)

■ Thin filaments consist primarily of the protein actin, which can bind and interact with the myosin cross bridges to bring about contraction. Accordingly, myosin and actin are known as contractile proteins. However, in the resting state two other regulatory proteins, tropomyosin and troponin, lie across the surface of the thin filament to prevent this cross-bridge interaction. (Review Figure 7-2.)

7.3 | Molecular Basis of Skeletal Muscle Contraction (pp. 302–309)

■ Excitation of a skeletal muscle fibre by its motor neuron brings about contraction through a series of events that results in the thin filaments sliding closer together between the thick filaments. (Review Figure 7-7.)

■ This sliding filament mechanism of muscle contraction is switched on by the release of calcium ions from the lateral sacs of the sarcoplasmic reticulum. (Review Figures 7-9, 7-10, and 7-11.)

■ Calcium release occurs in response to the spread of a muscle fibre action potential into the central portions of the fibre via the T tubules. (Review Figures 7-9 and 7-11.)

■ Released Ca^{2+} binds to the troponin–tropomyosin complex of the thin filament, slightly repositioning the complex to uncover actin's cross-bridge binding sites. (Review Figures 7-6 and 7-11.)

■ After the exposed actin attaches to a myosin cross bridge, molecular interaction between actin and myosin releases energy within the myosin head that was stored from the prior splitting of ATP by the myosin ATPase site. This released energy powers cross-bridge stroking. (Review Figure 7-12.)

■ During a power stroke, an activated cross bridge bends toward the centre of the thick filament, pulling in the thin filament to which it is attached. (Review Figure 7-8.)

■ With the addition of a fresh ATP molecule to the myosin cross bridge, myosin and actin detach, the cross bridge returns to its original shape, and the cycle is repeated. (Review Figure 7-12.)

■ Repeated cycles of cross-bridge activity slide the thin filaments inward step by step. (Review Figure 7-8.)

■ When there is no longer a local action potential, the lateral sacs actively take up the Ca^{2+} , troponin and tropomyosin slip back into their blocking position, and relaxation occurs. (Review Figure 7-11.)

■ The entire contractile response lasts about 100 times longer than the action potential. (Review Figure 7-13.)

7.4 | Skeletal Muscle Mechanics (pp. 309–317)

■ Gradation of whole-muscle contraction can be accomplished by (1) varying the number of muscle fibres contracting within the muscle and (2) varying the tension developed by each contracting fibre. (Review Table 7-3.)

■ The greater the tension developed by each contracting fibre, the stronger the contraction of the whole muscle. Two readily variable factors that affect fibre tension are (1) frequency of stimulation (firing frequency), which determines the extent of twitch summation; and (2) length of the fibre before the onset of contraction. (Review Figure 7-16 and Table 7-3.)

■ The term *twitch summation* refers to the increase in tension accompanying repetitive stimulation of the muscle fibre. After undergoing an action potential, the muscle cell membrane recovers from its refractory period and can be restimulated while some contractile activity triggered by the first action potential still remains. As a result, the contractile responses (twitches) induced by the two rapidly successive action potentials can sum, thereby increasing the tension developed by the fibre. If the muscle fibre is stimulated so rapidly that it does not have a chance to start relaxing between stimuli, a smooth, sustained maximal (maximal for the fibre at that length) contraction known as tetanus occurs. (Review Figure 7-15.)

- The two primary types of muscle contraction—*isometric* (constant length) and *isotonic* (constant tension)—depend on the relationship between muscle tension and the load. The load is the force opposing contraction: that is, the weight of an object being lifted. (1) If tension is less than the load, the muscle cannot shorten and lift the object but remains at constant length, producing an *isometric* contraction. (2) In an *isotonic* contraction, the tension exceeds the load so the muscle can shorten and lift the object, maintaining constant tension throughout the period of shortening. (Review Figure 7-18.)

- The velocity, or speed, of shortening is inversely proportional to the load. (Review Figure 7-20.)

- The bones, muscles, and joints form lever systems. The most common type amplifies the velocity and distance of muscle shortening to increase the speed and range of motion of the body part moved by the muscle. This increased manoeuvrability is accomplished at the expense of the muscle having to exert considerably more force than the load. (Review Figure 7-21.)

7.5 | ATP and Fibre Types (pp. 317–322)

- The transfer of high-energy phosphates from stored creatine phosphate to ADP provides the first source of ATP at the onset of exercise.

- Fatigue is of two types: (1) muscle fatigue, which occurs when an exercising muscle can no longer respond to neural stimulation with the same degree of contractile activity; and (2) central fatigue, which occurs when the CNS no longer adequately activates the motor neurons.

- The three types of muscle fibres are classified by the pathways they use for ATP synthesis (oxidative or glycolytic) and the rapidity with which they split ATP and subsequently contract (slow-twitch or fast-twitch): (1) slow-oxidative fibres, (2) fast-oxidative fibres, and (3) fast-glycolytic fibres. (Review Table 7-2.)

- Muscle fibres adapt in response to different demands placed on them. Regular endurance exercise promotes improved oxidative capacity in oxidative fibres, whereas high-intensity resistance training promotes hypertrophy of fast glycolytic fibres. The two types of fast-twitch fibres are interconvertible, depending on the type and extent of training. Fast- and slow-twitch fibres are not interconvertible. Muscles atrophy when not used.

7.6 | Control of Motor Movement (pp. 322–326)

- Control of any motor movement depends on the activity levels of the presynaptic inputs that converge on the motor neurons supplying various muscles. These inputs come from three sources: (1) spinal reflex pathways, which originate with afferent neurons; (2) the corticospinal (pyramidal) motor system, which originates at the pyramidal cells in the primary motor cortex and is concerned primarily with discrete, intricate movements of the hands; and (3) the multineuronal (extrapyramidal) motor

system, which originates in the brain stem and is mostly involved with postural adjustments and involuntary movements of the trunk and limbs. The final motor output from the brain stem is influenced by the cerebellum, basal nuclei, and cerebral cortex. (Review Figure 7-22.)

- Establishment and adjustment of motor commands depend on continuous afferent input, especially feedback about changes in muscle length (monitored by muscle spindles) and muscle tension (monitored by Golgi tendon organs). (Review Figure 7-23.)

7.7 | Smooth and Cardiac Muscle (pp. 326–334) (Review Table 7-4.)

- The thick and thin filaments of smooth muscle are not arranged in an orderly pattern, so the fibres are not striated. (Review Figures 7-24 and 7-25.)

- In smooth muscle, cytosolic Ca^{2+} , which enters from the extracellular fluid and is also released from sparse intracellular stores, activates cross-bridge cycling by initiating a series of biochemical reactions that result in phosphorylation of the myosin cross bridges to enable them to bind with actin. (Review Figures 7-26 and 7-27.)

- Multiunit smooth muscle is neurogenic, requiring stimulation of individual muscle fibres by its autonomic nerve supply to trigger contraction.

- Single-unit smooth muscle is myogenic; it can initiate its own contraction without any external influence, as a result of spontaneous depolarizations to threshold potential brought about by automatic shifts in ionic fluxes. Only a few of the smooth muscle cells in a functional syncytium are self-excitable. The two major types of spontaneous depolarizations displayed by self-excitable smooth muscle cells are pacemaker potentials and slow-wave potentials. (Review Figure 7-28 and Table 7-5.)

- The autonomic nervous system, as well as hormones and local metabolites, can modify the rate and strength of the self-induced smooth muscle contractions. All these factors influence smooth muscle activity by altering cytosolic Ca^{2+} concentration.

- Smooth muscle does not have a clear-cut length–tension relationship. It can develop tension when considerably stretched and inherently relaxes when stretched.

- Smooth muscle contractions are energy efficient, enabling this type of muscle to economically sustain long-term contractions without fatigue. This economy, coupled with the fact that single-unit smooth muscle can exist at a variety of lengths with little change in tension, makes single-unit smooth muscle ideally suited for its task of forming the walls of hollow organs that can distend.

- Cardiac muscle is found only in the heart. It has highly organized striated fibres, like skeletal muscle. Like single-unit smooth muscle, some cardiac muscle fibres can generate action potentials, which are spread throughout the heart with the aid of gap junctions.

NOTES

This image shows a single sheet of white paper with horizontal ruling lines. The lines are evenly spaced and run across the width of the page. There are no margins, text, or other markings on the paper.

8.1 | Introduction (pp. 345–346)

- The circulatory system is the transport system of the body.
- The three basic components of the circulatory system are the heart (the pump), the blood vessels (the passageways), and the blood (the transport medium).

8.2 | Anatomy of the Heart (pp. 346–351)

- The heart is basically a dual pump that provides the driving pressure for blood flow through the pulmonary and systemic circulations. (Review Figures 8-1 and 8-2.)
- The heart has four chambers: each half of the heart consists of an atrium, or venous input chamber, and a ventricle, or arterial output chamber. (Review Figures 8-2 and 8-4.)
- Four heart valves direct the blood in the right direction and keep it from flowing in the other direction. (Review Figures 8-3, 8-4, and 8-5.)
- Contraction of the spirally arranged cardiac muscle fibres produces a wringing effect important for efficient pumping. It is also important for efficient pumping that the muscle fibres in each chamber act as a functional syncytium, contracting as a coordinated unit. (Review Figure 8-6.)

8.3 | Electrical Activity of the Heart (pp. 352–361)

- The heart is self-excitable, initiating its own rhythmic contractions.
- Autorhythmic cells are 1 percent of the cardiac muscle cells; they do not contract but are specialized to initiate and conduct action potentials. Autorhythmic cells display a pacemaker potential, a slow drift to threshold potential, as a result of a complex interplay of inherent changes in ion movement across the membrane. (Review Figure 8-7.) The other 99 percent of cardiac cells are contractile cells that contract in response to the spread of an action potential initiated by autorhythmic cells.
- The cardiac impulse originates at the SA node, the pacemaker of the heart, which has the fastest rate of spontaneous depolarization to threshold. (Review Table 8-1 and Figure 8-8.)
- Once initiated, the action potential spreads throughout the right and left atria, partially facilitated by specialized conduction pathways, but mostly by cell-to-cell spread of the impulse through gap junctions. (Review Figures 8-8 and 8-9.)
- The impulse passes from the atria into the ventricles through the AV node, the only point of electrical contact between these chambers. The action potential is delayed briefly at the AV node, ensuring that atrial contraction precedes ventricular contraction to allow complete ventricular filling. (Review Figures 8-8 and 8-9.)

- The impulse then travels rapidly down the interventricular septum via the bundle of His and rapidly disperses throughout the myocardium by means of the Purkinje fibres. The rest of the ventricular cells are activated by cell-to-cell spread of the impulse through gap junctions. (Review Figures 8-8 and 8-9.)
- Thus, the atria contract as a single unit, followed after a brief delay by a synchronized ventricular contraction. The action potentials of cardiac contractile cells exhibit a prolonged positive phase, or plateau, accompanied by a prolonged period of contraction, which ensures adequate ejection time. This plateau is primarily due to activation of slow L-type Ca²⁺ channels. (Review Figure 8-10.)

- Calcium entry through the L-type channels in the T tubules triggers a much larger release of Ca^{2+} from the sarcoplasmic reticulum. This Ca^{2+} -induced Ca^{2+} release leads to cross-bridge cycling and contraction. (Review Figure 8-11.)

- Because a long refractory period occurs in conjunction with this prolonged plateau phase, summation and tetanus of cardiac muscle are impossible, ensuring the alternate periods of contraction and relaxation essential for pumping of blood. (Review Figure 8-12.)

- The spread of electrical activity throughout the heart can be recorded from the body surface. This record, the ECG, can provide useful information about the status of the heart. (Review Figures 8-13, 8-14, and 8-15.)

8.4 | Mechanical Events of the Cardiac Cycle (pp. 361–365)

- The cardiac cycle consists of three important events:
 1. The generation of electrical activity as the heart auto-rhythmically depolarizes and repolarizes
 2. Mechanical activity consisting of alternate periods of systole (contraction and emptying) and diastole (relaxation and filling), which are initiated by the rhythmic electrical cycle
 3. Directional flow of blood through the heart chambers, guided by valve opening and closing induced by pressure changes that are generated by mechanical activity
- Valve closing gives rise to two normal heart sounds. The first heart sound is caused by closing of the atrioventricular (AV) valves and signals the onset of ventricular systole. The second heart sound is due to closing of the aortic and pulmonary valves at the onset of diastole.
- The atrial pressure curve remains low throughout the entire cardiac cycle, with only minor fluctuations (normally varying between 0 and 8 mmHg). The aortic pressure curve remains high the entire time, with moderate fluctuations (normally varying between a systolic pressure of 120 mmHg and a diastolic pressure of 80 mmHg). The ventricular pressure curve fluctuates dramatically, because ventricular pressure must be below the low atrial pressure during diastole to allow the AV valve to open for filling, and it must be above the high aortic pressure during systole to force the aortic valve open to allow emptying. Therefore, ventricular pressure normally varies from 0 mmHg during diastole to slightly more than 120 mmHg during systole. (Review Figure 8-16.)
- The end-diastolic volume is the volume of blood in the ventricle when filling is complete at the end of diastole. The end-systolic volume is the volume of blood remaining in the ventricle when ejection is complete at the end of systole. The stroke volume is the volume of blood pumped out by each ventricle each beat. (Review Figure 8-16.)
- Defective valve function produces turbulent blood flow, which is audible as a heart murmur. Abnormal valves may be either stenotic and not open completely or insufficient and not close completely. (Review Table 8-2.)

8.5 | Cardiac Output and Its Control (pp. 365–373)

- Cardiac output, the volume of blood ejected by each ventricle each minute, is determined by the heart rate multiplied by the stroke volume. (Review Figure 8-23.)
- Heart rate is varied by altering the balance of parasympathetic and sympathetic influence on the SA node. Parasympathetic stimulation slows the heart rate, and sympathetic stimulation speeds it up. (Review Figure 8-18 and Table 8-3.)
- Stroke volume depends on (1) the extent of ventricular filling, with an increased end-diastolic volume resulting in a larger stroke volume by means of the length–tension relationship (Frank–Starling law of the heart, a form of intrinsic control); and (2) the extent of sympathetic stimulation, with increased sympathetic stimulation resulting in increased contractility of the heart—that is, increased strength of contraction and increased stroke volume at a given end-diastolic volume (extrinsic control). (Review Figures 8-19 through 8-22.)

8.6 | Nourishing the Heart Muscle (pp. 373–379)

- Cardiac muscle is supplied with oxygen and nutrients by blood delivered to it by the coronary circulation, not by blood within the heart chambers.
- Most coronary blood flow occurs during diastole, because during systole the contracting heart muscle compresses the coronary vessels. (Review Figure 8-25.)
- Coronary blood flow is normally varied to keep pace with cardiac oxygen needs. (Review Figure 8-26.)
- Coronary blood flow may be compromised by development of atherosclerotic plaques, which can lead to ischemic heart disease, ranging in severity from mild chest pain on exertion to fatal heart attacks. (Review Figures 8-27 through 8-29 and Table 8-4.)

9.1 | Introduction (pp. 386–389)

■ Materials can be exchanged between various parts of the body and with the external environment by means of the blood vessel network that transports blood to and from all organs. (Review Figure 9-1.)

■ Organs that replenish nutrient supplies and remove metabolic wastes from the blood receive a greater percentage of the cardiac output than is warranted by their metabolic needs. These “reconditioning” organs can better tolerate reductions in blood supply than can organs that receive blood solely for meeting their own metabolic needs.

■ The brain is especially vulnerable to reductions in its blood supply. Therefore, maintaining adequate flow to this vulnerable organ is a high priority in circulatory function.

■ The flow rate of blood through a vessel is directly proportional to the pressure gradient and inversely proportional to the resistance. The higher pressure at the beginning of a vessel is established by the pressure imparted to the blood by cardiac contraction. The lower pressure at the end is due to frictional losses as flowing blood rubs against the vessel wall. (Review Figure 9-2.)

■ Resistance, the hindrance to blood flow through a vessel, is influenced most by the vessel’s radius. Resistance is inversely proportional to the fourth power of the radius, so small changes in radius profoundly influence flow. As the radius increases, resistance decreases and flow increases. (Review Figure 9-3.)

■ Blood flows in a closed loop between the heart and the organs. The arteries transport blood from the heart throughout the body. The arterioles regulate the amount of blood that flows through each organ. The capillaries are the actual site where materials are exchanged between blood and surrounding tissue cells. The veins return blood from the tissue level back to the heart. (Review Figure 9-4 and Table 9-1.)

9.2 | Arteries (pp. 389–394)

■ Arteries are large-radius, low-resistance passageways from the heart to the organs.

■ They also serve as a pressure reservoir. Because of their elasticity, arteries expand to accommodate the extra volume of blood pumped into them by cardiac contraction and then recoil to continue driving the blood forward when the heart is relaxing. (Review Figures 9-5 and 9-6.)

■ Systolic pressure is the peak pressure exerted by the ejected blood against the vessel walls during cardiac systole. Diastolic pressure is the minimum pressure in the arteries when blood is draining off into the vessels downstream during cardiac diastole. (Review Figures 9-7 and 9-8.)

■ The average driving pressure throughout the cardiac cycle is the mean arterial pressure, which can be estimated using the following formula: mean arterial pressure = diastolic pressure + $1/3$ pulse pressure. (Review Figure 9-9.)

9.3 | Arterioles (pp. 394–402)

■ Arterioles are the major resistance vessels. Their high resistance produces a large drop in mean pressure between the arteries and capillaries. This decline enhances blood flow by contributing to the pressure differential between the heart and organs. (Review Figure 9-9.)

■ Tone, a baseline of contractile activity, is maintained in arterioles at all times.

■ Arteriolar vasodilation, an expansion of arteriolar calibre above tonic level, decreases resistance and increases blood flow through the vessel, whereas vasoconstriction, a narrowing of the vessel, increases resistance and decreases flow. (Review Figure 9-10.)

■ Arteriolar calibre is subject to two types of control mechanisms: local (intrinsic) controls and extrinsic controls.

■ Local controls primarily involve local chemical changes associated with changes in the level of metabolic activity in an organ. These changes in local metabolic factors cause the release of vasoactive mediators from the endothelial cells in the vicinity. Examples include vasodilating nitric oxide and vasoconstricting endothelin. These vasoactive mediators act on the underlying arteriolar smooth muscle to bring about an appropriate change in the calibre of the arterioles supplying the organ. By adjusting the

resistance to blood flow in this manner, the local control mechanism adjusts blood flow to the organ to match the momentary metabolic needs of the organ. (Review Figures 9-10, 9-11, and 9-14, and Tables 9-2 and 9-3.)

- Arteriolar calibre can be adjusted independently in different organs by local control factors. Such adjustments are important in variably distributing cardiac output. (Review Figure 9-12.)
- Extrinsic control is accomplished primarily by sympathetic nerve influence and to a lesser extent by hormonal influence over arteriolar smooth muscle. Extrinsic controls are important in maintaining mean arterial pressure. Arterioles are richly supplied with sympathetic nerve fibres, whose increased activity produces generalized vasoconstriction and a subsequent increase in total peripheral resistance, thus increasing mean arterial pressure. Decreased sympathetic activity produces generalized arteriolar vasodilation, which lowers mean arterial pressure. These extrinsically controlled adjustments of arteriolar calibre help maintain the appropriate pressure head for driving blood forward to the tissues. (Review Figure 9-14.)

9.4 | Capillaries (pp. 402–413)

- The thin-walled, small-radius, extensively branched capillaries are ideally suited to serve as sites of exchange between the blood and surrounding tissue cells. Anatomically, the surface area for exchange is maximized and diffusion distance is minimized in the capillaries. Furthermore, because of their large total cross-sectional area, the velocity of blood flow through capillaries is relatively slow, providing adequate time for exchanges to take place. (Review Figures 9-15 through 9-17.)
- Two types of passive exchanges—diffusion and bulk flow—take place across capillary walls.
- Individual solutes are exchanged primarily by diffusion down concentration gradients. Lipid-soluble substances pass directly through the single layer of endothelial cells lining a capillary, whereas water-soluble substances pass through water-filled pores between the endothelial cells. Plasma proteins generally do not escape. (Review Figures 9-18 and 9-21.)
- Imbalances in physical pressures acting across capillary walls are responsible for bulk flow of fluid through the pores back and forth between plasma and interstitial fluid. (1) Fluid is forced out of the first portion of the capillary (ultrafiltration), where outward pressures (mainly capillary blood pressure) exceed inward pressures (mainly plasma-colloid osmotic pressure). (2) Fluid is returned to the capillary along its last half, when outward pressures fall below inward pressures. The reason for the shift in balance down the length of the capillary is the continuous decline in capillary blood pressure while the plasma-colloid osmotic pressure remains constant. (Review Figures 9-9, 9-22, and 9-23.)
- Bulk flow is responsible for the distribution of extracellular fluid between plasma and interstitial fluid.
- Normally, slightly more fluid is filtered than is reabsorbed. The extra fluid, any leaked proteins, and bacteria in the tissue are picked up by the lymphatic system. Bacteria are destroyed as lymph passes through the lymph nodes en route to being returned to the venous system. (Review Figures 9-24 and 9-25.)

9.5 | Veins (pp. 414–418)

- Veins are large-radius, low-resistance passageways through which blood returns from the organs to the heart.
- In addition, veins can accommodate variable volumes of blood and therefore act as a blood reservoir. The capacity of veins to hold blood can change markedly with little change in venous pressure. Veins are thin-walled, highly distensible vessels that can passively stretch to store a larger volume of blood. (Review Figure 9-27.)
- The primary force that produces venous flow is the pressure gradient between the veins and atrium (i.e., what remains of the driving pressure imparted to the blood by cardiac contraction). (Review Figures 9-9 and 9-28.)
- Venous return is enhanced by sympathetically induced venous vasoconstriction and by external compression of the veins from contraction of surrounding skeletal muscles, both of which drive blood out of the veins. These actions help counter the effects of gravity on the venous system. (Review Figures 9-28 through 9-31.)
- One-way venous valves ensure that blood is driven toward the heart and kept from flowing back toward the tissues. (Review Figure 9-32.)
- Venous return is also enhanced by the respiratory pump and the cardiac suction effect. Respiratory activity produces a less-than-atmospheric pressure in the chest cavity, thus establishing an external pressure gradient that encourages flow from the lower veins that are exposed to atmospheric pressure to the chest veins that empty into the heart. (Review Figure 9-33.)
- In addition, slightly negative pressures created within the atria during ventricular systole and within the ventricles during ventricular diastole exert a suctioning effect that further enhances venous return and facilitates cardiac filling.

9.6 | Blood Pressure (pp. 419–428)

- Regulation of mean arterial pressure depends on control of its two main determinants: cardiac output and total peripheral resistance. (Review Figure 9-34.)
- Control of cardiac output, in turn, depends on regulation of heart rate and stroke volume, whereas total peripheral resistance is determined primarily by the degree of arteriolar vasoconstriction. (Review Figures 8-23 and 9-14.)
- Short-term regulation of blood pressure is accomplished mainly by the baroreceptor reflex. Carotid sinus and aortic arch baroreceptors continuously monitor mean arterial pressure. When they detect a deviation from normal, they signal the medullary cardiovascular centre, which responds by adjusting autonomic output to the heart and blood vessels to restore the blood pressure to normal. (Review Figures 9-35 through 9-38.)
- Long-term control of blood pressure involves maintaining proper plasma volume through the kidneys' control of salt and water balance. (Review Figure 9-34.)
- Blood pressure can be abnormally high (hypertension) or abnormally low (hypotension). Severe, sustained hypotension resulting in generalized inadequate blood delivery to the tissues is known as circulatory shock. (Review Figures 9-39 and 9-40.)

10.1 | Introduction (pp. 433–434)

- Blood consists of three types of cellular elements—erythrocytes (red blood cells), leukocytes (white blood cells), and platelets (thrombocytes)—suspended in the liquid plasma. (*Review Table 10-1.*)

- The 5–5.5 L volume of blood in an adult consists of 42–45 percent erythrocytes, less than 1 percent leukocytes and platelets, and 55–58 percent plasma. The percentage of whole-blood volume occupied by erythrocytes is the haematocrit. (*Review Figure 10-1.*)

10.2 | Plasma (pp. 434–435)

- Plasma is a complex liquid consisting of 90 percent water that serves as a transport medium for substances being carried in the blood.

- The most abundant inorganic constituents in plasma are sodium and chloride. The most plentiful organic constituents in plasma are plasma proteins.

- All plasma constituents are freely diffusible across the capillary walls, except the plasma proteins, which remain in the plasma, where they perform a variety of important functions. Plasma proteins include the albumins, globulins, and fibrinogen. (*Review Table 10-1.*)

10.3 | Erythrocytes (pp. 436–444)

- Erythrocytes are specialized for their primary function of O₂ transport in the blood. Their biconcave shape maximizes the surface area available for diffusion of oxygen into cells of this volume. (*Review Figure 10-1.*) Erythrocytes do not contain a nucleus, organelles, or ribosomes, but instead are packed full of haemoglobin—an iron-containing molecule that can loosely and reversibly bind with oxygen. Because oxygen is poorly soluble in blood, haemoglobin is indispensable for oxygen transport. (*Review Figure 10-2.*)

- Haemoglobin also contributes to carbon dioxide transport and buffering of blood by reversibly binding with carbon dioxide and hydrogen ions.

- Unable to replace cell components, erythrocytes are destined to a short lifespan of about 120 days.

- Undifferentiated multipotent stem cells in the red bone marrow give rise to all cellular elements of the blood. (*Review Figure 10-8.*) Erythrocyte production (erythropoiesis) by the marrow normally keeps pace with the rate of erythrocyte loss, keeping the red cell count constant. Erythropoiesis is stimulated by erythropoietin, a hormone secreted by the kidneys in response to reduced O₂ delivery. (*Review Figure 10-3.*)

10.4 | Leukocytes (pp. 444–447)

- Leukocytes are the defence corps of the body. They attack foreign invaders (the most common of which are bacteria and viruses), destroy cancer cells that arise in the body, and clean up cellular debris. Leukocytes as well as certain plasma proteins make up the immune system.

- Each of the five types of leukocytes has a different task: (1) Neutrophils, the phagocytic specialists, are important in engulfing bacteria and debris. (2) Eosinophils specialize in attacking parasitic worms and play a role in allergic responses. (3) Basophils release two chemicals: histamine, which is also important in allergic responses; and heparin, which helps clear fat particles from the blood. (4) Monocytes, on leaving the blood, set up residence in the tissues and greatly enlarge to become the large-tissue phagocytes known as macrophages. (5) Lymphocytes provide immune defence against bacteria, viruses, and other targets for which they are specifically programmed. Their means of defence include the production of antibodies that mark the victim for destruction by phagocytosis or other processes (for B lymphocytes) and the release of chemicals that punch holes in the victim (for T lymphocytes). (*Review Figure 10-8 and Table 10-1.*)

- Leukocytes are present in the blood only while in transit from their site of production and storage in the bone marrow (and also in the lymphoid tissues in the case of the lymphocytes) to their site of action in the tissues. (*Review Figure 10-9.*) At any given time, most leukocytes are out in the tissues on surveillance missions or performing actual combat missions.

- All leukocytes have a limited lifespan and must be replenished by ongoing differentiation and proliferation of precursor cells. The total number and percentage of each of the different types of leukocytes produced vary depending on the momentary defence needs of the body.

10.5 | Platelets and Haemostasis (pp. 447–454)

- Platelets are cell fragments derived from large megakaryocytes in the bone marrow. (*Review Figures 10-8, 10-9, and 10-10.*)

- Platelets play a role in haemostasis, the arrest of bleeding from an injured vessel. The three main steps in haemostasis are (1) vascular spasm, (2) platelet plugging, and (3) clot formation.

- Vascular spasm reduces blood flow through an injured vessel.
- Aggregation of platelets at the site of vessel injury quickly plugs the defect. Platelets start to aggregate on contact with exposed collagen in the damaged vessel wall. (*Review Figures 10-11 and 10-15.*)

- Clot formation reinforces the platelet plug and converts blood in the vicinity of a vessel injury into a nonflowing gel.

- Most factors necessary for clotting are always present in the plasma in inactive precursor form. When a vessel is damaged, exposed collagen initiates a cascade of reactions involving successive activation of these clotting factors, ultimately converting fibrinogen into fibrin via the intrinsic clotting pathway. (Review Figures 10-13, 10-14, and 10-15.)

- Fibrin, an insoluble threadlike molecule, is laid down as the meshwork of the clot; the meshwork in turn entangles blood

cellular elements to complete clot formation. (Review Figure 10-12.)

- Blood that has escaped into the tissues clots on exposure to tissue thromboplastin, which sets the extrinsic clotting pathway into motion. (Review Figure 10-14.)

- When no longer needed, clots are dissolved by plasmin, a fibrinolytic factor also activated by exposed collagen. (Review Figure 10-16.)

11.1 | Introduction (p. 460)

- The most common invaders are bacteria and viruses. Bacteria are self-sustaining, single-celled organisms, which produce disease by virtue of the destructive chemicals they release. Viruses are protein-coated nucleic acid particles, which invade host cells and take over the cellular metabolic machinery for their own survival to the detriment of the host cell.

11.2 | External Defences (pp. 460–464)

- The body surfaces exposed to the outside environment—both the outer covering of skin and the linings of internal cavities that communicate with the external environment—not only serve as mechanical barriers to deter would-be pathogenic invaders but also play an active role in thwarting the entry of bacteria and other unwanted materials.
- The epidermis contains four cell types:
 1. Melanocytes produce a pigment, melanin, the colour and amount of which is responsible for the varying shades of skin colour. Melanin protects the skin by absorbing harmful UV radiation.
 2. The most abundant cells are the keratinocytes, producers of the tough keratin that forms the outer, protective layer of the skin. This physical barrier discourages bacteria and other harmful environmental agents from entering the body and prevents water and other valuable body substances from escaping. Keratinocytes further serve immunologically by secreting interleukin 1, which enhances post-thymic T-cell maturation within the skin.
 3. Langerhans cells also function in specific immunity by presenting antigen to helper T cells.
 4. Granstein cells suppress skin-activated immune responses.
- The dermis contains (1) blood vessels, (2) sensory nerve endings, and (3) several exocrine glands and hair follicles. (*Review Figure 11-1.*)
- The skin's exocrine glands include sebaceous glands, which produce sebum, an oily substance that softens and waterproofs the skin, and sweat glands, which produce cooling sweat. Hair follicles produce hairs, the distribution and function of which are minimal in humans.
- In addition, the skin synthesizes vitamin D in the presence of sunlight.
- Besides the skin, the other main routes by which potential pathogens enter the body are (1) the digestive system, which is defended by an antimicrobial salivary enzyme, destructive acidic gastric secretions, gut-associated lymphoid tissue, and harmless colonic resident flora; (2) the genitourinary system, which is protected by destructive acidic and particle-entrapping

mucus secretions; and (3) the respiratory system, whose defence depends on alveolar macrophage activity and on secretion of a sticky mucus that traps debris, which is subsequently swept out by ciliary action.

11.3 | Internal Defences (pp. 464–466)

- Leukocytes and their derivatives are the major effector cells of the immune system and are reinforced by a number of different plasma proteins. Leukocytes include neutrophils, eosinophils, basophils, monocytes, and lymphocytes.
- Leukocytes are primarily produced in the bone marrow, but some lymphocytes are also produced and differentiated and perform their defence activities within lymphoid tissues strategically located at likely points of foreign infiltration. (*Review Figure 11-2 and Table 11-1.*)

11.4 | Innate Immunity (pp. 466–473)

- Innate immune responses, which form a first line of defence against atypical cells (foreign, mutant, or injured cells) within the body, include inflammation, interferon, natural killer cells, and the complement system.
- Inflammation is a nonspecific response to foreign invasion or tissue damage mediated largely by the professional phagocytes (neutrophils and monocytes-turned-macrophages) and their secretions. (*Review Figure 11-3.*)
- The phagocytic cells destroy foreign and damaged cells both by phagocytosis and by the release of lethal chemicals.
- Histamine-induced vasodilation and increased permeability of local capillaries at the site of invasion or injury permit enhanced delivery of more phagocytic leukocytes and inactive plasma protein precursors crucial to the inflammatory process, such as clotting factors and components of the complement system. These vascular changes also largely produce the observable local manifestations of inflammation—swelling, redness, heat, and pain. (*Review Figure 11-4.*)
- Interferon is nonspecifically released by virus-infected cells and transiently inhibits viral multiplication in other cells to which it binds. (*Review Figure 11-6.*) Interferon further exerts anticancer effects by slowing division and growth of tumour cells as well as by enhancing the power of killer cells. (*Review Figure 11-20.*)
- Natural killer (NK) cells nonspecifically lyse and destroy virus-infected cells and cancer cells on first exposure to them.

11.5 | Adaptive Immunity: General Concepts (pp. 473–475)

- There are two broad classes of adaptive immune responses: antibody-mediated immunity and cell-mediated immunity. In both instances, the ultimate outcome of a particular lymphocyte

binding with a specific antigen is destruction of the antigen, but the effector cells, stimuli, and tactics involved are different. Plasma cells derived from B lymphocytes (B cells) are responsible for antibody-mediated immunity, whereas T lymphocytes (T cells) accomplish cell-mediated immunity. (Review Figure 11-8.)

- B cells develop from a lineage of lymphocytes that originally matured within the bone marrow. The T-cell lineage arises from lymphocytes that migrated from the bone marrow to the thymus to complete their maturation. (Review Figure 11-8.)

11.6 | B Lymphocytes: Antibody-Mediated Immunity (pp. 475–481)

- Each B cell recognizes specific free extracellular antigen that is not associated with cell-bound self-antigens, such as that found on the surface of bacteria.

- After being activated by binding with its specific antigen, a B cell rapidly proliferates, producing a clone of its own kind that can specifically wage battle against the invader. Most lymphocytes in the expanded B-cell clone become plasma cells that participate in the primary response against the invader. (Review Figures 11-10 and 11-13.)

- Antibodies are Y-shaped molecules. The antigen-binding sites on the tips of each arm of the antibody determine with what specific antigen the antibody can bind. Properties of the antibody's tail portion determine what the antibody does once it binds with antigen. (Review Figure 11-11.)

- There are five subclasses of antibodies, depending on differences in the biological activity of their tail portion: IgM, IgG, IgE, IgA, and IgD immunoglobulins.

- Antibodies do not directly destroy material. Instead, they exert their protective effect by physically hindering antigens through neutralization or agglutination or by intensifying lethal innate immune responses already called into play by the foreign invasion. Antibodies activate the complement system, enhance phagocytosis, and stimulate killer cells. (Review Figure 11-12.)

- Some of the newly developed lymphocytes in the activated B-cell clone do not participate in the attack but become memory cells that lie in wait, ready to launch a swifter and more forceful secondary response should the same foreigner ever invade the body again. (Review Figures 11-13 and 11-14.)

11.7 | T Lymphocytes: Cell-Mediated Immunity (pp. 482–491)

- T cells accomplish cell-mediated immunity by being in direct contact with their targets.

- There are three main subpopulations of T cells: cytotoxic T cells, helper T cells, and regulatory T cells.

- The targets of cytotoxic T cells are virally invaded cells and cancer cells, which they destroy by releasing perforin molecules that form a lethal hole-punching complex that inserts into the

membrane of the victim cell or by releasing granzymes that trigger the victim cell to undergo apoptosis. (Review Figures 11-16 and 11-17, and Table 11-2.)

- Like B cells, T cells bear receptors that are antigen specific, undergo clonal selection, exert primary and secondary responses, and form memory pools for long-lasting immunity against targets to which they have already been exposed.

- Those lymphocytes produced by chance that can attack the body's own antigen-bearing cells are eliminated or suppressed so that they are prevented from functioning. In this way, the body is able to "tolerate" (not attack) its own antigens. Tolerance is accomplished by clonal deletion, clonal anergy, receptor editing, regulatory (suppressor) T cells, immunological ignorance, and immune privilege.

- The major self-antigens on the surface of body cells are known as MHC molecules, which are coded for by the major histocompatibility complex (MHC), a group of genes with DNA sequences unique for each individual.

- The presence of class I or class II MHC self-antigens on the surface of these foreign antigen-bearing host cells causes the two different types of T cells to differentially interact with them. (Review Figure 11-18.)

1. Cytotoxic T cells are able to bind only with virus-infected host cells or cancer cells, which always bear the class I MHC self-antigen in association with foreign or abnormal antigen. On binding with the abnormal host cell, these T cells release toxic substances that kill the dangerous body cell.

2. Helper T cells can bind only with other T cells, B cells, and macrophages that have encountered foreign antigen. These immune cells bear the class II MHC self-marker in association with foreign antigen. Subsequently, helper T cells enhance the immune powers of these other effector cells by secreting specific chemical mediators.

- In the process of immune surveillance, natural killer cells, cytotoxic T cells, macrophages, and the interferon they collectively secrete normally eradicate newly arisen cancer cells before they have a chance to spread. (Review Figure 11-20.)

11.8 | Immune Diseases (pp. 491–494)

- Immune diseases are of two types: immunodeficiency diseases (insufficient immune responses) or inappropriate immune attacks (excessive or mistargeted immune responses).

- With immunodeficiency diseases, the immune system fails to defend normally against bacterial or viral infections through a deficit of B or T cells, respectively.

- With inappropriate immune attacks, the immune system becomes overzealous. There are three categories of inappropriate attacks: (1) autoimmune diseases; (2) immune complex diseases; and (3) allergies or hypersensitivities.

12.1 | Introduction (pp. 499–505)

- Internal respiration encompasses the intracellular metabolic reactions that use oxygen and produce carbon dioxide during energy-yielding oxidation of nutrient molecules.
- Respiratory airways conduct air from the atmosphere to the alveoli, the gas-exchanging portion of the lungs. (Review Figure 12-1.)
- External respiration involves the transfer of oxygen and carbon dioxide between the external environment and tissue cells. The respiratory and circulatory systems function together to accomplish external respiration. (Review Figure 12-2.)
- The respiratory system moves air between the atmosphere and lungs through the process of ventilation.
- In the lungs, oxygen and carbon dioxide diffuse across the extremely thin walls of the alveoli for exchange between the gas in the alveoli and the blood in the pulmonary capillaries. The alveolar walls are formed by Type I alveolar cells. Type II alveolar cells secrete pulmonary surfactant. (Review Figure 12-4.)
- The lungs are housed within the thorax, the volume of which is changed by contraction of respiratory muscles.
- Each lung is surrounded by a double-walled, closed sac, the pleural space. (Review Figure 12-6.)

12.2 | Respiratory Mechanics (pp. 505–523)

- Ventilation, or breathing, is the process of cyclically moving air in and out of the lungs so that alveolar air that has already participated in the exchange of oxygen and carbon dioxide with the pulmonary capillary blood is exchanged for fresh atmospheric air.
- The respiratory system consists of two components: the lungs and the chest wall. The lungs always exert an expiratory (deflationary) pressure, whereas the chest wall exerts an inspiratory (inflationary) pressure at lung volumes below about 60 percent of its capacity and expiratory (deflationary) pressures above this volume. These two components account for the pressure–volume relationship of the respiratory system. At approximately 40 percent of the vital capacity, the inspiratory and expiratory pressures are in equilibrium due to the equal and opposite pressures of the lung and chest wall. (Review Figure 12-8).
- Ventilation is accomplished by alternating the pressure gradient for airflow between the atmosphere and alveoli. When alveolar pressure decreases below atmospheric pressure as a result of decompression of the pleural space, air flows into the lungs. When alveolar pressure increases above atmospheric as a result of increased lung recoil at higher lung volumes, and this recoil pressure is not opposed by an equal and opposite pleural pressure (due to contraction of inspiratory muscles), air flows out of the lungs. (Review Figures 12-7, 12-15, 12-16, and 12-18.)

- Alternate contraction and relaxation of the inspiratory muscles (primarily the diaphragm) indirectly produce periodic inflation and deflation of the lungs by cyclically decompressing and compressing the pleural space, and therefore reducing and increasing intrathoracic pressure; the lungs passively follow the movements of the thorax. (Review Figures 12-7, 12-16, and 12-18.)
- The lungs can be stretched to varying degrees during inspiration; they then recoil to their pre-inspiratory size during expiration because of their elastic recoil.
- The term *compliance* refers to the distensibility of the lungs—the change in volume per unit change in the pressure gradient across the lung wall.
- Elastic recoil depends on the connective tissue meshwork within the lungs and, mostly, on alveolar surface tension. Surface tension, due to the attractive forces between the surface water molecules in the liquid film lining each alveolus, opposes alveolar expansion (decreases compliance). (Review Table 12-3.)
- Because energy is required for contracting the inspiratory muscles, inspiration is an active process, but expiration is passive during quiet breathing because it is accomplished by elastic recoil of the lungs on relaxing inspiratory muscles.
- For more forceful active expiration, contraction of the expiratory muscles (primarily the abdominal muscles) increases the alveolar-to-atmospheric pressure gradient. (Review Figures 12-15.)
- The larger the gradient between the alveoli and atmosphere in either direction, the greater the airflow. Air continues to flow until the alveolar pressure equilibrates with atmospheric pressure. (Review Figures 12-16 and 12-18.)
- Besides being directly proportional to the pressure gradient, airflow is also inversely proportional to airway resistance. (Review Table 12-4.) Because airway resistance, which depends on the calibre of the conducting airways, is normally very low, airflow depends primarily on the pressure gradient between the alveoli and atmosphere.
- If airway resistance is increased by disease, either the respiratory muscles must generate more pressure to maintain airflow or the person must breathe more slowly.
- If the alveoli were lined by water alone, the surface tension would be so great that the lungs would not be compliant and would tend to collapse. Pulmonary surfactant interspersed between the water molecules lowers the alveolar surface tension, thereby increasing the compliance of the lungs and counteracting the tendency for alveoli to collapse. Alveolar independence also counteracts the tendency for alveoli to collapse, because a collapsing alveolus is pulled open by the recoil of surrounding alveoli that have been stretched by the collapsing alveolus. (Review Figures 12-10 and 12-12 and Table 12-3.)

- Normally, the lungs operate at “half full.” Lung volume typically varies from about 2 to 2.5 L as an average tidal volume of 500 mL of air is moved in and out with each breath. (Review Figures 12-20 and 12-21.)

- The amount of air moved in and out of the lungs in one minute, the pulmonary ventilation, is equal to tidal volume multiplied by respiratory frequency.

- Not all the air moved in and out is available for O₂ and CO₂ exchange with the blood, because part occupies the conducting airways, known as the *anatomic dead space*. Alveolar ventilation, the volume of air exchanged between the atmosphere and alveoli in one minute, is a measure of the air actually available for gas exchange with the blood. Alveolar ventilation = (tidal volume – dead space volume) respiratory rate. (Review Figure 12-23 and Table 12-4.)

12.3 | Gas Exchange (pp. 523–531)

- Oxygen and carbon dioxide move across membranes by passive diffusion down partial pressure gradients.

- The partial pressure of a gas is that fraction of the total atmospheric pressure contributed by this individual gas, which in turn is directly proportional to the percentage of this gas in the air. The partial pressure of a gas in blood depends on the amount of this particular gas dissolved in the blood. (Review Table 12-6.)

- Net diffusion of O₂ occurs first between the alveoli and blood and then between the blood and tissues as a result of the O₂ partial pressure gradients created by continuous use of O₂ in the cells and continuous replenishment of fresh alveolar O₂ provided by ventilation. (Review Figure 12-26.)

- Net diffusion of CO₂ occurs in the reverse direction, first between the tissues and blood and then between the blood and alveoli, as a result of the CO₂ partial pressure gradients created by continuous production of CO₂ in the cells and continuous removal of alveolar CO₂ through ventilation. (Review Figure 12-26.)

- Factors other than the partial pressure gradient that influence the rate of gas exchange are the surface area and thickness of the membrane across which the gas is diffusing and the diffusion coefficient of the gas in the membrane, according to Fick’s law of diffusion. (Review Table 12-7.)

12.4 | Gas Transport (pp. 531–541)

- Because carbon dioxide and especially oxygen are not very soluble in blood, they must be transported primarily by mechanisms other than simply being physically dissolved. (Review Table 12-8.)

- Only 1.5 percent of the oxygen is physically dissolved in the blood; the 98.5 percent is chemically bound to haemoglobin (Hb). (Review Figure 12-35.)

- The primary factor that determines the extent to which haemoglobin and oxygen are combined (the % Hb saturation) is the P_{O₂} of the blood. This relation is depicted by an S-shaped curve known as the O₂–Hb dissociation curve. (Review Figure 12-33.)

1. In the P_{O₂} range of the pulmonary capillaries (the plateau portion of the curve), haemoglobin is still almost fully saturated even if the blood P_{O₂} falls to almost 60 mmHg. This provides a margin of safety by ensuring near-normal

oxygen delivery to the tissues, despite a substantial reduction in arterial P_{O₂}.

2. In the P_{O₂} range in the systemic capillaries (the steep portion of the curve), Hb unloading increases greatly in response to a small local decline in blood P_{O₂} associated with increased cellular metabolism. In this way, more oxygen is provided to match the increased tissue needs. (Review Figure 12-33.) The shape of the oxygen dissociation curve, when viewed from the perspective of the tissues, helps maintain the gradient for diffusion despite oxygen uptake by the tissues. (Review Figure 12-31.)

- Carbon dioxide picked up at the systemic capillaries is transported in the blood in three forms: (1) 10 percent is physically dissolved, (2) 30 percent is bound to haemoglobin, and (3) 60 percent takes the form of bicarbonate HCO₃[–]. (Review Table 12-8.)

- The erythrocyte enzyme carbonic anhydrase catalyzes conversion of CO₂ to HCO₃[–] according to the reaction CO₂ + H₂O ⇌ H₂CO₃ ⇌ H⁺ + HCO₃[–]. The carbon and oxygen originally present in CO₂ are now part of the HCO₃[–]. The generated H⁺ binds to Hb. These reactions are all reversed in the lungs as CO₂ is eliminated to the alveoli and then to the atmosphere. (Review Figure 12-37.)

12.5 | Control of Breathing (pp. 541–551)

- Ventilation involves three aspects, all subject to neural control: (1) rhythmic cycling between inspiration and expiration; (2) how frequently this cycling occurs (respiratory frequency); and (3) the amplitude of the signal sent to the respiratory muscles (tidal volume).

- Respiratory rhythm is established by a network of neurons in the medulla. The outputs are directed to both respiratory pump muscles and those that control the size of the upper airway. (Review Figures 12-39 and 12-41.)

- When the inspiratory neurons stop firing, the inspiratory muscles relax and expiration takes place. For active expiration to occur, the expiratory muscles are activated by output from the medullary expiratory neurons in the ventral respiratory group (VRG) of the medullary respiratory control centre.

- Three chemical factors play a role in determining the magnitude of ventilation: P_{CO₂}, P_{O₂}, and H⁺ concentration of the arterial blood. (Review Table 12-10.)

- The dominant factor in the minute-to-minute regulation of ventilation is the arterial P_{CO₂}. An increase in arterial P_{CO₂} is the most potent chemical stimulus for increasing ventilation. Changes in arterial P_{CO₂} alter ventilation primarily by bringing about corresponding changes in the brain ECF H⁺ concentration, to which the central chemoreceptors are exquisitely sensitive. (Review Figure 12-39.)

- The carotid chemoreceptors reflexly stimulate the respiratory centre in response to a marked reduction in arterial P_{CO₂} (< 60 mmHg).

- The carotid chemoreceptors respond to (or are sensitized by) an increase in arterial H⁺ concentration, which reflexly increases ventilation. The resulting adjustment in arterial H⁺–generating CO₂ is important in maintaining the acid–base balance of the body. (Review Figure 12-40.)

13.1 | Introduction (pp. 559–565)

- Each of the pair of kidneys consists of an outer renal cortex and inner renal medulla. (Review Figure 13-1.)
- The kidneys form urine. They eliminate unwanted plasma constituents in the urine while conserving materials of value to the body.
- The urine-forming functional unit of the kidneys is the nephron, which is composed of interrelated vascular and tubular components. (Review Figure 13-3.)
- The vascular component consists of two capillary networks in series: (1) the glomerulus, and (2) the peritubular capillaries. (Review Figures 13-3 and 13-4.)
- The tubular component begins with Bowman's capsule, which cups around the glomerulus to catch the filtrate, then continues a specific tortuous course to ultimately empty into the renal pelvis. (Review Figure 13-3.)
- The kidneys perform three basic processes in carrying out their regulatory and excretory functions: (1) glomerular filtration, the nondiscriminating movement of protein-free plasma from the blood into the tubules; (2) tubular reabsorption, the selective transfer of specific constituents in the filtrate back into the blood of the peritubular capillaries; and (3) tubular secretion, the highly specific movement of selected substances from peritubular capillary blood into the tubular fluid. Everything filtered or secreted but not reabsorbed is excreted as urine. (Review Figure 13-6.)

13.2 | Renal Blood Flow (pp. 565–566)

- RBF is greatest at rest (1200 mL/min) and becomes reduced during exercise. The purpose of this relatively high blood flow is to supply the kidney with sufficient plasma for filtration, secretion, and reabsorption.
- Control of RBF is primarily via the ANS, with the sympathetic division exerting the greatest control through vasoconstriction. The adrenal medulla reinforces the sympathetic vasoconstriction.

13.3 | Glomerular Filtration (pp. 566–573)

- Glomerular filtrate is produced when part of the plasma flowing through each glomerulus is passively forced under pressure through the glomerular membrane into the lumen of the underlying Bowman's capsule. (Review Figure 13-7.)
- The net filtration pressure that induces filtration is caused by an imbalance in the physical forces acting across the glomerular membrane. A high glomerular capillary blood pressure favouring filtration outweighs the combined opposing forces of plasma-colloid osmotic pressure and Bowman's capsule hydrostatic pressure. (Review Table 13-1.)
- Of the plasma flowing through the kidneys, normally 20 percent is filtered through the glomeruli, producing an average

glomerular filtration rate (GFR) of 125 mL/min. This filtrate is identical in composition to plasma, except for the plasma proteins, which are held back by the glomerular membrane.

- The GFR can be deliberately altered through a change in the glomerular capillary blood pressure by means of sympathetic influence on the afferent arterioles as part of the baroreceptor reflex response that compensates for changed arterial blood pressure.
- As the GFR is altered, the amount of fluid lost in urine changes correspondingly, and plasma volume adjusts as needed to help restore blood pressure to normal on a long-term basis. (Review Figure 13-12.)

13.4 | Tubular Reabsorption (pp. 573–582)

- After a protein-free plasma is filtered through the glomerulus, the tubules handle each substance discretely, so that even though the concentrations of all constituents in the initial glomerular filtrate are identical to their concentrations in the plasma (with the exception of plasma proteins), the concentrations of different constituents are variously altered as the filtered fluid flows through the tubular system. (Review Tables 13-2 and 13-3.)
- The reabsorptive capacity of the tubular system is tremendous. More than 99 percent of the filtered plasma is returned to the blood through reabsorption. On average, 124 mL out of the 125 mL filtered per minute are reabsorbed. (Review Table 13-2.)
- Tubular reabsorption involves transepithelial transport from the tubular lumen into the peritubular capillary plasma. This process may be active (requiring energy) or passive (using no energy). (Review Figure 13-14.)
- The pivotal event to which most reabsorptive processes are somehow linked is the active reabsorption of Na^+ , driven by an energy-dependent $\text{Na}^+ - \text{K}^+$ ATPase carrier located in the basolateral membrane of almost all tubular cells. The transport of Na^+ out of the cells into the lateral spaces between adjacent cells by this carrier induces the net reabsorption of Na^+ from the tubular lumen to the peritubular capillary plasma. (Review Figure 13-15.)
- Most Na^+ reabsorption takes place early in the nephron in constant unregulated fashion, but in the distal and collecting tubules, the reabsorption of a small percentage of the filtered Na^+ is variable and subject to control, depending primarily on the complex renin-angiotensin-aldosterone system. (Review Table 13-4.)
- Because Na^+ and its attendant anion, Cl^- , are the major osmotically active ions in the ECF, the ECF volume is determined by the Na^+ load in the body. In turn, the plasma volume, which reflects the total ECF volume, is important in the long-term determination of arterial blood pressure. Whenever the Na^+ load, ECF volume, plasma volume, and arterial blood pressure are below normal, the juxtaglomerular apparatus of the kidneys secretes renin, an enzymatic hormone that triggers a series of events

ultimately leading to increased secretion of aldosterone from the adrenal cortex. Aldosterone increases Na^+ reabsorption from the distal portions of the tubule, thereby correcting for the original reduction in Na^+ , ECF volume, and blood pressure. (Review Figures 13-11 and 13-16.)

- By contrast, Na^+ reabsorption is inhibited by atrial natriuretic peptide, a hormone released from the cardiac atria in response to expansion of the ECF volume and a subsequent increase in blood pressure. (Review Figure 13-17.)

- In addition to driving the reabsorption of Na^+ , the energy used to supply the $\text{Na}^+ - \text{K}^+$ ATPase carrier is ultimately responsible for the reabsorption of organic nutrient molecules from the proximal tubule by secondary active transport. Specific cotransport carriers located at the luminal border of the proximal tubular cell are driven by the Na^+ concentration gradient to selectively transport glucose or an amino acid from the luminal fluid into the tubular cell, from which the nutrient eventually enters the plasma.

- The other electrolytes besides Na^+ that are actively reabsorbed by the tubules, such as PO_4^{3-} and Ca^{2+} , have their own independently functioning carrier systems within the proximal tubule.

- Because these carriers, like the organic-nutrient cotransport carriers, can become saturated, each exhibits a maximal carrier-limited transport capacity (T_m). Once the filtered load of an actively reabsorbed substance exceeds the T_m , reabsorption proceeds at a constant maximal rate, and the additional filtered quantity of the substance is excreted in urine. (Review Figure 13-18.)

- Active Na^+ reabsorption also drives the passive reabsorption of Cl^- (via an electrical gradient), H_2O (by osmosis), and urea (down a urea concentration gradient created as a result of extensive osmotic-driven H_2O reabsorption). Sixty-five percent of the filtered H_2O is reabsorbed from the proximal tubule in unregulated fashion, driven by active Na^+ reabsorption. Reabsorption of H_2O increases the concentration of other substances remaining in the tubular fluid, most of which are filtered waste products. The small urea molecules are the only waste products that can passively permeate the tubular membranes. Accordingly, urea is the only waste product partially reabsorbed as a result of being concentrated. About 50 percent of the filtered urea is reabsorbed. (Review Figures 13-19 and 13-20 and Table 13-4.)

- The other waste products, which are not reabsorbed, remain in the urine in highly concentrated form.

13.5 | Tubular Secretion (pp. 583–585)

- By tubular secretion, the kidney tubules can selectively add some substances to the quantity already filtered. Secretion of substances hastens their excretion in the urine.

- The most important secretory systems are for (1) H^+ , which is important in regulating acid–base balance; (2) K^+ , which keeps the plasma K^+ concentration at an appropriate level to maintain normal membrane excitability in muscles and nerves; and (3) organic ions, which accomplish more efficient elimination of

foreign organic compounds from the body. (Review Figures 13-21 and 13-22.)

- H^+ is secreted in the proximal, distal, and collecting tubules. K^+ is secreted only in the distal and collecting tubules under control of aldosterone. Organic ions are secreted only in the proximal tubule. (Review Table 13-3.)

13.6 | Urine Excretion and Plasma Clearance (pp. 585–601)

- Of the 125 mL/min of filtrate formed in the glomeruli, normally only 1 mL/min remains in the tubules to be excreted as urine.

- Only wastes and excess electrolytes not wanted by the body are left behind, dissolved in a given volume of H_2O to be eliminated in the urine.

- Because the excreted material is removed, or cleared, from the plasma, the term *plasma clearance* refers to the volume of plasma cleared of a particular substance each minute by renal activity. (Review Figure 13-23.)

- The kidneys can excrete urine of varying volumes and concentrations to either conserve or eliminate H_2O , depending on whether the body has a H_2O deficit or excess, respectively. The kidneys can produce urine ranging from 0.3 mL/min at 1200 mOsm/L to 25 mL/min at 100 mOsm/L by reabsorbing variable amounts of H_2O from the distal portions of the nephron.

- This variable reabsorption is made possible by a vertical osmotic gradient in the medullary interstitial fluid, which is established by the long loops of Henle of the juxtamedullary nephrons via countercurrent multiplication and preserved by the vasa recta of these nephrons via countercurrent exchange. (Review Figures 13-5, 13-24, 13-25, and 13-28.) This vertical osmotic gradient, to which the hypotonic (100 mOsm/L) tubular fluid is exposed as it passes through the distal portions of the nephron, establishes a passive driving force for progressive reabsorption of H_2O from the tubular fluid, but the actual extent of H_2O reabsorption depends on the amount of vasopressin (antidiuretic hormone) secreted. (Review Figure 13-27.)

- Vasopressin increases the permeability of the distal and collecting tubules to H_2O ; they are impermeable to H_2O in its absence. (Review Figure 13-26.) Vasopressin secretion increases in response to a H_2O deficit, and H_2O reabsorption increases accordingly. Vasopressin secretion is inhibited in response to a H_2O excess, reducing H_2O reabsorption. In this way, adjustments in vasopressin-controlled H_2O reabsorption help correct any fluid imbalances.

- The bladder can accommodate approximately 250–400 mL of urine before stretch receptors within its wall initiate the micturition reflex. (Review Figure 13-30.) This reflex causes involuntary emptying of the bladder by simultaneous bladder contraction and the opening of both the internal and external urethral sphincters. Micturition can transiently be voluntarily prevented until a more opportune time by deliberate tightening of the external sphincter and surrounding pelvic diaphragm. (Review Figure 13-29.)

14.1 | Balance Concept (pp. 608–609)

- The internal pool of a substance is the quantity of that substance in the ECF.
- Inputs to the pool occur by way of ingestion or metabolic production of the substance. Outputs from the pool occur by way of excretion or metabolic consumption of the substance. (Review Figure 14-1.)
- Input must equal output to maintain a stable balance of the substance.

14.2 | Fluid Balance (pp. 609–619)

- On average, the body fluids compose 60 percent of total body weight. This figure varies among individuals, depending on how much fat (a tissue with a low H₂O content) a person has.
- Two-thirds of the body H₂O is found in the intracellular fluid (ICF). The remaining third present in the extracellular fluid (ECF) is distributed between plasma (20% of ECF) and interstitial fluid (80% of ECF). (Review Table 14-1.)
- Because all plasma constituents are freely exchanged across the capillary walls, the plasma and interstitial fluid are nearly

identical in composition, except for the lack of plasma proteins in the interstitial fluid. In contrast, the ECF and ICF have markedly different compositions, because the plasma membrane barriers are highly selective as to what materials are transported into or out of the cells. (Review Figure 14-2.)

- The essential components of fluid balance are control of ECF volume by maintaining salt balance and control of ECF osmolarity by maintaining water balance. (Review Tables 14-2, 14-3, and 14-5.)
- Because of the osmotic holding power of Na⁺, the major ECF cation, a change in the body's total Na⁺ content brings about a corresponding change in ECF volume, including plasma volume, which, in turn, alters arterial blood pressure in the same direction. Appropriately, in the long run, Na⁺-regulating mechanisms compensate for changes in ECF volume and arterial blood pressure. (Review Table 14-5.)
- Salt intake is not controlled in humans, but control of salt output in the urine is closely regulated. Blood pressure–regulating mechanisms can vary the GFR, and, accordingly, the amount of Na⁺ filtered, by adjusting the radius of the afferent arterioles that supply the glomeruli. Simultaneously, blood pressure–regulating

mechanisms can vary the secretion of aldosterone to adjust Na^+ reabsorption by the renal tubules. Varying Na^+ filtration and Na^+ reabsorption can adjust how much Na^+ is excreted in the urine to regulate plasma volume and, consequently, arterial blood pressure in the long term. (Review Figure 14-3.)

- Changes in ECF osmolarity are primarily detected and corrected by the systems that maintain H_2O balance.
- ECF osmolarity must be closely regulated to prevent osmotic shifts of H_2O between the ECF and ICF, because cell swelling or shrinking is harmful, especially to brain neurons. Excess free H_2O in the ECF dilutes ECF solutes; the resulting ECF hypotonicity drives H_2O into the cells. An ECF free H_2O deficit, by contrast, concentrates ECF solutes, so H_2O leaves the cells to enter the hypertonic ECF. (Review Table 14-5.)
- To prevent these harmful fluxes, free H_2O balance is regulated largely by vasopressin and, to a lesser degree, by thirst.
- Changes in vasopressin secretion and thirst are both governed primarily by hypothalamic osmoreceptors, which monitor ECF osmolarity. The amount of vasopressin secreted determines the extent of free H_2O reabsorption by distal portions of the nephrons, thereby determining the volume of urinary output. (Review Figure 14-4 and Table 14-4.)
- Simultaneously, intensity of thirst controls the volume of fluid intake. However, because the volume of fluid drunk is often not directly correlated with the intensity of thirst, control of urinary output by vasopressin is the most important regulatory mechanism for maintaining H_2O balance.

14.3 | Acid–Base Balance (pp. 620–637)

- Acids liberate free hydrogen ions (H^+) into solution; bases bind with free H^+ ions and remove them from solution. (Review Figure 14-5.)
- Acid–base balance refers to regulation of H^+ concentration ($[\text{H}^+]$) in the body fluids. To precisely maintain $[\text{H}^+]$, input of H^+ by metabolic production of acids within the body must continually be matched with H^+ output by urinary excretion of H^+ and respiratory removal of H^+ -generating CO_2 . Furthermore, between the time of its generation and its elimination, H^+ must be buffered within the body to prevent marked fluctuations in $[\text{H}^+]$.
- Hydrogen ion concentration is often expressed in terms of pH, which is the logarithm of $1/[\text{H}^+]$.
- The normal pH of the plasma is 7.4, slightly alkaline compared to neutral H_2O , which has a pH of 7.0. A pH lower than normal (higher $[\text{H}^+]$ than normal) indicates a state of acidosis. A pH higher than normal (lower $[\text{H}^+]$ than normal) characterizes a state of alkalosis. (Review Figure 14-6.)
- Fluctuations in $[\text{H}^+]$ have profound effects on body chemistry, most notably (1) changes in neuromuscular excitability, with acidosis depressing excitability, especially in the central nervous system, and alkalosis producing overexcitability of both the peripheral and the central nervous systems; (2) disruption of normal metabolic reactions by altering the structure and function of all enzymes; and (3) alterations in plasma $[\text{K}^+]$ brought about by H^+ -induced changes in the rate of K^+ elimination by the kidneys.

- The primary challenge in controlling acid–base balance is maintaining normal plasma alkalinity despite continual addition of H^+ to the plasma from ongoing metabolic activity. The major source of H^+ is from the dissociation of CO_2 -generated H_2CO_3 .
- The three lines of defence for resisting changes in $[\text{H}^+]$ are (1) the chemical buffer systems, (2) respiratory control of pH, and (3) renal control of pH.
- Chemical buffer systems, the first line of defence, each consist of a pair of chemicals involved in a reversible reaction, one that can liberate H^+ and the other that can bind H^+ . By acting according to the law of mass action, a buffer pair acts immediately to minimize any changes in pH. (Review Figure 14-8 and Table 14-6.)
- The respiratory system, the second line of defence, normally eliminates the metabolically produced CO_2 so that H_2CO_3 does not accumulate in the body fluids.
- When chemical buffers alone have been unable to immediately minimize a pH change, the respiratory system responds within a few minutes by altering its rate of CO_2 removal. An increase in $[\text{H}^+]$ from sources other than carbonic acid stimulates respiration so that more H_2CO_3 -forming CO_2 is blown off, thereby compensating for acidosis by reducing the generation of H^+ from H_2CO_3 . Conversely, a fall in $[\text{H}^+]$ depresses respiratory activity so that CO_2 and thus H^+ -generating H_2CO_3 can accumulate in the body fluids to compensate for alkalosis. (Review Table 14-7.)
- The kidneys are the third and most powerful line of defence. They require hours to days to compensate for a deviation in body-fluid pH. However, they not only eliminate the normal amount of H^+ produced from non- H_2CO_3 sources but they can also alter their rate of H^+ removal in response to changes in both non- H_2CO_3 and H_2CO_3 acids. In contrast, the lungs can adjust only H^+ generated from H_2CO_3 . Furthermore, the kidneys can regulate $[\text{HCO}_3^-]$ in body fluids as well.
- The kidneys compensate for acidosis by secreting the excess H^+ in the urine while adding new HCO_3^- to the plasma to expand the HCO_3^- -buffer pool. During alkalosis, the kidneys conserve H^+ by reducing its secretion in urine. They also eliminate HCO_3^- which is in excess because less HCO_3^- than usual is tied up buffering H^+ when H^+ is in short supply. (Review Figures 14-9, 14-10, and 14-11 and Table 14-8.)
- Secreted H^+ must be buffered in the tubular fluid to prevent the H^+ concentration gradient from becoming so great that it blocks further H^+ secretion. Normally, H^+ is buffered by the urinary phosphate buffer pair, which is abundant in the tubular fluid because excess dietary phosphate spills into the urine to be excreted from the body.
- In acidosis, when all the phosphate buffer is already used up in buffering the extra secreted H^+ , the kidneys secrete NH_3 into the tubular fluid to serve as a buffer so that H^+ secretion can continue.
- The four types of acid–base imbalances are respiratory acidosis, respiratory alkalosis, metabolic acidosis, and metabolic alkalosis. Respiratory acid–base disorders stem from deviations from normal $[\text{CO}_2]$, whereas metabolic acid imbalances include all deviations in pH other than those caused by abnormal $[\text{CO}_2]$. (Review Figure 14-12 and Table 14-9.)

15.1 | Introduction (pp. 645–652)

- The four basic digestive processes are motility, secretion, digestion, and absorption.
- The three classes of energy-rich nutrients are digested into absorbable units as follows: (1) Dietary carbohydrates in the form of the polysaccharides starch and glycogen are digested into their absorbable units of monosaccharides, especially glucose. (*Review Figure 15-1.*) (2) Dietary proteins are digested into their absorbable units of amino acids and a few small polypeptides. (3) Dietary fats in the form of triglycerides are digested into their absorbable units of monoglycerides and free fatty acids.
- The digestive system consists of the digestive tract and accessory digestive organs (salivary glands, exocrine pancreas, and biliary system). (*Review Table 15-1.*)
- The lumen of the digestive tract is continuous with the external environment, so its contents are technically outside the body; this arrangement permits digestion of food without self-digestion occurring in the process.
- The digestive tract wall has four layers throughout most of its length. From innermost outward, they are the mucosa, submucosa, muscularis externa, and serosa. (*Review Figure 15-2.*)

15.2 | Mouth (pp. 652–654)

- **Motility:** Food enters the digestive system through the mouth, where it is chewed and mixed with saliva to facilitate swallowing.
- **Secretion:** The salivary enzyme, amylase, begins the digestion of carbohydrates. More important than its minor digestive function, saliva is essential for articulating speech and plays an important role in dental health. Salivary secretion is controlled by a salivary centre in the medulla, mediated by autonomic innervation of the salivary glands. (*Review Figure 15-4.*)
- **Digestion:** Salivary amylase begins to digest polysaccharides into the disaccharide maltose, a process that continues in the stomach after the food has been swallowed and until amylase is eventually inactivated by the acidic gastric juice. (*Review Figure 15-1, and Table 15-6.*)
- **Absorption:** No absorption of nutrients occurs from the mouth.

15.3 | Pharynx and Esophagus (pp. 654–656)

- **Motility:** Following chewing, the tongue propels the bolus of food to the rear of the throat, which initiates the swallowing reflex. The swallowing centre in the medulla coordinates a complex group of activities that result in closure of the respiratory passages and propulsion of food through the pharynx and esophagus into the stomach. (*Review Figure 15-5.*)
- **Secretion:** The esophageal secretion, mucus, is protective in nature.

- **Digestion and absorption:** No nutrient digestion or absorption occurs in the pharynx or esophagus.

15.4 | Stomach (pp. 656–667)

- **Motility:** The four aspects of gastric motility are gastric filling, storage, mixing, and emptying.
 - Gastric filling is facilitated by vagally mediated receptive relaxation of the stomach muscles.
 - Gastric storage takes place in the body of the stomach, where peristaltic contractions of the thin muscle walls are too weak to mix the contents.
 - Gastric mixing in the thick-muscle antrum results from vigorous peristaltic contractions. (*Review Figure 15-7.*)
 - Gastric emptying is influenced by the following factors in the stomach and duodenum: (1) the volume and fluidity of chyme in the stomach; and (2) the duodenal factors, which are the dominant factors controlling gastric emptying. The specific factors in the duodenum that delay gastric emptying are fat, acid, hypertonicity, and distension. (*Review Figure 15-7 and Table 15-2.*)
- **Secretion:** Gastric secretions into the stomach lumen include (1) HCl (from the parietal cells), which activates pepsinogen, denatures protein, and kills bacteria; (2) pepsinogen (from the chief cells), which, once activated, initiates protein digestion; (3) mucus (from the mucous cells), which provides a protective coating to supplement the gastric mucosal barrier, enabling the stomach to contain harsh luminal contents without self-digestion; and (4) intrinsic factor (from the parietal cells), which plays a vital role in vitamin B12 absorption, a constituent essential for normal red blood cell production. (*Review Table 15-3 and Figures 15-8, 15-9, and 15-10.*)
- The stomach also secretes the following endocrine and paracrine regulatory factors: (1) the hormone gastrin (from the G cells), which plays a dominant role in stimulating gastric secretion; (2) the paracrine histamine (from the ECL cells), a potent stimulant of acid secretion by the parietal cells; and (3) the paracrine somatostatin (from the D cells), which inhibits gastric secretion. (*Review Table 15-3.*)
- Gastric secretion is under complex control mechanisms. Gastric secretion is increased during the cephalic and gastric phases of gastric secretion before and during a meal by mechanisms involving excitatory vagal and intrinsic nerve responses along with the stimulatory actions of gastrin and histamine. (*Review Tables 15-4 and 15-5.*)
- **Digestion:** Carbohydrate digestion continues in the body of the stomach under the influence of the swallowed salivary amylase. Protein digestion is initiated by pepsin in the antrum of the stomach, where vigorous peristaltic contractions mix the food

with gastric secretions, converting it to a thick liquid mixture known as *chyme*. (Review Table 15-6.)

- **Absorption:** No nutrients are absorbed from the stomach.

15.5 | Pancreatic and Biliary Secretions (pp. 667–676)

- Pancreatic exocrine secretions and bile from the liver both enter the duodenal lumen.
- Pancreatic secretions include (1) potent digestive enzymes from the acinar cells, which digest all three categories of foodstuff; and (2) an aqueous NaHCO_3 solution from the duct cells, which neutralizes the acidic contents emptied into the duodenum from the stomach. This neutralization is important to protect the duodenum from acid injury and to allow pancreatic enzymes, which are inactivated by acid, to perform their important digestive functions. (Review Figure 15-11.)
- The pancreatic digestive enzymes include (1) the proteolytic enzymes trypsinogen, chymotrypsinogen, and procarboxypeptidase, which are secreted in inactive form and are activated in the duodenal lumen on exposure to enterokinase and activated trypsin; (2) pancreatic amylase, which continues carbohydrate digestion; and (3) lipase, which accomplishes fat digestion. (Review Table 15-6.)
- Pancreatic secretion is primarily under hormonal control, which matches composition of the pancreatic juice with the needs in the duodenal lumen. Secretin stimulates the pancreatic duct cells, and cholecystokinin (CCK) stimulates the acinar cells. (Review Figure 15-12.)
- The liver, the body's largest and most important metabolic organ, performs many varied functions. (Review Figure 15-14.) Its contribution to digestion is the secretion of bile, which contains bile salts.
- Bile salts aid fat digestion through their detergent action and facilitate fat absorption by forming water-soluble micelles that can carry the water-insoluble products of fat digestion to their absorption site. (Review Figures 15-13 and 15-15 to 15-17.)
- Bile also contains bilirubin, a derivative of degraded haemoglobin, which is the major excretory product in the feces.

15.6 | Small Intestine (pp. 676–688)

- The small intestine is the main site for digestion and absorption.
- **Motility:** Segmentation, the small intestine's primary motility during digestion of a meal, thoroughly mixes the food with pancreatic, biliary, and small-intestine juices to facilitate digestion; it also exposes the products of digestion to the absorptive surfaces. (Review Figure 15-18.)
- **Secretion:** The juice secreted by the small intestine does not contain any digestive enzymes.
- **Digestion:** The pancreatic enzymes continue carbohydrate and protein digestion in the small-intestine lumen. The

small-intestine brush-border enzymes complete the digestion of carbohydrates and protein. Fat is digested entirely in the small-intestine lumen, by pancreatic lipase. (Review Figure 15-22a and Table 15-6.)

- **Absorption:** The small-intestine lining is remarkably adapted for its digestive and absorptive functions. Its folds bear a rich array of finger-like projections, the villi, which have a multitude of even smaller hairlike protrusions, the microvilli. Together, these surface modifications tremendously increase the area available to house the membrane-bound enzymes and to accomplish both active and passive absorption. (Review Figures 15-20, 15-21, and 15-22.)
- The energy-dependent process of Na^+ absorption provides the driving force for Cl^- , water, glucose, and amino acid absorption. All these absorbed products enter the blood. (Review Figures 15-23 and 15-24.)
- Because they are not soluble in water, the products of fat digestion must undergo a series of transformations that enable them to be passively absorbed, eventually entering the lymph.

15.7 | Large Intestine (pp. 688–692)

- The colon serves primarily to concentrate and store undigested food residues (fibre, the indigestible cellulose in plant walls) and bilirubin until they can be eliminated from the body as feces. (Review Figure 15-28.)
- **Motility:** Haustral contractions slowly shuffle the colonic contents back and forth to mix and facilitate absorption of most of the remaining fluid and electrolytes. Mass movements several times a day, usually after meals, propel the feces long distances. Movement of feces into the rectum triggers the defecation reflex, which the person can voluntarily prevent by contracting the external anal sphincter if the time is inopportune for elimination.
- **Secretion:** The alkaline mucous secretion of the large intestine is primarily protective in function.
- **Digestion and absorption:** No secretion of digestive enzymes or absorption of nutrients takes place in the colon, as all nutrient digestion and absorption was previously completed in the small intestine. Absorption of some of the remaining salt and water converts the colonic contents into feces.

15.8 | Overview of the Gastrointestinal Hormones (pp. 692–693)

- Each of these hormones performs multiple interrelated functions.
- Gastrin is released primarily in response to the presence of protein products in the stomach, and its effects promote digestion of protein, movement of materials through the digestive tract, and maintenance of the integrity of the stomach and small-intestine mucosa.

■ Secretin is released primarily in response to the presence of acid in the duodenum, and its effects neutralize the acid in the duodenal lumen and maintain the integrity of the exocrine pancreas.

■ Cholecystokinin is released primarily in response to the presence of fat products in the duodenum, and its effects optimize conditions for digesting fat and other nutrients and for maintaining the integrity of the exocrine pancreas.

NOTES

This image shows a single sheet of white paper with horizontal ruling lines. The lines are evenly spaced and run across the width of the page. There are no margins, text, or other markings on the paper.

16.1 | Energy Balance (pp. 699–710)

- Energy input to the body in the form of food energy must equal energy output, because energy cannot be created or destroyed.
- Energy output or expenditure includes (1) external work, performed by skeletal muscles to move an external object or move the body through the external environment; and (2) internal work, which consists of all other energy-dependent activities that do not accomplish external work, including active transport, smooth and cardiac muscle contraction, glandular secretion, and protein synthesis. *(Review Figure 16-1.)*
- Only about 25 percent of the chemical energy in food is harnessed to do biological work. The rest is immediately converted to heat. Furthermore, all the energy expended to accomplish internal work is eventually converted into heat, and 75 percent of the energy expended by working skeletal muscles is lost as heat. Therefore, most of the energy in food ultimately appears as body heat.
- The metabolic rate, which is energy expenditure per unit of time, is measured in kilocalories of heat produced per hour.
- The basal metabolic rate (BMR) is a measure of the body's minimal waking rate of internal energy expenditure.
- For a neutral energy balance, the energy in ingested food must equal energy expended in performing external work and transformed into heat. If more energy is consumed than is expended, the extra energy is stored in the body, primarily as adipose tissue, so body weight increases. By contrast, if more energy is expended than is available in the food, body energy stores are used to support energy expenditure, so body weight decreases.
- Usually, body weight remains fairly constant over a prolonged period of time (except during growth), because food intake is adjusted to match energy expenditure on a long-term basis.
- Food intake is controlled primarily by the hypothalamus by means of complex regulatory mechanisms in which hunger and satiety are important components. Feeding or appetite signals give rise to the sensation of hunger and promote eating, whereas satiety signals lead to the sensation of fullness and suppress eating.
- The arcuate nucleus of the hypothalamus plays a key role in energy homeostasis by virtue of the two clusters of appetite-regulating neurons it contains: neurons that secrete neuropeptide Y (NPY), which increases appetite and food intake; and neurons that secrete melanocortins, which suppress appetite and food intake. *(Review Figure 16-2.)*
- Adipocytes in fat stores secrete the hormone leptin, which reduces appetite and decreases food consumption by inhibiting the NPY-secreting neurons and stimulating the

melanocortins-secreting neurons of the arcuate nucleus. This mechanism is primarily important in the long-term matching of energy intake with energy output, thereby maintaining body weight over the long term. *(Review Table 16-2 and Figure 16-2.)*

- Insulin released by the endocrine pancreas in response to increased glucose and other nutrients in the blood also inhibits the NPY-secreting neurons and contributes to long-term control of energy balance and body weight.
- NPY and melanocortins bring about their effects by acting on the lateral hypothalamus area (LHA) and paraventricular nucleus (PVN) to alter the release of chemical messengers from these areas. The LHA secretes orexins that are potent stimulators of food intake, whereas the PVN releases neuropeptides such as corticotropin-releasing hormone that decrease food intake. *(Review Figure 16-2.)*
- Short-term control of the timing and size of meals is mediated primarily by the actions of signals arising from the digestive tract and pancreas. Of major importance are two peptides secreted by the digestive tract. (1) Ghrelin, a mealtime initiator, is secreted by the stomach before a meal and signals hunger. Its secretion drops when food is consumed. Ghrelin stimulates appetite and promotes feeding behaviour by stimulating the NPY-secreting neurons. (2) PYY_{3–36}, a mealtime terminator, is secreted by the small and large intestines during a meal and signals satiety. Its secretion is lowest before a meal. PYY_{3–36} inhibits the NPY-secreting neurons. *(Review Figure 16-2.)*
- The nucleus tractus solitarius (NTS) in the brain stem serves as the satiety centre and in this capacity also plays a key role in the short-term control of meals. The NTS receives input from the higher hypothalamic areas concerned with control of energy balance and food intake as well as input from the digestive tract and pancreas. Satiety signals acting through the NTS to inhibit further food intake include stomach distension and increased cholecystokinin, a hormone released from the duodenum in response to the presence of nutrients, especially fat, in the digestive tract lumen. *(Review Figure 16-2.)*
- Psychosocial and environmental factors can also influence food intake above and beyond the internal signals that govern feeding behaviour.

16.2 | Temperature Regulation (pp. 710–719)

- The body can be thought of as a heat-generating core (internal organs, CNS, and skeletal muscles) surrounded by a shell of variable insulating capacity (the skin).
- The skin exchanges heat energy with the external environment, with the direction and amount of heat transfer depending on the environmental temperature and the momentary insulating capacity of the shell.

© 2016 Cengage

■ The four physical means by which heat is exchanged between the body and external environment are (1) radiation (net movement of heat energy via electromagnetic waves); (2) conduction (exchange of heat energy by direct contact); (3) convection (transfer of heat energy by means of air currents); and (4) evaporation (extraction of heat energy from the body by the heat-requiring conversion of liquid H_2O to H_2O vapour). Because heat energy moves from warmer to cooler objects, radiation, conduction, and convection can be channels for either heat loss or heat gain, depending on whether surrounding objects are cooler or warmer, respectively, than the body surface.

■ Normally, they are avenues for heat loss, along with evaporation resulting from sweating. (Review Figure 16-4.)

■ To prevent serious cell malfunction, the core temperature must be held constant at about $36.8^{\circ}C$ (equivalent to an average oral temperature of $36.8^{\circ}C$) by continuously balancing heat gain and heat loss despite changes in environmental temperature and variation in internal heat production. (Review Figure 16-3.)

■ This thermoregulatory balance is controlled by the hypothalamus. Peripheral thermoreceptors inform the hypothalamus of the skin temperature, and central thermoreceptors—the most important of which are located in the hypothalamus itself—inform the hypothalamus of the core temperature.

■ The primary means of heat gain is heat production by metabolic activity; the biggest contributor is skeletal muscle contraction.

■ Heat loss is adjusted by sweating and by controlling to the greatest extent possible the temperature gradient between the skin and surrounding environment. The latter is

accomplished by regulating the diameter of the skin's blood vessels. (1) Vasoconstriction of the skin vessels reduces the flow of warmed blood through the skin so that skin temperature falls. The layer of cool skin between the core and environment increases the insulating barrier between the warm core and the external air. (2) Conversely, skin vasodilation brings more warmed blood through the skin so that skin temperature approaches the core temperature, thus reducing the insulative capacity of the skin.

■ On exposure to cool surroundings, the core temperature starts to fall as heat loss increases, because of the larger-than-normal skin-to-air temperature gradient. The hypothalamus responds to reduce the heat loss by inducing skin vasoconstriction, while simultaneously increasing heat production through heat-generating shivering. (Review Table 16-4.)

■ Conversely, in response to a rise in core temperature (resulting either from excessive internal heat production accompanying exercise or from excessive heat gain on exposure to a hot environment), the hypothalamus triggers heat-loss mechanisms, such as skin vasodilation and sweating, while simultaneously decreasing heat production, such as by reducing muscle tone. (Review Table 16-4.)

■ In both cold and heat responses, voluntary behavioural actions also contribute importantly to maintenance of thermal homeostasis.

■ A fever occurs when endogenous pyrogen released from macrophages in response to infection raises the hypothalamic set point. An elevated core temperature develops as the hypothalamus initiates cold-response mechanisms to raise the core temperature to the new set point. (Review Figure 16-5.)

17.1 | Introduction (pp. 723–731)

- Both sexes produce gametes (reproductive cells), sperm in males and ova (eggs) in females, each of which bears one member of each of the 23 pairs of chromosomes present in human cells. Union of a sperm and an ovum at fertilization results in the beginning of a new individual that has 23 complete pairs of chromosomes, half from the father and half from the mother. (Review Figure 17-3.)
- In both sexes, the reproductive system consists of (1) a pair of gonads, testes in males and ovaries in females, which are the primary reproductive organs that produce the gametes and secrete sex hormones; (2) a reproductive tract composed of a system of ducts that transport and/or house the gametes after they are produced; and (3) accessory sex glands that provide supportive secretions for the gametes. The externally visible portions of the reproductive system constitute the external genitalia. (Review Figures 17-1 and 17-2.)
- Secondary sexual characteristics are the distinguishing features between males and females not directly related to reproduction.
- Sex determination is a genetic phenomenon dependent on the combination of sex chromosomes at the time of fertilization: an XY combination is a genetic male, and an XX combination, a genetic female. (Review Figure 17-4.)
- The term *sex differentiation* refers to the embryonic development of the gonads, reproductive tract, and external genitalia along male or female lines, which gives rise to the apparent anatomic sex of the individual. In the presence of masculinizing factors, a male reproductive system develops; in their absence, a female system develops. (Review Figures 17-4, 17-5, and 17-6.)

17.2 | Male Reproductive Physiology (pp. 731–741)

- The testes are located in the scrotum. The cooler temperature in the scrotum than in the abdominal cavity is essential for spermatogenesis.
- Spermatogenesis (sperm production) occurs in the testes' highly coiled seminiferous tubules. (Review Figures 17-7 and 17-8.)
- Leydig cells in the interstitial spaces between these tubules secrete the male sex hormone, testosterone, into the blood. (Review Figure 17-7.)
- Testosterone is secreted before birth to masculinize the developing reproductive system; then its secretion ceases until puberty, at which time it begins once again and continues throughout life. Testosterone is responsible for maturation and maintenance of the entire male reproductive tract, for development of secondary sexual characteristics, and for stimulating libido. (Review Table 17-1.)

- The testes are regulated by the anterior pituitary hormones: luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These gonadotropic hormones, in turn, are under control of hypothalamic gonadotropin-releasing hormone (GnRH). (Review Figure 17-10.)
- Testosterone secretion is regulated by LH stimulation of the Leydig cells, and, in negative-feedback fashion, testosterone inhibits gonadotropin secretion. (Review Figure 17-10.)
- Spermatogenesis requires both testosterone and FSH. Testosterone stimulates the mitotic and meiotic divisions required to transform the undifferentiated diploid germ cells, the spermatogonia, into undifferentiated haploid spermatids. FSH stimulates the remodelling of spermatids into highly specialized motile spermatozoa. (Review Figure 17-8.)
- Also present in the seminiferous tubules are Sertoli cells, which protect, nurse, and enhance the germ cells throughout their development. Sertoli cells also secrete inhibin, a hormone that inhibits FSH secretion, completing the negative-feedback loop. (Review Figures 17-7b and 17-7d and 17-10.)
- The still immature sperm are flushed out of the seminiferous tubules into the epididymis by fluid secreted by the Sertoli cells.
- The epididymis and ductus deferens store and concentrate the sperm and increase their motility and fertility prior to ejaculation. (Review Table 17-2 and Figure 17-7.)
- During ejaculation, the sperm are mixed with secretions released by the accessory glands. (Review Table 17-2.)
- The seminal vesicles supply fructose for energy and prostaglandins, which promote smooth muscle motility in both the male and female reproductive tracts, for enhancement of sperm transport. The seminal vesicles also contribute the bulk of the semen.
- Prostaglandins are produced throughout the body, not just in the reproductive tract. These ubiquitous chemical messengers are derived from arachidonic acid, a component of the plasma membrane. By acting as paracrine, specific prostaglandins exert a variety of local effects. (Review Figure 17-11 and Table 17-3.)
- The prostate gland contributes an alkaline fluid for neutralizing the acidic vaginal secretions.
- The bulbourethral glands release lubricating mucus.

17.3 | Sexual Intercourse between Males and Females (pp. 741–744)

- The male sex act consists of erection and ejaculation, which are part of a much broader systemic, emotional response that typifies the male sexual response cycle. (Review Table 17-4.)
- Erection is a hardening of the normally flaccid penis that enables it to penetrate the female vagina. Erection is accomplished by marked vasocongestion of the penis brought about

by reflexly induced vasodilation of the arterioles supplying the penile erectile tissue. (Review Figure 17-12.)

- When sexual excitation reaches a critical peak, ejaculation occurs. It consists of two stages: (1) emission, the emptying of semen (sperm and accessory sex gland secretions) into the urethra; and (2) expulsion of semen from the penis. The latter is accompanied by a set of characteristic systemic responses and intense pleasure referred to as *orgasm*. (Review Table 17-4.)

- Females experience a sexual cycle similar to that of males, with both having excitation, plateau, orgasmic, and resolution phases. The major difference is that women do not ejaculate.

- During the female sexual response, the outer portion of the vagina constricts to grip the penis, whereas the inner part expands to create space for sperm deposition.

17.4 | Female Reproductive Physiology (pp. 745–774)

- The ovaries perform the dual and interrelated functions of oogenesis (producing ova) and secretion of estrogen and progesterone. (Review Table 17-6.) Two related ovarian endocrine units sequentially accomplish these functions: the follicle and the corpus luteum.

- The same steps in chromosome replication and division take place in oogenesis as in spermatogenesis, but the timing and end result are markedly different. Spermatogenesis is accomplished within two months, whereas the similar steps in oogenesis take anywhere from 12 to 50 years to complete on a cyclic basis from the onset of puberty until menopause. A female is born with a limited, largely nonrenewable supply of germ cells, whereas post-pubertal males can produce several hundred million sperm each day. Each primary oocyte yields only one cytoplasm-rich ovum along with three doomed cytoplasm-poor polar bodies that disintegrate, whereas each primary spermatocyte yields four equally viable spermatozoa. (Review Figure 17-13 and Figure 17-8.)

- Oogenesis and estrogen secretion take place within an ovarian follicle during the first half of each reproductive cycle (the follicular phase) under the influence of FSH, LH, and estrogen. (Review Figures 17-14 through 17-18.)

- At approximately midcycle, the maturing follicle releases a single ovum (ovulation). Ovulation is triggered by an LH surge brought about by the high level of estrogen produced by the mature follicle. (Review Figures 17-14, 17-16, and 17-19.)

- Under the influence of LH, the empty follicle is then converted into a corpus luteum, which produces progesterone as well as estrogen during the last half of the cycle (the luteal phase). This endocrine unit prepares the uterus for implantation if the released ovum is fertilized. (Review Figures 17-14, 17-16, and 17-20.)

- If fertilization and implantation do not occur, the corpus luteum degenerates. The consequent withdrawal of hormonal support for the highly developed uterine lining causes it to disintegrate and slough, producing menstrual flow. Simultaneously, a new follicular phase is initiated. (Review Figures 17-14 and 17-16.)

- Menstruation ceases and the uterine lining (endometrium) repairs itself under the influence of rising estrogen levels from the newly maturing follicle. (Review Figure 17-16.)

- If fertilization does take place, it occurs in the oviduct as the released egg and sperm deposited in the vagina are both transported to this site. (Review Figures 17-21 through 17-23.)

- The fertilized ovum begins to divide mitotically. Within a week it grows and differentiates into a blastocyst capable of implantation. (Review Figure 17-24.)

- Meanwhile, the endometrium has become richly vascularized and stocked with stored glycogen under the influence of luteal-phase progesterone. (Review Figure 17-16.) Into this especially prepared lining the blastocyst implants by means of enzymes released by the trophoblasts, which form the blastocyst's outer layer. These enzymes digest the nutrient-rich endometrial tissue, accomplishing the dual function of carving a hole in the endometrium for implantation of the blastocyst while simultaneously releasing nutrients from the endometrial cells for use by the developing embryo. (Review Figure 17-25.)

- After implantation, an interlocking combination of fetal and maternal tissues—the placenta—develops. The placenta is the organ of exchange between the maternal and fetal blood and also acts as a transient, complex endocrine organ that secretes a number of hormones essential for pregnancy. Human chorionic gonadotropin, estrogen, and progesterone are the most important of these hormones. (Review Figures 17-26, 17-28, and 17-29, and Table 17-5.)

- Human chorionic gonadotropin maintains the corpus luteum of pregnancy, which secretes estrogen and progesterone during the first trimester of gestation until the placenta takes over this function in the last two trimesters. High levels of estrogen and progesterone are essential for maintaining a normal pregnancy. (Review Figure 17-28.)

- Parturition is initiated by a complex interplay of multiple maternal and fetal factors. Once the contractions are initiated at the onset of labour, a positive-feedback cycle is established that progressively increases their force. As contractions push the fetus against the cervix, secretion of oxytocin, a powerful uterine muscle stimulant, is reflexly increased. The extra oxytocin causes stronger contractions, giving rise to even more oxytocin release, and so on. This positive-feedback cycle progressively intensifies until cervical dilation and delivery are complete. (Review Figure 17-30.)

- Prolactin stimulates the synthesis of enzymes essential for milk production by the alveolar epithelial cells. However, the high gestational level of estrogen and progesterone prevents prolactin from promoting milk production. Withdrawal of the placental steroids at parturition initiates lactation.

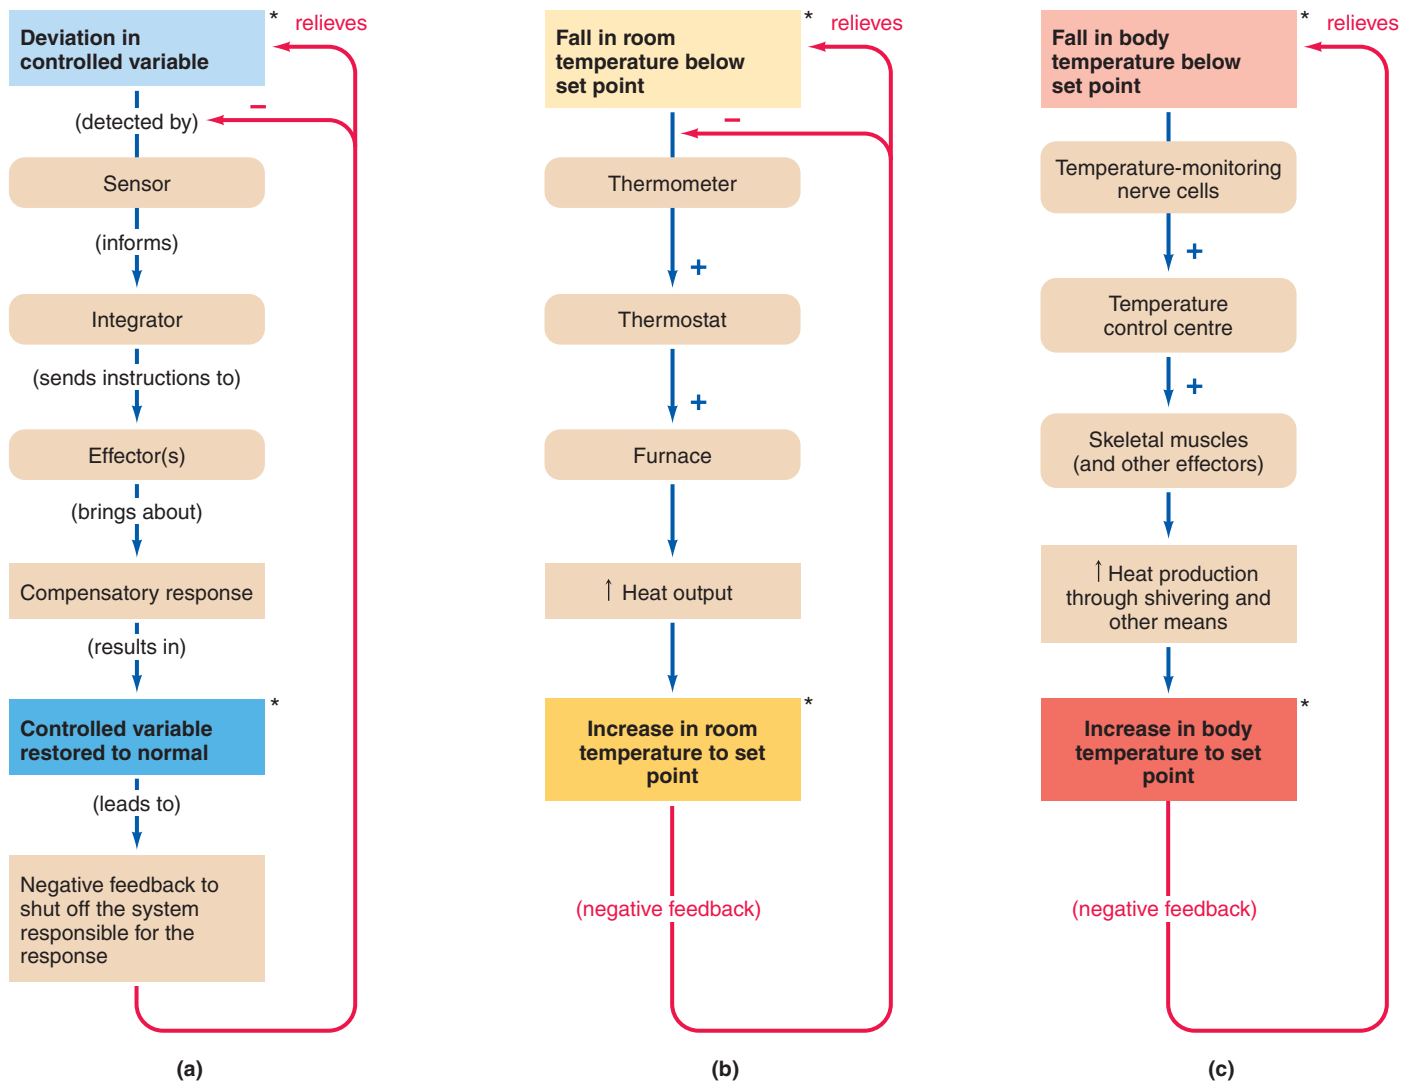

- Lactation is sustained by suckling, which triggers the release of oxytocin and prolactin. Oxytocin causes milk ejection by stimulating the myoepithelial cells surrounding the alveoli to squeeze the secreted milk out through the ducts. Prolactin stimulates the secretion of more milk to replace the milk ejected as the baby nurses. (Review Figures 17-32 and 17-33.)

Anatomical Terms Used to Indicate Direction and Orientation

<i>anterior</i>	situated in front of or in the front part of
<i>posterior</i>	situated behind or toward the rear
<i>ventral</i>	toward the belly or front surface of the body; synonymous with anterior
<i>dorsal</i>	toward the back surface of the body; synonymous with posterior
<i>medial</i>	denoting a position nearer the midline of the body or a body structure
<i>lateral</i>	denoting a position toward the side or farther from the midline of the body or a body structure
<i>superior</i>	toward the head
<i>inferior</i>	away from the head
<i>proximal</i>	closer to a reference point
<i>distal</i>	farther from a reference point
<i>sagittal section</i>	a vertical plane that divides the body or a body structure into right and left sides
<i>longitudinal section</i>	a plane that lies parallel to the length of the body or a body structure
<i>cross-section</i>	a plane that runs perpendicular to the length of the body or a body structure
<i>frontal (or coronal) section</i>	a plane parallel to and facing the front part of the body

KEY

For flow diagrams throughout the text:

+ = Stimulates or activates

- = Inhibits or shuts off

○ = Physical entity, such as body structure or a chemical

□ = Actions

— = Compensatory pathway

— = Turning off of compensatory pathway (negative feedback)

* Note that lighter and darker shades of the same colour are used to denote, respectively, a decrease or an increase in a controlled variable.
